Total protein concentration, measured ... ... 1·78 g./100 ml.
"% diff." in total protein values ... ... 18 %
Calculated proportion of *G* fraction ... ... 36 %
Spreading coefficient of *A* boundary ... ... $6·6 \times 10^{-7}$

it appears that a small part of the total area cannot be included in the area of the symmetrical component curves. This small area lying in the region between the two curves we have called the *X* fraction in Table XVI, but if, like the *X* fraction in the undiluted serum, it has an average sedimentation constant very close to that of the *A* fraction it is probable that what we have classed as "*A*" fraction is not homogeneous but contains significant quantities of an *X* fraction. With the markedly increased boundary spreading in dilute protein solutions it is not possible to attempt a resolution of the lighter component into *A* and *X* fractions with any degree of accuracy. The value which we give in Table XVI for the *X* fraction is, therefore, merely an estimate of the refractive equivalent of the asymmetrical area not included in the *A* and *G* curves and has a doubtful connection with the *X* fraction of undiluted serum.

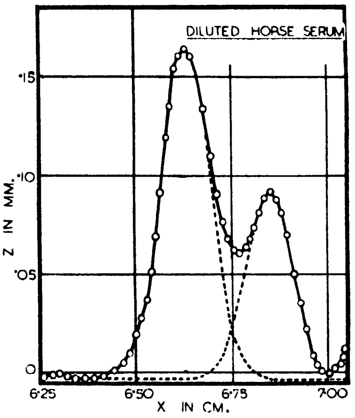

Fig. 13.

A comparison of the results of this experiment with those of Exp. 3 will show that the increase in the proportion of the *G* fraction on diluting cow serum is much less than the increase on diluting horse serum to the same extent. No doubt this is related to the higher albumin : globulin ratio in cow serum obtained by precipitation methods.

SECTION 3. THE SEDIMENTATION DIAGRAM OF NORMAL HUMAN SERUM.

Our first experiment using fresh undiluted human serum in a 2·0 mm. cell gave rise to a curve of the same general three-component type as the curves of undiluted cow and horse serum, but with two points of difference. The concentration of the *G* fraction was considerably smaller than in those sera, and the composite *A*+*X* curve showed marked distortion of the type illustrated in Fig. 2D. In attempts to reduce this distortion we decided to try diluting the serum with small amounts of 1 % sodium chloride such as would not be expected to give rise to any significant change in the relative concentrations of the fractions.

Exp. 17. ***Normal human serum diluted with one-third its volume of 1 °/₀ sodium chloride.*** A 2·0 mm. cell was used. Optical scale distance = 1·54 cm. Mean centrifugal force = 240,000 times gravity. $T_f = 33{\cdot}2°$. $T_l = 35{\cdot}1°$. The results are shown opposite the reference initials J.S.P. in Table XVII and the curve in Fig. 14 is from a photograph taken 92 mins. after reaching full speed. It will be seen that the concentration of the *G* fraction is small, and that a certain amount of distortion is still present in the $A + X$ curve. In the exposure taken 150 mins. after reaching full speed, however, the *A* and *X* curves had become sufficiently separated for each boundary to be free of the distorting influence of the other and we find two symmetrical curves. We are able, therefore, to estimate with considerable accuracy the sedimentation constant and concentration of the *X* fraction in this serum.

Exp. 18. The same normal human serum (J.S.P.) diluted with an equal volume of 1 °/₀ sodium chloride. The same cell was used as in Exp. 17. Optical scale distance = 2·74 cm. Mean centrifugal force = 235,000 times gravity. $T_f = 30{\cdot}3°$. $T_l = 32{\cdot}4°$. The results are also shown in Table XVII.

The curve in Fig. 15 was obtained from a photograph taken 83 mins. after reaching full speed, and shows that practically no change has occurred in the concentration of the *G* fraction, but owing to the increased boundary spreading it is now impossible to obtain an accurate graphical separation of the *A* and *X* curves.

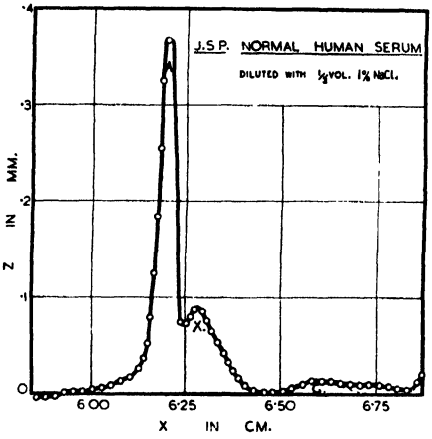

Fig. 14.

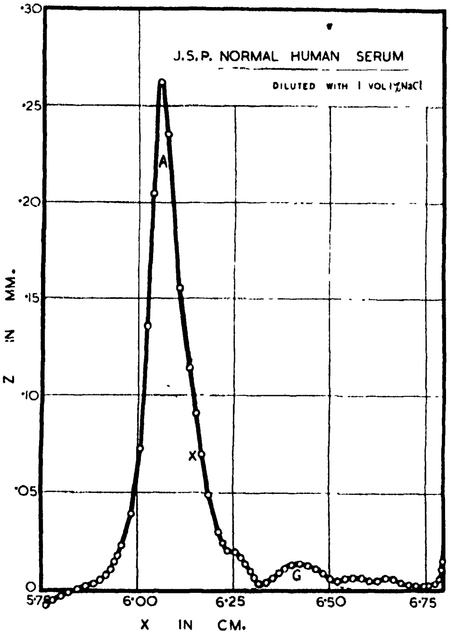

Fig. 15.

Since small additions of 1 % sodium chloride do not appear to affect significantly the concentrations of the fractions in human serum it appears to be permissible to adopt the method of slight dilution in order to obtain a more satisfactory separation of the *A* and *X* curves. It is probable that the addition to a normal serum of more than half its own volume of 1 % sodium chloride will defeat the purpose for which it is added and give rise to a curve of the type shown in Fig. 15 which cannot be used to obtain accurate concentration values for the *A* and *X* fractions. Somewhere between this dilution and a state of no dilution there must be an optimum total protein concentration for symmetrical separation of the *A* and *X* curves. It does not appear that we can predict this dilution beforehand in any particular case because in addition to the total protein concentration, which we can control, there is the concentration ratio of the *A* and *X* fractions, which we cannot alter. We believe from our experiences to date that under the present conditions of an ultracentrifuge experiment the concentration ratio of the *A* and *X* fractions may influence the degree of distortion of the curves. We suspect, indeed, that it is the higher average proportion of *X* fraction in normal human serum which gives rise to the more pronounced distortion in this curve than in the curves of normal cow or horse serum. Our evidence for this, however, is mainly presumptive at present and it is possible that the true reason lies in slight differences in the sedimentation constants of the *A* and *X* proteins in the serum of different species—differences which are too small to be measurable by present methods. It is also possible that even slight changes in the total protein concentration of a serum may cause small changes in the concentration ratio of the *A* and *X* fractions, which, although not great enough to be measurable in the diagrams so far obtained, may nevertheless influence the degree of distortion of the curve.

Altogether, the variable factors are so numerous and the data available at present are so scanty that we have no choice but to resort to a method of trial and error in order to find the best dilution at which to examine a human serum. A factor which we have not mentioned, and which from several points of view must play an important part in the separation of the *A* and *X* curves, is the centrifugal force used. Here again, however, it is not possible to be sure of the nature of the effect, but it seems probable that with higher centrifugal forces the degree of boundary spreading will be reduced and the rate of separation of the two boundaries increased so that we may hope to obtain a satisfactory separation of the *A* and *X* fractions even using undiluted serum. Fortunately, also, much higher centrifugal forces have recently been obtained and a new rotor for serum work is under construction, which Prof. Svedberg hopes will enable us to take advantage of these forces and even permit at the same time of a slight increase in the height of fluid column in the cell. When this rotor is available we hope that it may be possible to investigate as a separate problem the effect of a wide range of centrifugal forces on the diagram of a normal human serum. In the following experiments we have had to employ a standardised centrifugal force in order to make the results more strictly comparable. We have, however, employed various dilutions of human serum so that the curves in some cases are rather more symmetrical than in others.

Exp. 19. The same normal human serum (J.S.P.) diluted with 7 volumes of 1 °/₀ sodium chloride. A 4·0 mm. cell was used and an optical scale distance of 8·0 cm. Mean centrifugal force = 235,000 times gravity. $T_f = 30{\cdot}3°$. $T_l = 32{\cdot}4°$. Fig. 16 shows the curve of a scale photograph taken 51 mins. after reaching full speed, and the results are recorded in Table XVII. The concentration of the *G* fraction is still remarkably small, especially in comparison with diluted cow and horse serum. We have in another experiment examined the same serum diluted with 31 volumes of 1 % sodium chloride. The curves obtained all show irregularities which may be due to a disintegration of the protein molecules, or, on the other hand, may arise from convection effects in the cell. We do not, therefore, publish the results but we may state, from the general appearance of the curve, that even at this dilution no dramatic appearance of globulin molecules takes place.

* The protein concentration values are obtained from the refraction increment values by means of the value 0·00202 [Schretter, 1926] for the specific refraction increment of total human serum protein.

Exp. 20. A series of normal human sera. We have next examined in turn the serum from a number of apparently healthy normal persons of both sexes. The results are collected in Table XVII. In all cases a 2·0 mm. cell was used and the general experimental conditions were very similar to those in the previously recorded experiments. The general shape of the corresponding curves in all these experiments coincides remarkably, and the curve in Fig. 14 may be taken as characteristic of the curves obtained at about the middle of each run. As we shall show in a subsequent paper the similarity of these curves of normal serum among themselves is quite sufficient to distinguish any of them at a glance from the curves which are obtained from many pathological sera. We regard a curve of the general shape shown in Fig. 14, with due consideration of the conditions of dilution, centrifugal force and time at which it was obtained, as a valuable physico-chemical criterion of the state of the proteins in a normal human serum. In the table of results it will be seen that while the calculated total protein concentration of the untreated serum has varied within wide limits (5·09 g./100 ml. (I.S.) to 8·43 g./100 ml. (J.S.P.)) the proportion of *G* fraction in all cases can be represented by the formula (10·5 ± 5) % of the total protein. The concentration of *X* fraction is (25 ± 5) % of the total protein, if we exclude the solutions diluted with more than an equal volume of 1 % sodium chloride. In the case of the latter solutions, owing to the increased boundary spreading, the *X* concentration values are very inaccurate, and indeed, must be regarded as little more than an empirical allowance for the small area between the *A* and *G* curves which cannot be included with graphical symmetry in either of these curves. It is probable that the true *X* values are greater than the values given.

The spreading coefficient and sedimentation constant values in Table XVII call for little comment as they are in the main what one would expect to find under the conditions of the various experiments. In certain cases no value is given for the sedimentation constant of the *X* molecules because the separation of the *X* curve was not sufficient to enable a sufficiently accurate location of the position of the "ideal" sedimentation boundary. Within the limits of comparability it appears from these results that the sedimentation constants of the fractions in human serum are the same as those of the corresponding fractions in cow and horse serum.

We have repeatedly obtained an irregular appearance of the *G* curve which will be seen on close consideration of the curve in Fig. 14. It is not clear to what extent this is due to the accentuation of the effect of base-line irregularities in relation to the small *G* curve, but we are of opinion on the whole that the *G* fraction in normal human serum is not homogeneous.

In only two cases in this series have we dialysed the serum beforehand and measured the total protein refraction increment, because we desired to examine the sera in as fresh and untreated a state as possible. The sera subjected to preliminary dialysis were those of C.A. and W.L., and the calculated values of the protein refraction increments were found to be respectively 7·5 and 14 % less than the measured values.

Another feature which we have noted is the occasional presence in human serum of quantities up to 5 % of the total protein of fractions which sediment between two and three times as fast as globulin and can usually only be seen in the first photograph. The molecular weight of these substances must be at least half a million. We have ignored these fractions in this work because they could only be satisfactorily studied with lower centrifugal forces than we wished to use. We mention their presence, however, because they must contribute in some degree to the discrepancies found between calculated and measured protein refraction increment.

The considerable disagreement among the three calculated values for the total protein refraction increment in the case of J.S.P. shows a phenomenon which we have found generally throughout this work, *viz.* much greater discrepancies between measured and calculated protein refraction increment values in the case of dilute solutions than of concentrated solutions. The explanation of this is not clear.

Exp. 21. The serum of mother and child. It is well known that the serum of a newborn infant contains smaller amounts of protein than the mother's serum. It occurred to us that the small amount of globulin present in normal adult serum might be associated with the development of immunity to various diseases acquired in the early years of life. We have therefore examined in the centrifuge serum from umbilical blood in the newborn infant, and serum from the mother's blood taken at the time of parturition. Owing to the lower concentration of total protein in the former serum we examined this without dilution. The same cell was used in both experiments and the other experimental conditions were comparable in the two cases. The results are shown in Table XVII opposite the reference letters I.S. (infant's serum), and M.S. (mother's serum). It is clear that our original idea is disproved since the infant's serum contains 8·8 % of a *G* fraction. The mother's serum has an abnormally low concentration of *X* fraction, the proportion being approximately half that in the infant's serum.

Exp. 22. A test of the reproducibility of a particular sedimentation diagram. The experiment which we mention here was actually carried out at the beginning of this work. After we had examined the writer's serum (*cf.* Table XVII), diluted 1:1·25 with 1 % sodium chloride, and discovered the surprisingly low concentration of globulin in it, our first concern was to repeat the finding. Another portion of the same diluted serum was, therefore, examined again a few days later using the same cell and approximately the same centrifugal force. The photographs were taken as far as possible at the same time in relation to the start of the experiment. We do not reproduce the results because these do not show any appreciable difference from the results of the earlier experiment shown in Table XVII. We found that if the curves of corresponding photographs were superimposed they coincided in practically every detail. Even some irregularities on the base-line, which we had previously ignored, were faithfully reproduced in the later experiment.

Exp. 23. Normal human serum dried by the Hardy-Gardner method. Serum dried by simple evaporation does not usually redissolve well, a residue of insoluble protein remaining behind on redissolving the powder. Hardy and Gardner [1910] have used a method of drying with alcohol in the cold which yields a white lipoid-free powder which redissolves completely. Sørensen [1930] has subjected the redissolved powder to a variety of tests and comes to the conclusion that the procedure "hardly involves any real chemical splitting, but only a purification of the proteins from the contained substances soluble in ether and alcohol". Also "reconstituted plasma can still be made to clot and albumins may be recrystallised" [Hewitt, 1927].

In view of our previous findings with serum dried by simple evaporation we have thought it of value to submit redissolved serum proteins obtained by the Hardy-Gardner method to the rather searching analysis of the ultracentrifuge. We divided a normal human serum into two portions one of which was dialysed (during which process some dilution took place) and examined in the centrifuge after the refractive indices of protein solution and dialysate had been measured.

The other portion was subjected to all the steps in the Hardy-Gardner drying procedure as described and modified by Hewitt [1927]. In particular, great care was taken to keep the temperature low and by the use of a refrigerator, itself contained in a cold room at −4°, the whole procedure was carried out at −16°. The serum-alcohol mixture was allowed to stand at −16° for 2 hours, and the subsequent filtration and washing of the protein precipitate occupied 6 hours at the same temperature. As recommended by Hewitt we have further minimised the time of contact between the proteins and the alcohol by omitting to dry the powder *in vacuo* before extracting with ether.

The final powder was pure white and redissolved completely in water. The solution was then dialysed against 1 % sodium chloride and the total protein concentration was arranged to be approximately the same as that in which the original serum was examined. The same cell, scale distance and centrifugal force were used in the two experiments. The results are shown in Table XVIII and we reproduce in Fig. 17 two curves—one from the original serum obtained 40 mins. after reaching full speed, and one from the dried serum obtained 25 mins. after reaching full speed.

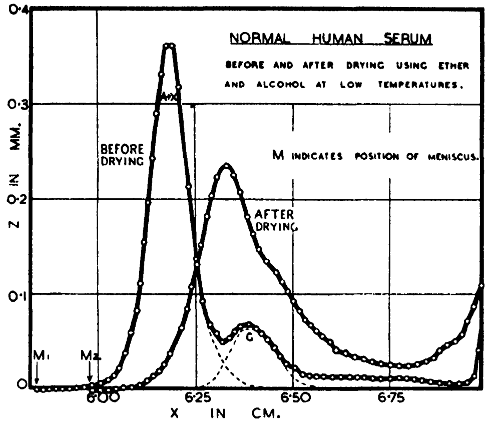

Fig. 17.

Table XVIII. *Results obtained with a diluted normal human serum and the same serum after drying with ether and alcohol.*

Cell thickness = 3·0 mm. Optical scale distance = 3·64 cm.
Mean centrifugal force = 255,000 times gravity.

	Average $S_{W,20}$		Average $(n_1 - n_0).10^3$			Measured total $(n_1 - n_0).10^3$ corr. to $\lambda = 366 m\mu$	"% diff." total $(n_1 - n_0)$	Calculated proportion of G mol.
	$A+X$ mol.	G mol.	$A+X$ mol.	G mol.	Total			
Original serum	3·9	5·70	5·42	0·56	5·98	7·31	−18·2	15·2
Dried serum	3·8	—	—	—	5·95	8·14	−26·9	—

It is clear that a marked change has taken place on drying. The solution of dried protein appears to contain considerable quantities of polydisperse protein, as shown by the irregularity of the curve and the discrepancy of 27 % between measured and calculated total protein refraction increment. We cannot say whether any unchanged native protein is still present or not. Signs of a *G* fraction can be discerned. It will be noted from Table XVIII that the average sedimentation constant of a boundary (taken as the position of the apex of the curve) in the case of the dried protein is in good agreement with the value for the same boundary in the case of untreated serum. It is possible that each fraction in the original serum has given rise to a group of polydisperse molecules with the same mean molecular weight as the parent protein fractions. If any of the original serum protein is still present in significant quantity we must conclude that the drying procedure has in some way given this native protein an abnormally high power of diffusion. We can imagine changes in the shape and charge of the protein molecules which might cause small alterations in the diffusion constant, but we cannot imagine a change which, without affecting the weight or homogeneity of the molecules in a fraction, could cause such a gross alteration in the degree of boundary spreading as we are concerned with here. The same phenomenon has been found in the case of a preparation of serum globulin dried in the same way.

SECTION 4. THE OSMOTIC PRESSURE OF UNDILUTED SERUM.

It has been noted by numerous observers [*e.g.* Mayrs, 1926; Verney, 1926; Krogh and Nakazawa, 1927] that when serum is diluted the colloid osmotic pressure falls more rapidly than corresponds to the fall in protein concentration. Various workers have attempted to correlate the osmotic pressure of a serum with the partial osmotic pressures of the albumin and globulin fractions in it [Govaerts, 1925; 1927; Marrack and Hewitt, 1927; Farkas, 1927; Adair and Robinson, 1930, 2; Elias and Goldstein, 1932], and it has been clearly established that a considerable proportion of the colloid osmotic pressure of a serum must be attributed to the uneven distribution of diffusible electrolytes across the membrane. The problem of determining accurately the proportion of the total pressure due to the diffusible electrolytes is one of great difficulty because we are concerned with a non-ideal solution. Adair and Robinson [1930, 2] in a careful consideration of the problem have come to the conclusion that Donnan's formulae, which refer to infinitely dilute solutions, are not applicable to serum as suggested by Hecht [1925] and Marrack and Hewitt [1927]. They put forward a new treatment of the problem which is essentially based on the calculation of the partial pressure of the diffusible ions from the membrane potential by means of the equation

$$p_i = 15{\cdot}4\,JE_m^2,$$

where p_i = the partial osmotic pressure due to the excess of diffusible ions inside the membrane;

J = the ionic strength, or the sum of the concentrations of the ions in the dialysate multiplied by the squares of their valencies;

E_m = the membrane potential in millivolts.

Adair and Robinson have obtained good agreement between the observed osmotic pressure of dilute unfractionated serum proteins and the partial osmotic pressures of the albumin and globulin. They, therefore, suggest that the state of aggregation of these purified proteins is the same as in the diluted parent serum, a view with which the ultracentrifuge results are in agreement. They have also found that, if due allowance is made for p_i in the case of concentrated ox serum proteins, the relationship between the partial protein osmotic pressure and the total protein concentration of the solution approximates to a straight line. This fact is also not in essential disagreement with our results. Adair and Robinson conclude from the two sets of experiments, however, that the "state of aggregation of the proteins in untreated serum appears to be the same as their state of aggregation in the purified proteins", and with this conclusion we cannot agree.

Adair and Robinson have not attempted to demonstrate quantitative agreement between the observed osmotic pressure of undiluted serum and the partial osmotic pressures of the constituent albumin and globulin. We are informed in a private communication that this omission was intentional because of lack of confidence in the existing methods of estimating the albumin and globulin fractions in serum (which, incidentally, we regard as well justified), and because the osmotic coefficient g_p (a factor representing the effects of the attractive and repulsive forces between the molecules and presumed to be constant), may not be constant in concentrated solutions.

We have endeavoured to apply Adair and Robinson's theory to the results of osmotic pressure measurements which were carried out on the cow and horse serum used in the experiments of Sections 1 and 2, and on a specimen of human serum from Section 3 (C.A., Table XVII) of this work. The serum in each case was dialysed until ionic equilibrium was obtained against approximately ten times its volume of 1 % sodium chloride, and the height of fluid column in the manometer measured. The osmotic pressures are corrected to mm. mercury at 0°. We have also subjected each serum to a standard method of anaylsis involving precipitation with ammonium sulphate and thus obtained values for the albumin and globulin concentrations in the serum. We have no confidence that these values represent exact albumin and globulin concentrations, but they are as good as any that can be obtained to our knowledge and sufficient for our present purpose.

Osmotic pressure of undiluted cow serum.

Observed osmotic pressure of undiluted cow serum = 22·3 mm. Hg
Total protein concentration (C) = 7·64 g./100 ml. solution
Corrected protein concentration (C_v) = 8·27 g./100 ml. solvent

By precipitation analysis the serum was found to contain 58 % albumin and 42 % globulin. Therefore

$$C_{v\ \mathrm{albumin}} = 4{\cdot}80 \text{ g./100 ml. solvent}$$

and

$$C_{v\ \mathrm{globulin}} = 3{\cdot}47 \text{ g./100 ml. solvent}$$

By reference to Adair and Robinson's curve [1930, 2, Fig. 5, p. 1885] showing the variation of total osmotic pressure $(p_i + p_p)$ of crystalline serum albumin with protein concentration we obtain the value 15·5 mm. for an albumin concentration of 4·80 g./100 ml. solvent. This value is made up of 10·5 mm. due to the protein and 5 mm. due to p_i. Similarly, from their curve in Fig. 6 (p. 1886) we obtain the value 3·3 mm. for the total osmotic pressure of a solution containing 3·47 g. globulin/100 ml. solvent. This is made up of 3·0 mm. due to the protein and 0·3 mm. due to p_i. We may not add the total values together because it may not be assumed that the total p_i of a mixture is equal to the sum of the p_i values for the individual components in separate solution. It is more probable that the membrane potentials are strictly additive, especially in view of the rather constant E_m/C_v values which Adair and Robinson obtain for ox serum protein over a range of concentrations. That is

$$E_{m\ \mathrm{mixture}} = E_{m\ \mathrm{albumin}} + E_{m\ \mathrm{globulin}}.$$

Squaring both sides and substituting from the equation given above

$$p_{i\,\text{mixture}} = p_{i\,\text{albumin}} + p_{i\,\text{globulin}} + 2\sqrt{p_{i\,\text{albumin}} \times p_{i\,\text{globulin}}},$$

p_i will, therefore, be greater in the mixture than the sum of the p_i values due to each protein in separate solution, and by an amount which will be significant when the two components contribute approximately equally to the total p_i of the mixture, and negligible when one contributes much more than the other.

In the present case, the osmotic pressure of the serum

$$= 15{\cdot}5 + 3{\cdot}3 + 2\sqrt{5 \times 0{\cdot}3} = 21{\cdot}3 \text{ mm.}$$

Alternatively, we may use the albumin and globulin concentration values obtained from the sedimentation diagrams, *viz.* 83 % albumin and 17 % globulin (*cf.* Exp. 1). These are found to correspond respectively to partial osmotic pressures of 24·5 mm. and 1·3 mm. In this case $p_{i\,\text{globulin}}$ is negligibly small, and, therefore,

$$\text{Osmotic pressure of cow serum} = 24{\cdot}5 + 1{\cdot}3 = 25{\cdot}8 \text{ mm.}$$

Osmotic pressure of undiluted horse serum.

Observed osmotic pressure of undiluted horse serum = 20·5 mm.

Total protein concentration = 7·25 g./100 ml. solution

$C_{v\,\text{total protein}}$ = 7·82 g./100 ml. solvent

By precipitation analysis the serum was found to contain 51 % albumin and 49 % globulin. Therefore

$$C_{v\,\text{albumin}} = 3{\cdot}99 \text{ g./100 ml. solvent}$$

and $$C_{v\,\text{globulin}} = 3{\cdot}83 \text{ g./100 ml. solvent}$$

Again from Adair and Robinson's curves we obtain the corresponding osmotic pressures, *viz.* (4 + 8·2) mm. and (3·6 + 0·1) mm., giving a total osmotic pressure for the serum of $15{\cdot}9 + 2\sqrt{0{\cdot}82} = 17{\cdot}7$ mm.

By ultracentrifugal analysis the same serum was found to contain 80 % albumin and 20 % globulin (*cf.* Exp. 12). In this case, therefore,

$$C_{v\,\text{albumin}} = 6{\cdot}26 \text{ g./100 ml. solvent}$$
$$C_{v\,\text{globulin}} = 1{\cdot}56 \text{ g./100 ml. solvent}$$

and the corresponding osmotic pressures are

Albumin = 21·5 mm.
Globulin = 1·5 mm.
and Total serum protein = 23·0 mm.

Osmotic pressure of undiluted human serum (*C.A.*).

Observed osmotic pressure of undiluted human serum = 30·8 mm.

Total protein concentration = 7·91 g./100 ml. solution

$C_{v\,\text{total protein}}$ = 8·59 g./100 ml. solvent

Precipitation analysis gave 74·5 % albumin and 25·5 % globulin. Therefore

$$C_{v\,\text{albumin}} = 6{\cdot}40 \text{ g./100 ml. solvent}$$

and $$C_{v\,\text{globulin}} = 2{\cdot}19 \text{ g./100 ml. solvent}$$

Corresponding osmotic pressure of albumin = 22·0 mm.
Corresponding osmotic pressure of globulin = 2·2 mm.
and Corresponding osmotic pressure of serum protein = 24·2 + 0·3 = 24·5 mm.

Ultracentrifugal analysis gave 87 % albumin and 13 % globulin. Therefore

$$C_{v\ \text{albumin}} = 7{\cdot}47 \text{ g./100 ml. solvent}$$

and

$$C_{v\ \text{globulin}} = 1{\cdot}12 \text{ g./100 ml. solvent}$$

Corresponding osmotic pressure of albumin = 2·8 mm.
Corresponding osmotic pressure of globulin = 1·1 mm.
and Corresponding osmotic pressure of serum protein = 29·1 mm.

The results are collected in Table XIX.

Table XIX. *Comparing the observed osmotic pressure of undiluted serum with the theoretical value based on the albumin/globulin ratio obtained by ultracentrifugal and precipitation analysis.*

		Theoretical osmotic pressure	
Undiluted serum	Observed osmotic pressure mm. Hg	Based on precipitation *A*/*G* ratio	Based on ultracentrifugal *A*/*G* ratio
Cow	22·3	21·3	25·8
Horse	20·5	17·7	23·0
Man	30·8	24·5	29·1

In the derivation of the ultracentrifugal figures we have classed the combined *A* and *X* fractions as albumin, since we are unable to introduce allowances for the molecular weight of the *X* fraction. If we had sufficient data to do so, the serum osmotic pressure values which are based on the ultracentrifugal albumin/globulin ratio would be somewhat lower.

Strictly, we should only utilise Adair and Robinson's curves to obtain values for the osmotic pressure of albumin and globulin in equilibrium with a buffer solution of p_H 7·4 and ionic strength (J) equal to 0·3466. We have measured our serum osmotic pressures at approximately the p_H of the untreated serum and against an approximately 1 % solution of sodium chloride. These two factors, however, can only introduce small errors in our results since Mayrs [1926] and Marrack and Hewitt [1927] find the osmotic pressure of serum proteins to be only slightly influenced by changes of p_H in the neighbourhood of neutrality, and the ionic strength of our dialysate is approximately 0·34.

As already mentioned it is not yet proved that Adair and Robinson's theory may be applied in its present form to undiluted serum. We have ventured to apply it here for two reasons. Firstly, we wish to show that if the theory is applicable to undiluted serum it appears to agree with the ultracentrifugal albumin/globulin ratio at least as well as with the ratio obtained by precipitation analysis; and, secondly, we wish to put forward the above figures in order to give some idea of the magnitude of the difference in the theoretical osmotic pressures of undiluted serum based on the two conflicting analytical values for the albumin/globulin ratio.

GENERAL DISCUSSION.

We hesitate to attempt to generalise on the basis of the experimental results which have been given in this paper, because it will be clear that little more than a start has been made in the investigation of a very wide field. We have endeavoured to place on record an exact account of these experiments on normal sera in the hope that they may form a basis for the accumulation in the future of the considerably greater amount of experimental material which is clearly necessary before we may try to establish a comprehensive definition of the molecular dimensional state of the proteins in a normal serum. The necessity of having a much greater amount of experimental material than is at present available arises not merely because the exact definition of the normal serum of a species can only be obtained by averaging the results of a large number of normal members of the group, but also because we are attempting an exact physico-chemical definition of a non-ideal protein solution, and practically no general principles, such as we are familiar with in the case of dilute ideal solutions, can be applied. It will have been noticed in the foregoing description of our experimental results that the majority of our deductions have had to be based on comparisons between experiments. Our values for the sedimentation constant, for instance, have only a relative significance because of the high viscosity effects in strong protein solutions. Similarly, the molecular homogeneity of the serum fractions can only be estimated in a relative way by comparison of boundary spreading coefficients. We have no theoretical knowledge of the value of the boundary spreading coefficient of a pure protein in the same circumstances. Finally, the absolute concentration values of the serum fractions are subject to inaccuracies because of the effect of the total protein concentration which varies from one serum to another. All these facts raise difficulties in the way of generalising from the results obtained. They do not mean that established generalisations in this field can never be obtained. We believe that all that is required is a great many more results, preferably obtained with rather more standardised conditions of the centrifuge experiment than we have been able to adopt in this work. We believe that in the near future many new facts will be added to those quoted in this paper and we shall, therefore, attempt to draw the results together in the form of a few general deductions in the hope that these may form a framework of theory in relation to which present facts may be more easily viewed as a whole, and future facts may be tested.

In general, we have found that the normal serum of the cow, horse and man is constituted in a similar manner of three molecular species which can be identified by ultracentrifugal analysis. The corresponding fractions in the three types of serum appear to have the same sedimentation constants.

The heaviest of the three fractions separates easily from the other two sediments with a speed approximately the same as that of horse serum globulin in corresponding concentration and is present in variable amount up to 20 % of the total protein. The concentration of this fraction in a range of normal human sera was found to be rather constant, *viz.* (10 ± 5) % of the total protein concentration, which varied widely. The homogeneity of this fraction is doubtful in the case of human serum, which is also distinguished from cow and horse sera by a tendency to contain small amounts of substances sedimenting 2–3 times as quickly as globulin. These substances have not been specially examined.

The two lighter fractions differ so little in average molecular weight that it is difficult under the present conditions of a centrifuge experiment to obtain a satisfactory separation of the boundaries. We have, however, obtained a good separation in the cases of a few human sera by diluting slightly, and in these cases the average concentration of the more rapidly sedimenting fraction is 24 % of the total protein. We have no knowledge of the chemical nature of this substance, and the sedimentation constant tells us little more than that the molecular weight is slightly greater than that of serum albumin and considerably less than that of serum globulin. The sedimentation constant of the lightest fraction corresponds approximately to that of recrystallised horse serum albumin in the same circumstances, and consideration of the degree of boundary spreading suggests that the fraction is homogeneous. The separation of these two fractions is not so satisfactory in the case of cow and horse serum, and we can only give approximate values for the relative concentrations of the fractions and the sedimentation constant of the heavier of the two. The concentration of the latter is 14 % of the total protein in the cow serum and 16 % of the total protein in the horse serum which we have examined.

All three types of serum on dilution with 1 % sodium chloride show an increased concentration of the globulin fraction with correspondingly diminished concentration of the lighter fractions. In these diluted sera it is impossible to discern a separation of the lighter fraction into two owing to the increased boundary spreading. Whereas the dilution effect is very marked with horse serum it is much less marked with cow and human sera. It is only necessary to dilute horse serum with 3 volumes of 1 % sodium chloride in order to raise the globulin proportion from 20 to 36 %. In the cow serum, on the other hand, 28 % appears to be the maximum globulin obtainable by dilution. Dilution of a human serum with an equal volume of 1 % sodium chloride had no significant effect on the globulin concentration, and dilution with 7 volumes of 1 % sodium chloride could only raise the proportion from 8·6 to 15 %.

It appears that in certain circumstances a solution of the serum proteins may contain a considerable amount of polydisperse protein molecules. We have found that drying cow serum by simple evaporation over P_2O_5, or drying and then ether-extracting the powder, or treating the serum with ammonium sulphate, all gave rise in varying degree to this polydisperse protein. We have also found that the discrepancy between measured and calculated protein values is always greater when we are examining dilute solutions, and this may also indicate the presence of polydisperse protein in these solutions. These facts suggest a considerable sensitivity on the part of the proteins to environmental changes. Svedberg and collaborators have shown in numerous investigations that changes of hydrogen ion concentration outside certain limits give rise to pronounced associative or dissociative changes, and these facts have frequently been confirmed by other investigators using different methods. Altogether, it would appear that in the examination of protein solutions only a few very restricted methods may be used and most careful standardisation of technique must be observed. We have found in this work that it is at least possible to dialyse serum against 1 % sodium chloride or acetate buffer at p_H 4·6 without affecting the molecular dimensional state of the proteins.

In addition to the production of some polydisperse protein, treatment with ammonium sulphate appears to cause an irreversible alteration in the concentrations of the two lighter fractions in serum. This fact, which will require further investigation, raises difficulties in the way of applying to untreated serum facts derived from a study of the properties of the fractions obtained by ammonium sulphate precipitation.

We have found that treating serum with alcohol at low temperatures, which is an integral step in a method of obtaining dry lipoid-free serum protein, gives rise to a marked change in the sedimentation diagram. It is probable that the major part of the protein exists in a polydisperse state, and the mean molecular weight of the fractions of this polydisperse protein which separate in the centrifugal field appears to be the same as that of the fractions in the parent serum. This latter fact explains why the redissolved powder in the hands of various investigators has shown physico-chemical properties very similar to those of the original serum. We find the phenomenon of interest not only because it indicates a serious defect in this technique of drying, but also because we visualise the change which takes place to be an early stage in the complex phenomenon of denaturation, and there would appear to be placed in our hands a convenient method of studying the latter, *viz.* by examining various proteins after treatment with alcohol at low temperatures.

In the investigation of the various problems dealt with in this paper we have, as already stated, obtained only the barest experimental data in many cases. We hope, however, that in the presentation of these data we have, at least, adequately demonstrated an important aspect of the ultracentrifuge, *viz.* as a unique analytical instrument capable of separating the components of a mixture in respect of their molecular dimensions and estimating with considerable accuracy the concentration of each.

SUMMARY.

1. The ultracentrifugal sedimentation diagram appears to describe a strictly reproducible physical property of a protein solution.

2. The sedimentation diagrams obtained for the serum of the normal cow, horse and man all show the presence of three molecular types characterised by their sedimentation constants. The sedimentation constants of corresponding molecular types in serum from different species are the same. The diagram appears to be a common qualitative characteristic of normal serum generally, such differences as exist between sera being of the nature of quantitative differences in the concentrations of the individual fractions and of the total protein.

3. Heat inactivation of cow serum at 56° has little or no effect on the sedimentation diagram.

4. The sedimentation diagrams in the sera examined are changed fundamentally by simple dilution, the change consisting always in an absolute increase in the concentration of the globulin fraction and a corresponding decrease in the concentrations of the two lighter fractions. In dilute solutions it is not possible to separate the two lighter fractions in the centrifugal field.

The dilution effect is marked in the case of horse serum and much less so in the case of cow and human serum. Slight dilution had no significant effect on the sedimentation diagram of human serum, and dilution with 7 volumes of 1 % sodium chloride only increased the globulin concentration from 8·6 to 15·4 % of the total protein.

5. Dialysis of cow serum against 1 % sodium chloride or acetate buffer does not affect the sedimentation diagram. Complete removal of electrolytes induces certain changes which may be due to charge effects.

6. If cow serum is dried by simple evaporation at reduced pressures, with or without ether-extraction of the dry powder, the redissolved protein gives rise to a solution which differs significantly from the original serum in containing considerable quantities of polydisperse protein. A similar irreversible formation of polydisperse protein is caused by treating the serum with ammonium sulphate.

7. There is evidence that, in addition, ammonium sulphate causes an irreversible increase in the concentration of the intermediate fraction in cow and horse serum at the expense of the lightest (or "albumin") fraction.

8. A study of the behaviour of the serum and plasma from the same horse shows that no characteristic fibrinogen molecule is present in the plasma, but the two show certain differences in the concentrations of the three characteristic protein fractions.

9. In the study of a range of normal human sera there has been found a very close similarity in the general shape of all the sedimentation curves, indicating an approximately constant concentration for the constituent fractions.

The concentration of the heaviest or globulin fractions throughout the series is (10 ± 5) % of the total protein concentration, which latter value varied from 5·09 g./100 ml. to 8·43 g./100 ml.

10. The theory that the small amount of the globulin fraction in normal serum may owe its presence to the acquired immunities of childhood is proved to be wrong by the finding that in the serum of a baby at the time of birth 8 % of this fraction was present. There are some points of difference between this diagram and that of the mother's serum taken at the same time.

11. Drying a normal human serum by a recognised procedure using ether and alcohol at −16° causes a fundamental change in the physical state of the proteins. The interpretation of this change is discussed.

12. Osmotic pressure measurements have been performed on certain of the sera used in this work, and the values obtained are considered in the light of a recent theory of the osmotic pressure of untreated serum.

I wish to express my great indebtedness to Prof. Svedberg and to his assistants, and to acknowledge the financial assistance of the Nobel Foundation, the Rockefeller Foundation and the Andersson Foundation.

LXXX. BLOOD PYRUVATE IN VITAMIN B_1 DEFICIENCY.

By ROBERT HENRY STEWART THOMPSON[1]
AND ROBERT EUGENE JOHNSON.

From the Department of Biochemistry, Oxford.

(*Received February 1st, 1935.*)

In the course of recent work on the rôle of vitamin B_1 in the metabolism of brain, it was discovered [Peters and Sinclair, 1933] that lactate solutions in which avitaminous pigeon's brain cells had respired for 2 hours gave a positive nitroprusside reaction for pyruvic acid [Simon and Piaux, 1924]. This led to a quantitative investigation of the formation of pyruvic acid during the respiration of normal and avitaminous brain tissue *in vitro* [Peters and Thompson, 1934]. In the course of this work it was discovered that relatively large amounts of pyruvic acid appear during the respiration in lactate of the minced brain tissue from vitamin B_1-deficient pigeons, whereas only a negligible amount (too little to be detected by the nitroprusside reaction) appears during the respiration under similar conditions of the brain tissue from normal pigeons. Further indirect evidence was thereby obtained in support of the recent Embden-Meyerhof scheme, which includes pyruvic acid as a normal intermediary in the metabolism of carbohydrate in the animal organism [see Embden *et al.*, 1933; Meyerhof and Kiessling, 1933; Meyerhof, 1933].

But although it was shown that there was this marked difference in the rates of pyruvate formation during respiration *in vitro*, no significant difference between the contents of pyruvic acid of normal and avitaminous brains could be detected when the estimations were performed immediately after the death of the animal, that is to say, without any period of respiration *in vitro*. A possible explanation is that although avitaminous brain tissue does produce abnormally large amounts of pyruvic acid *in vivo*, this substance is not detectable owing to the fact that it largely diffuses out into the blood stream.

The pyruvic acid in the blood of normal and avitaminous pigeons and rats was therefore investigated. Our results show that there is a marked accumulation of pyruvic acid in the blood of both these animals when in a state of avitaminosis B_1. A preliminary account of this work has already been published [Thompson and Johnson, 1934].

METHOD.

The method employed has been firstly to investigate the bisulphite-binding capacity of trichloroacetic acid centrifugates of the blood of normal and avitaminous animals, which were being used in brain experiments. In order to determine the percentage of pyruvic acid in the total bisulphite-binding compounds present in the blood, parallel estimations were also made by isolating the 2:4-dinitrophenylhydrazone of pyruvic acid and estimating it colorimetrically by a modification of the Neuberg-Case method [see Case, 1932; Peters and Thompson, 1934].

---

[1] Senior Demy of Magdalen College.

Determination of the bisulphite-binding capacity of pigeon's blood.

The experiments with pigeons were carried out as follows. The bird was first rested for one hour by being wrapped in a duster and placed in a dosing-box kept in the dark; we have found that by this method more uniform results are obtained than if the bird is taken straight from the cage. At the end of the hour the bird was taken out of the box and killed by guillotining. The blood was allowed to drain into a clean dry beaker, and 3 ml. were then rapidly measured with a clean dry pipette into a weighed 25 ml. centrifuge-tube containing 2 ml. of 25 % trichloroacetic acid and 5 ml. of distilled water. The exact amount of blood taken was obtained by re-weighing the tube. The mixture was then allowed to stand for half an hour, at the end of which time it was centrifuged and re-extracted twice with 5 ml. portions of 5 % trichloroacetic acid. The combined centrifugates were then brought approximately to p_H 2·0 with 40 % sodium hydroxide and made up to 25 ml. in a glass-stoppered volumetric flask.

10 ml. aliquots were taken, treated with sodium bisulphite and titrated with $N/100$ iodine for bisulphite-binding capacity by the method of Clift and Cook [1932]. In order to prevent the frothing which tends to occur on the addition of the sodium bicarbonate to hydrolyse the bisulphite compound, one drop of capryl alcohol was added in some of the experiments immediately before the addition of the bicarbonate; capryl alcohol used in this way has no bisulphite-binding capacity.

All but one of the avitaminous birds used had been dosed with glucose once, according to the usual procedure adopted in this laboratory, and all showed head-retraction at the time of use.

RESULTS.

The values obtained with pigeons are shown in Table I (see also Fig. 1). This table shows that there is a very large and constant increase in the bisulphite-binding capacity over the normal level in the blood of vitamin B_1-deficient pigeons.

Table I. *Bisulphite-binding substances in the blood of normal and avitaminous pigeons.*

mg. pyruvic acid per 100 g. blood (1 ml. $N/100$ I = 0·44 mg. pyruvic acid).

Normal		Avitaminous	
Exp.	B.B.S.	Exp.	B.B.S.
5	4·34	6	10·53
7	4·94	8	17·03
9	3·97	16	12·60
15	4·45	18	11·39
20	3·92	22	10·64
21	3·57	23	13·10
25	4·07	24	10·92
36	2·82	26	8·20
38	5·14	28	6·27
48	3·18	29	11·95
63	3·69	39	9·12
64	3·71	40	6·82
66	3·67	42	12·12
		59	17·70
Average	**3·96**	Average	**11·31**

In order to correlate this difference specifically with vitamin B_1-deficiency, estimations were also made on the blood of birds which had developed opisthotonus, but which had been cured by the administration of vitamin B_1 concentrates; in one experiment (Exp. 60) crystalline vitamin B_1 was used. No food was given after dosing, so that their condition of starvation remained strictly analogous to that of the avitaminous birds. The water allowed after dosing was limited to 5 ml. in order to control any possible "washing-out" of the pyruvic acid. The results obtained with the "cured" birds are shown in Table II. Mr H. W. Kinnersley dosed the birds for us. We should like to thank him at this point.

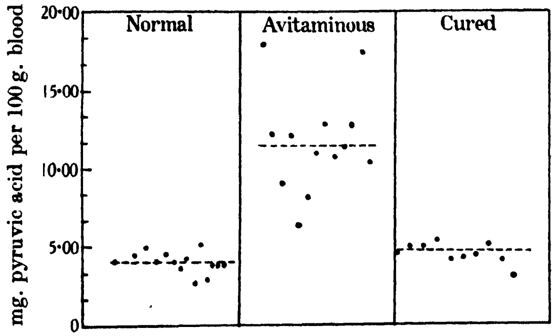

Fig. 1. Bisulphite-binding capacity of pigeon's blood. Broken lines through averages.

Table II. *Bisulphite-binding substances in the blood of "cured" birds.*

Results expressed as in Table I.

Exp.	B.B.S.	Condition
27	3·77	
30	4·73	
32	5·72	Bird still showed "leg weakness"
33	5·10	
34	4·89	
35	4·77	
37	7·03	"Leg weakness" and partial blindness still present; previously gave anomalous tests
53	6·12	
54	5·55	
60	5·25	Dosed with crystalline vitamin B_1.
Average	**5·29**	

These results show that the bisulphite-binding capacity of the blood returns to a figure only a little above the normal (and not statistically different from the normal) after the nervous symptoms have disappeared on dosing with vitamin B_1. This increase in the bisulphite-binding capacity of avitaminous blood is therefore a specific effect of the avitaminosis and is not merely the result of the accompanying starvation.

The results in Tables I and II have been examined statistically by means of Fisher's "t" test. The difference between the normal and avitaminous levels is certainly significant, whereas no real difference exists between the normal level and that found for the "cured" birds.

Determination of pyruvic acid as 2:4-dinitrophenylhydrazone.

Parallel estimations on pigeon's blood, made by a modification of the Neuberg-Case method [Peters and Thompson, 1934], showed that this increase in the bisulphite-binding capacity of the avitaminous bird's blood is probably due entirely to pyruvic acid. The results are shown in Table III. It was unnecessary to extract the blood of "cured" birds, because even if all the bisulphite-binding capacity of their blood were due to pyruvic acid, which is highly unlikely, the level of pyruvic acid in the avitaminous bird's blood would still be higher than that in the "cured" bird's blood.

40	6·82	4·38	2·44
26	8·20	6·34	1·86

For these estimations the blood centrifugates, at p_H 2·0, were made up to 25 ml.; 5 ml. aliquots were then taken for bisulphite estimations, the remaining 15 ml. being used for 2:4-dinitrophenylhydrazine extractions. Only six experiments of this type were done because of the unequivocal results.

Identification of pyruvic acid. The blood centrifugates were first tested by the nitroprusside reaction of Simon and Piaux [1924]. Normal pigeon's blood gave a centrifugate showing a faint and evanescent red colour, probably due to sulphhydryl groups. Avitaminous bird's blood showed a slowly developing green colour; in one case the blue of pyruvic acid in fairly large concentrations was seen.

For more certain identification, however, the 2:4-dinitrophenylhydrazone of pyruvic acid was extracted and purified as follows.

Trichloroacetic acid centrifugates were collected from the blood of fifteen avitaminous pigeons. The mixed centrifugates were kept in strongly acid solution in the presence of 2:4-dinitrophenylhydrazine for 24 hours. The mixture of hydrazine and hydrazones was then taken up in ethyl acetate. The ethyl acetate solution was repeatedly shaken with alkaline sodium phosphate solution until no more of the pyruvic acid 2:4-dinitrophenylhydrazone came out. The phosphate solution was then acidified with hydrochloric acid, and the mixture of hydrazones with an accompanying impurity of hydrazine was once more brought into ethyl acetate solution. The whole procedure was repeated until the alkaline phosphate removed the last trace of yellow from the ethyl acetate phase. The ethyl acetate phase was then collected and evaporated to dryness *in vacuo* at 15°. The residue was extracted with light petroleum, and the yellow hydrazone left undissolved was taken up in ethyl acetate and purified by solution in sodium phosphate, acidification with HCl and re-extraction with ethyl acetate. This was repeated five times. The final ethyl acetate solution was washed with distilled water brought to p_H 2·0 with HCl, and the ethyl acetate phase was then drawn off and evaporated *in vacuo* at 15° to a small volume. The hydrazone was precipitated with excess light petroleum and was dried *in vacuo* at about 15° over sulphuric acid.

The final yellow product had the following characteristics:

(1) It gave a red colour with alcoholic potash identical with that given by synthetic pyruvic acid 2:4-dinitrophenylhydrazone.

(2) It melted variously at 210°, 216°, 214°, 220°, 216°, 214° (corrected). The melting-point of pyruvic acid 2:4-dinitrophenylhydrazone is given as 214° [Allen, 1930; Case, 1932]; 216° [Neuberg and Kobel, 1929]; and 219° [Lohmann and Meyerhof, 1934]. We have noticed that different crystals of our purest products melt at different temperatures from 214–220°.

(3) Mixed with synthetic pyruvic acid 2:4-dinitrophenylhydrazone, it melted at 213°, 219°, 216° (corrected). Average 216°.

Enough hydrazone has not yet been collected for a satisfactory analysis, but this is now being carried out. We feel however that there is little doubt that the compound responsible for the rise in the bisulphite-binding capacity of polyneuritic pigeon's blood above normal is pyruvic acid, or some labile compound of pyruvic acid which yields free pyruvic acid in strongly acid or alkaline solution. Phosphopyruvic acid [Lohmann and Meyerhof, 1934] would give the same results as we have found under the conditions of our experiments.

EXPERIMENTS WITH RATS.

The bisulphite-binding capacity of the blood of normal rats and of rats in acute avitaminosis B_1 was determined in essentially the same way as for pigeons.[1] The rats however were taken straight from the cage, without any preliminary period of resting, and the blood was drained from the neck directly into a weighed 50 ml. centrifuge-tube containing the usual amount of trichloroacetic acid. *N*/200 iodine was used for the titrations instead of *N*/100. The results are shown in Table IV.

Table IV. *Bisulphite-binding substances in the blood of normal and avitaminous rats.*

mg. pyruvic acid per 100 g. blood.

Normal		Avitaminous	
Exp.	B.B.S.	Exp.	B.B.S.
95	3·28	75	11·67
96	3·82	76	7·13
129	4·82	93	11·61
130	4·95	94	9·18
		97	11·21
		120	6·81
		123	8·13
Average	**4·22**	Average	**9·39**

These results are in complete agreement with those obtained with pigeon's blood. Hydrazone extractions have not been done in the case of rat's blood, but we have found that in every case the solutions from the avitaminous rats gave the green nitroprusside reaction characteristic of pyruvic acid in low concentration, while the solutions from normal blood gave only the evanescent pink reaction of sulphhydryl compounds.

---

[1] We thank Mr J. R. P. O'Brien for supplying the rats used.

DISCUSSION.

The results presented in this paper interested us primarily in view of the possible interpretation which they provided for the previous results obtained by Peters and Thompson [1934] with the brain. It is possible that the amounts of brain used by these workers were too small to allow the detection of the increased pyruvic acid in avitaminosis B_1 without a period of respiration *in vitro* to allow for its accumulation, but the raised blood pyruvate suggests that there is also a diffusion of pyruvic acid out into the blood stream.

There now arises the question of whether this raised blood pyruvate is due to metabolic disturbances in the brain alone, or whether it is a reflection of a general lesion throughout the tissues. In view of the work of Fisher [1931] on the lactic acid metabolism of various tissues in avitaminosis B_1, it seems unlikely that the brain alone is responsible for so large an increase in the level of this acid in the blood. In this connection it is also of interest that one of us (R.H.S.T.) found a powerful nitroprusside reaction for pyruvate in lactate solutions in which avitaminous kidney tissue had respired for two hours, whereas the solution in which the normal tissue had respired showed only a very faint colour. Moreover, Embden *et al.* [1933] have shown that pyruvic acid is a normal intermediary in the carbohydrate metabolism of muscle, and Elliott and Schroeder [1934] showed that kidney slices are capable of oxidising pyruvic acid about twice as fast as lactic acid. It seems likely therefore that there is a general lesion throughout the tissues in avitaminosis B_1 resulting in increased blood pyruvate, although we have not attempted to correlate the rise in blood pyruvate with the onset of symptoms.

We feel that the work of Rüter [1923] and of Bornstein and Ascher [1926] excludes any possible interference with our results for avian blood by glycolysis *in vitro*; it was shown by these workers that glycolysis in avian blood occurs very slowly in the absence of inhibitors of cellular respiration. We have ourselves tested this point by allowing the pigeon's blood to drain directly into the trichloroacetic acid and have found that the values obtained did not differ from those obtained when the blood stood for 30–40 seconds before being mixed with trichloroacetic acid. In the experiments with rats the blood has always been drained directly into the protein precipitant.

In view of the possible clinical application of this work as a test for vitamin B_1 deficiency, we are investigating the bisulphite-binding capacity of human blood.

SUMMARY.

1. The bisulphite-binding capacity of the blood of normal and B_1-avitaminous pigeons and rats has been investigated.

2. There are abnormally large amounts of bisulphite-binding substances in the blood of B_1-avitaminous pigeons and rats, an accumulation independent of the accompanying starvation.

3. This accumulation is specifically related to the vitamin B_1 deficiency, and not to the accompanying starvation, because the blood of pigeons cured by vitamin B_1 of the acute symptoms of avitaminosis has a normal level.

4. The increase in bisulphite-binding capacity of the blood of avitaminous pigeons is probably due entirely to pyruvic acid.

We should like to express our gratitude to Prof. R. A. Peters for his encouragement and advice during this research, to Mr R. B. Fisher for the statistical examination of our result and to the Medical Research Council for a grant towards expenses.

LXXXI. CRYSTALLINE VITAMIN B_1.

By HENRY WULFF KINNERSLEY, JOHN RICHARD O'BRIEN AND RUDOLPH ALBERT PETERS.

From the Department of Biochemistry, Oxford.

(*Received February 1st, 1935.*)

Crystals with vitamin B_1 activity isolated from baker's yeast by Kinnersley *et al.* [1932; 1933] differed from those of others in certain respects. Further work failed to resolve differences [Kinnersley *et al.*, 1934]. But lately, co-operation with Prof. Windaus and collaboration with Dr Holiday [Holiday *et al.*, 1934] have led to a revision of some of the facts published from other laboratories, which eliminates the main differences between ourselves and them. Valuable help has also been obtained from X-ray analysis methods. So that in our opinion, there is now no valid reason for questioning the view that vitamin B_1 has been isolated, though certain details have not yet been settled.

Historical.

Jansen and Donath [1926] were the first to isolate crystalline vitamin B_1 preparations. These were not quite pure; they contained substances precipitable by mercuric sulphate in acid solution, which is not a property of the vitamin [Kinnersley and Peters, 1928; Van Veen, 1932]. Much later, Ohdake [1932]; Van Veen [1933]; Windaus *et al.* [1932]; ourselves [1934]; Williams *et al.* [1934] obtained crystals, which were claimed to be of higher activity; this issue of activity was however somewhat blurred. Windaus *et al.* [1932] stated that their crystals reached an activity (pigeon dose) of 2·4γ per diem under the conditions of their tests (injection of 6γ). Later it was concluded by Van Veen that the Windaus preparation had the same activity as that of Jansen and Donath [1926]. Since the activity of a sample of this latter had been determined previously in this laboratory [Jansen *et al.*, 1930], and had been found to be less active, there were grounds for thinking that our own preparations actually had a higher potency. Such a view was confirmed by a parallel test upon some crystals (Windaus 1) sent by Prof. Windaus and some of our own; ours proved more active than theirs. The difference between the two crystalline samples was also found to persist for two other new methods of test devised in this laboratory, namely the catatorulin test upon brain enzyme systems [Passmore *et al.*, 1933] and the formaldehyde azo-colour test [Kinnersley and Peters, 1934]. In the meanwhile Seidell and Smith [1933] reported for our crystals as tested upon rats an activity of 80γ as against 120γ for a sample from Windaus. They did not consider the difference to be significant. Van Veen [1934] however reported that our crystals were more potent; and later he claimed to have made a preparation of higher activity than ours. We hesitated to accept this because he mentioned that his most active sample contained 500 units of vitamin B_1 per mg. which was very little different from our estimates. In fact a new specimen of his vitamin B_1 was not distinguishable from ours by animal test, though this specimen might have become less active in transit. Our conclusion had to be that there was no difference between our preparation and that of Van Veen, but that the Windaus 1 sample was not the same as these two.

The differences between the products of this laboratory and those of others were reflected in other attributes of the crystals. All seemed to be agreed that the formula was either $C_{12}H_{18}O_2N_4S$ or $C_{12}H_{16}ON_4S$ for the base. Bernal and Crowfoot [1933] stated in a report on the X-ray analysis that the crystals from different laboratories were the same. On the other hand we found slightly different analytical figures, in particular a C content of 42·2 against 40·6 %, and slightly higher S and Cl values. There was also a marked difference in the ultraviolet absorption spectra; the band reported by Windaus *et al.* was at 260 $m\mu$ in alcoholic solution, whereas that of ours was at 247–249 $m\mu$ [Peters and Philpot, 1933]; (see Holiday [1935] for a discussion of this point).

Convinced that our facts were correct, and that these differences were therefore real, we searched for a more active vitamin component. It was found possible to refractionate the vitamin crystals with phosphotungstate, which has proved a powerful method of attack at earlier stages. By collection of the precipitates at different p_H values however, no certainly more potent sample was reached.

Fractionation experiments with phosphotungstate were carried out by taking the crystals and refractionating within narrow limits. In the later experiments formalin was added. Though the question has not been properly investigated there is some evidence in our hands that formalin shifts the points of precipitation of some bases more than others; in this case it should prove a refinement of phosphotungstate fractionation. Theoretically, it should influence the point of precipitation by interfering with the basicity of a group such as —NH [*cf.* Barnes and Peters, 1932]. In its presence vitamin B_1 is stable provided that the p_H is not made greater than 6·0; the precipitation point is shifted towards a more acid reaction. The claim by Malcolm [1933] that formaldehyde destroys vitamin B_1 cannot readily be reconciled with our observations. A typical formalin experiment is as follows:

Exp. 1. A solution of about 50 mg. of the vitamin B_1 crystals in water was adjusted to p_H 7 and an equal volume of 40 % formalin added—volume 35 ml. 1·6 ml. of 10 % 24-phosphotungstic acid were added. The p_H was now 5·6–6. The precipitate was collected and washed with $N/10$ sulphuric acid and the washings were added to the filtrate. The precipitate was ground with solid baryta in the usual way and worked up into the crystals. By the addition of 1·0–1·5 ml. $N/10$ sulphuric acid and phosphotungstic acid as required, precipitates were collected in order at about p_H 4 A, B, C and D, and crystals were prepared from each fraction. The p_H was not determined exactly, the aim being to collect what appeared to be zonal precipitations. The total volumes used in the precipitation were 6 ml. $N/10$ sulphuric acid and 3 ml. 10 % sodium phosphotungstate. The precipitates C and D were too small for analysis. For A and B, we have (10γ doses given):

	Wt. of crystals recovered (mg.)	Birds	Day-dose γ
A	11·4	12	2·17
B	17·5	16	2·00

The colour reactions were of equal intensity. There is no evidence of increased activity in either A or B which might have been expected if the crystals were a mixture.

Procedures which would inactivate the vitamin were not valid, and benzoylation is eliminated by the well-known fact that the vitamin escapes this treatment [Seidell, 1929]. Attempts to fractionate by use of lead acetate also gave no success. Since such a procedure separates some nucleotides, substances of pyrimidine type might have been thus removed. More success attended the preparation of the nitrate and the sulphate, which gave opportunity for further tests and for observation by X-ray analysis. No more active vitamin was however reached.

At this stage, Dr Holiday reinvestigated the ultraviolet absorption curve of some of our sulphate and hydrochloride and also of the hydrochloride of Van Veen. The results in acid alcoholic solution reproduced those obtained earlier by Peters and Philpot. A second sample from Prof. Windaus (Windaus 2), which he stated to have been many times recrystallised as the chloroaurate, showed the same spectrum and molecular extinction coefficient as our own. Holiday [1935] has also found that the spectrum of vitamin B_1 changes profoundly according to the conditions of solution and p_H.

This accounts for puzzling points in the curves of Heyroth and Loufbarrow [1934]. It seems clear that all active specimens of vitamin B_1 have the same absorption band with the peak at 247–249 $m\mu$ when tested in acid alcohol solution. Preparation 2 of Windaus showed the same biological activity, catatorulin activity and intensity of formaldehyde-azo-reaction as our own; hence biological differences have disappeared. Furthermore in private communication Prof. Windaus has told us that intensive drying in high vacuum at 80° raises his values for C content to 42·2 %[1], in substantial agreement with our own which were obtained from material dried in a vacuum desiccator; and his values for absorption bands are now in agreement with ours. There are therefore no longer grounds for a belief that the purest crystalline preparations of vitamin B_1 from yeast and rice polishings are substantially different. Since we have been unable to prepare a more potent fraction in spite of strenuous endeavour, we must conclude that the crystals are actually vitamin B_1.

Though the problem as to identity of the crystals with vitamin B_1 may be considered to be settled, we do not feel that all questions connected with the formula are satisfactorily answered; we propose to give our data pointing out discrepancies. Doubtless, determination of the vitamin constitution by other methods will lead to their resolution.

Preparation of salts. The hydrochloride was prepared as before; nitrates and sulphates as follows. The sulphates prepared have the approximate composition $2X(SO_4)_3$ low M.P. and $2X(SO_4)_4$ high M.P. (X = base).

Vitamin B_1 sulphate. On converting the hydrochloride into the sulphate, two compounds are obtained with melting-points of 203°[2] and 276 to 278° respectively. The salt of low M.P. is obtained at p_H 3, that of high M.P. at p_H 1.

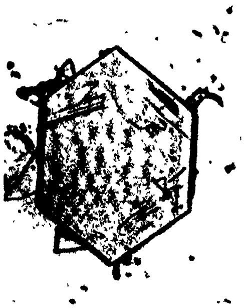

Fig. 1. Sulphate of low M.P. ×200.

Low M.P. *sulphate* (Fig. 1). To 20 mg. vitamin B_1. HCl a hot saturated solution of Ag_2SO_4 is added until a precipitate of AgCl is no longer obtained (about 2 ml.). Absolute alcoholic H_2SO_4 (p_H 3) is added, the precipitate centrifuged off and washed with 1 or 2 drops of water and absolute alcoholic H_2SO_4 (p_H 3)[3]. The filtrate is concentrated on the water-bath, first in a glass evaporating basin and then in a test-tube, and any inactive precipitate obtained is centrifuged off. Addition of absolute alcohol is made from time to time until most of the water has been removed and absolute alcoholic H_2SO_4 is added if necessary.

---

[1] It is to be noted that some of the analyses of Jansen *et al.* and Ohdake show figures for C content higher than 40·6 %.

[2] Values for M.P. corrected throughout.

[3] Prepared by adding 1–2 drops concentrated H_2SO_4 to 50 ml. redistilled absolute alcohol (not dried) so that a drop tested on a white plate with bromophenol blue shows approximately the colour for p_H 3·0.

A solution is finally obtained which inclines to be opaque and from which a precipitate settles out on cooling while it redissolves on warming. If the solution is left overnight in the cold chamber, there is obtained a clear solution with sulphate crystals round the sides of the test-tube.

Sulphate of high M.P. To 20 mg. vitamin B_1.HCl a drop of N H_2SO_4 is added before decomposing the hydrochloride with Ag_2SO_4. It is then worked up as above. The addition of N H_2SO_4 to p_H 1 is only made in the last stages in order to avoid the risk of inactivation by concentrating at this acid p_H.

Nitrate of vitamin B_1 crystals. To 10 mg. vitamin B_1.HCl is added 1 ml. 1 % $AgNO_3$ (theory: no excess); it is warmed upon the water-bath, 4 ml. absolute alcoholic HNO_3, p_H 2, are added, the solution is centrifuged and the precipitate of AgCl washed with 1 drop of water and absolute alcohol.

The filtrate is then concentrated on the water-bath to remove most of the water and worked into about 97 % alcohol at p_H 3 in the usual way. A yellow inactive precipitate which comes out is discarded. Yield 10·7 mg.

Melting-points. Various observers state that vitamin B_1 hydrochloride melts with decomposition; Windaus *et al.* [1932], 250° "unter Zersetzung"; Ohdake [1934], 249° (uncorrected) with decomposition; Van Veen [1933], 250° (corrected); Williams *et al.* [1934], 249–250°.

In spite of much attention to this point, we have never obtained melting-points as high as 250° for our hydrochlorides. We usually determine M.P. in small open tubes in Mason's melting-point apparatus under microscopic observation; we have satisfied ourselves that these results do not differ from those in sealed tubes. The M.P. for the hydrochloride is not sharp and is usually 230 ± 1–$2°$. It makes little difference whether the compound is heated up slowly or quickly to a temperature of 200–220°. It is best to allow the temperature to rise very slowly for the last 5°, taking 3 or 4 mins. for this period. After a definite change at about 230°, no further alteration is noticed up to 270°. In marked contrast to the hydrochloride the sulphates melt sharply, that of lower M.P. at 203°, and that of the higher M.P. at 274–276°. The nitrate decomposes sharply at 164–165°.

The empirical formula of vitamin B_1.

For the hydrochloride Windaus *et al.* [1932] proposed two alternative formulae (Nos. 1 and 2, Table I) differing by H_2O. Their hydrochloride agreed with No. 1, and their picrolonate with No. 2. Ohdake [1934] considers that the formula is $C_{12}H_{16}O_2N_4S.2HCl$, Van Veen $C_{12}H_{20}O_2N_4S.2HCl$, and Jansen *et al.* [1933] support the Windaus formula No. 1.

Our own analyses give as average the following (see Appendix I):

	C	H	N	S	Cl	
Hydrochloride	42·2	5·7	15·1	9·5	20·9	(Schoeller) previous value with addition of one further S analysis =9·42 %
	42·1	6·2	15·6	9·75	20·94	(Kinnersley and O'Brien, see Appendix I)

Sulphate	C	H	N	S	SO_4
High M.P.	30·33	5·8	12·33	18·11	40·1
Low M.P.	35·00	5·50	13·38	18·51	34·7

The possible formulae based upon $C_{12\pm1}$ are calculated in Table I.

Table I. *Possible formulae for vitamin B_1 hydrochloride.*

No.	Formula	C	H	N	S	Cl	Total mol. wt.	Base only
1	$C_{12}H_{18}O_2N_4S.2HCl$	40·6	5·7	15·8	9·0	20·0	355	282
2	$C_{12}H_{16}ON_4S.2HCl$	42·7	5·34	16·6	9·5	21·05	337	264
3	$C_{12}H_{18}ON_4S.2HCl$	42·45	5·9	16·5	9·44	20·92	339	266
4	$C_{24}H_{34}O_3N_8S_2.4HCl$	41·6	5·5	16·2	9·25	20·5	346*	273*
5	$C_{24}H_{36}O_3N_8S_2.4HCl$	41·4	5·76	16·1	9·24	20·45	347*	274*
6	$C_{24}H_{36}O_3N_7S_2.4HCl$	42·4	5·9	14·4	9·43	20·9	340*	267*
7	$C_{24}H_{34}O_3N_7S_2.4HCl$	42·5	5·61	14·45	9·46	20·95	339*	266*
8	$C_{24}H_{34}O_4N_7S_2.4HCl$	41·5	5·48	14·1	9·22	20·45	347*	274*
8*a*	$C_{24}H_{32}O_2N_7S_2.4HCl$	43·6	5·46	14·85	9·7	21·5	330*	257*
9	$C_{23}H_{34}O_2N_7S_2.4HCl$	42·4	5·84	15·1	9·85	21·8	325*	252*
10	$C_{25}H_{36}O_4N_7S_2.4HCl$	42·4	5·65	13·8	9·04	20·1	354*	281*
11	$C_{25}H_{36}O_3N_8S_2.4HCl$	42·5	5·66	15·85	9·08	20·1	353*	280*

= half mol. wt. values.

The most satisfactory fit for the analytical figures is evidently formula 9, but this must be excluded upon the results of X-ray analysis.

By crystallographic methods Bernal and Crowfoot [1934] obtain the values given in Table II; double the values given are not excluded by X-ray analysis. The value for the hydrochloride is the most accurate.

Table II. *Possible mol. wt. (lowest formula wt. for base).*

	Min.	Prob.	Max.
Hydrochloride	270	278	286
Sulphate* (low M.P.)	249	270	286
Nitrate*	263	274	286

* Personal communication.

Values below 263 are certainly excluded and below 270 doubtful. Hence 8*a* and 9 are eliminated. 1, 4, 5, 8 can be excluded upon C, Cl, S values, 10, 11 upon Cl, S values. The mol. wt. is not consistent with 8*a*, 9, or really with 2, 3, 6, 7.

No formula therefore agrees with the analyses and mol. wt. estimations by X-ray analysis. If we consider that the X-ray analysis is some 2 % in error, then formulae 2, 3, 6 and 7 are possible. The nitrogen determinations fit none of these, being intermediate in value. There is some fundamental difficulty about nitrogen estimation in the hydrochloride to which Windaus *et al.* [1932] have already drawn attention. Jansen *et al.* [1933] obtained values nearer 16 % by treating with potassium chlorate. For the sulphates, evidently the difficulty does not arise. It should be mentioned that the nitrogen analyses in the laboratory were controlled by estimations of known substances, such as sulphanilic acid, which gave theoretical results under the same conditions within an error of 0·5–1 %

In our view, the high C values mean that No. 1, the formula proposed by Windaus *et al.* and supported by the others mentioned, is not the simplest vitamin B_1 formula. We favour the second of their proposals Nos. 2 or 3, as a working hypothesis. But in doing so, it must be recognised that there are still unreconciled data. Possibly it is not water but —OH which is the difference between the two formulae; in this case the vitamin would exist in two states of oxidation, and act as an —OH donator. We are not inclined to favour the idea that the vitamin exists as an N_3 compound as well as N_4. This idea could be reconciled with the mol. wt. but not with the nitrogen determinations [*cf.* Heyroth and Loufbarrow, 1934]. A mixture however would explain these.

Biological activity.

The curative pigeon day dose method with injection of vitamin has been used in the majority of tests; it is not very satisfactory for the crystalline vitamin. The relation between dose and time of cure has broken down in some cases. In Table III are given the average values for injection of 10γ. The final values reached are controlled (*a*) by an integration of tests made throughout the year to avoid seasonal changes and (*b*) by simultaneous tests; 92 A 50, 34 A 3 for instance in July 1934 were made by the method of alternate dosing; these give results near the average.

Table III. *Curative pigeon test with vitamin B_1 salts.*

10γ doses injected.

Salt	Preparation	Year	Month	No. of birds	Av. cure days	γ/day dose	Colour reaction	Remarks
HCl	12. 7	1933	—	8	5·0	2·0	5·8	($HgSO_4$ technique)
	17. 0	1933	—	7	6·0	1·67	5·0	—
	92 A 50	1933	Sept.–Oct.	9	5·0	2·0	5·0	—
		1934	Mar.–Apr.	12	3·8	2·63	—	—
		1934	July	13	5·4	1·85	—	—
	19 A	1934	Feb.	6	4·7	2·13	6·0	—
		1934	Feb.	8	4·8	2·08	4·0	High M.P. SO_4 to HCl
	18	1934	Feb.	5	6·2	1·61	6·0	Low M.P. SO_4 to HCl.
	93	1933	Sept.–Nov.	10	4·3	2·33	—	—
	30. 10	1934	May	20	6·3	1·59	5·0	—
	34 A 3	1934	July	15	4·9	2·04	5·8	—
				113	5·093	1·96		

For the whole 113 tests, the mean duration of cure will only exceed 5·093 ±0·250 once in 100 times. The average value for the day dose of free base is 1·54γ.

HCl	V. Veen (1)	1933	Sept.	11	4·0	2·5	6·2	—
	V. Veen (2)	1934	Jan.–Feb.	15	5·3	1·89	6·0	—
	Windaus (2)	1934	June	12	6·1	1·64	4·9	—
HNO_3	7	1933	Nov.	9	5·1	1·96	4·0	—
H_2SO_4	19 A	1934	Feb.–Mar.	11	5·2	1·92	3·0	High M.P.
	19	1934	Feb.	9	6·3	1·59	5·5	Low M.P.
	19	1934	Feb.–Mar.	9	4·0	2·5	4·5	Low M.P.
	24α	1934	Mar.–Apr.	10	4·8	2·08	4·0	—
	24β	1934	Mar.–Apr.	8	5·0	2·0	4·0	—

Examples of tests.

30. 10. May, 1934. Days cure. 10, 9·5, 13, 5, 10, 4, 3, 10, 7, 2, 3, 7, 3, 11, 3, 3, 4, 3, 3, 12.
92 A 48. Mar.–Apr. Days cure. 4, 4, 2, 3, 3, 2, 6, 8, 3, 4, 2, 4.

The sulphate from the average figures appears more active, but the difference is not statistically significant. It is clear that by this test the preparations Van Veen (1) and (2) and Windaus (2) are identical within the limits of error.

Table IV.

			Birds	Days	Day cure
30. 10	June, 1934	Per os	14	4·35	2·3 [*s*]
	May	Injection	—	6·1	1·64
Windaus	June	Per os	9	4·3	2·32 [*s*]
	June	Injection	12	6·1	1·64

[*s*] simultaneous test.

Administration by mouth and by injection have also been compared in simultaneous tests. With extracts of the International Standard, results by the two routes are practically identical (see a paper in course of preparation).

In each case the result by injection is higher; this has been found previously. No stress can be laid upon it owing to the variation.

The average estimate of activity is $1{\cdot}96\gamma$ per day dose for the hydrochloride, and $1{\cdot}17^1 \times 1{\cdot}96\gamma$ per international unit $= 2{\cdot}29\gamma$ or 437 units/mg. The limits outside which the average for such a series of tests could be expected to fall less than 1 in 100 times will be 490–380 units/mg.

These values lie sufficiently close to those of others (estimated at 500 units/mg.) to give confidence that substantially the same activity has been reached.

The above tests have all been made with doses of the same amount. The values obtained agree well with the colorimetric tests and also fairly well with the catatorulin tests and ultraviolet absorption methods. There seems little doubt that they are substantially reliable.

Some discrepancies. Nevertheless, the curative pigeon test is not satisfactory with injection of crystalline vitamin. In previous work from this laboratory, with less pure vitamin given by mouth, it has been found that curative tests by the day dose method gave reliable answers. This was supported by Burn *et al.* [1933] in a comparison of their testing methods with our own. Further the day dose technique is also substantially supported by Birch and Harris [1934]. On the other hand, Williams and Eddy [1933] have criticised our methods in relation to the tests upon preparation Windaus 1 in view of the difference in dose used. This particular criticism was not well founded because with the smaller dose of 10γ in the case of Windaus 1 (by mouth) proper cures could not be effected; there was other evidence too of a lower activity in this sample. The criticism that wide variations occur by the day dose method for injected vitamin receives support from some recent comparisons of our own.

Table V. *Injections of vitamin B_1; simultaneous tests in each case.*

Preparation	Time	Amount	No. of birds	Average days of cure
52 A 15	May, 11–14	5	4	4·2
		10	4	3·7
30. 10	June, 14–16	5	24	5·2
		10	19	6·3
Windaus 2	June, 2–6	5	11	3·3
		10	12	6·1

Upon these figures for 5γ injections, the activity for hydrochloride 30. 10 might be considered to be of the order of 1γ. Small doses injected are evidently liable to give inaccurate results.

We have evidence here that the curative test does not work for injected crystalline vitamin. The matter justifies caution and requires more investigation. In our present opinion, the most reliable biological test for crystalline vitamin will ultimately prove to be the catatorulin test upon avitaminous brain, in which the individual variation is eliminated.

Method of testing and errors.

The probable value of the mean has been calculated for all the hydrochloride results pooled and is given in Table III together with the standard deviation of the figures considered as a whole. This value is considerably higher than that

---

[1] 1·17 day dose = 1 international unit upon average.

calculated for groups such as the 20 animals of 30. 10. We have refrained from discussing the individual averages further, because we are doubtful whether the standard formulae for a normal distribution apply to this case. At Mr R. B. Fisher's suggestion, we have found that the results when plotted form a skew-shaped distribution curve, and we wish to analyse this further.

It will be noticed that some comparisons of activity have been made by the method of alternate dosing in agreement with the latest modern practice [Burn *et al.*, 1933]. Though the general value of this method of control is indisputable, in the particular case here considered, there is much to be said for an average of tests made throughout the year. In our practice, successive batches of birds are put down weekly, 40 or 60 in number, birds from which develop symptoms in 18–30 days. Some of these will show temporary cures; by the time that birds are ripe for test we are really presented with a random selection of animals, which have been on the diet for variable periods. Thoroughly shuffled results are equally likely to be reached by alternating batches of control and batches of unknown birds as in the method of strict alternate dosing, provided that such tests are made within a reasonable period of time.

Catatorulin tests.

These were done by the method of Passmore *et al.* [1933] as modified (see Appendix II).

Table VI. *Catatorulin tests.*

Unknown vitamin preparation	Exp.	Standard (s) equivalent	Average
Van Veen 1	505	$0{\cdot}6\gamma = 0{\cdot}65\gamma$	
	510	$0{\cdot}4\gamma = 0{\cdot}45\gamma$	
	513	$0{\cdot}4\gamma = 0{\cdot}5\gamma$	10γ Van Veen $1 = 11{\cdot}5\gamma$ (s)
Van Veen 2	547	$0{\cdot}4\gamma = 0{\cdot}58\gamma$	
Windaus 2	623	$0{\cdot}35\gamma - 0{\cdot}34\gamma$	
	627	$0{\cdot}5\gamma = 0{\cdot}6\gamma$	10γ Windaus $2 = 10{\cdot}8\gamma$ (s)

The standard preparations were 64. 19 for 505, 510, 513; 92 A 50 for 547; 30. 10 for 623, 627. Na pyrophosphate (p_H 7·4) was used in experiments 510, 623, 627. The constants employed for calculation were $R = 20 \times 10^{-2}\gamma$ in all experiments; $k_c = 10 \times 10^{-2}\gamma$ in experiments 505, 513, 547; in experiment 623, $k_c = 30 \times 10^{-2}\gamma$, and in experiment 627 $20 \times 10^{-2}\gamma$; values in experiment 510 were read from an empirical curve.

Oxygen uptakes, μl./g./hr.

	Standard		
Exp.	$0{\cdot}3\gamma$	$1{\cdot}0\gamma$	Unknown
505	955	1090	1045
510	1100	1320	1175
513	700	800	748
547	1120	1268	1205
623	776	1025	810
627	1034	1255	1165

The results leave no doubt that the preparations have substantially the same activity; there is a tendency for the Van Veen material to give a higher value, which is interesting in view of his claim that his preparation is more active. One unreliable test had to be rejected for Van Veen 2.

The effect of crystalline vitamin B_1 on the growth of rats.

The potency of crystalline vitamin B_1 preparations has also been determined by the effect upon the growth of young rats. The rats weighing 30–40 g. were fed on a pure synthetic diet (rice starch 70, caseinogen 20, salt mixture 5, agar-agar 3 and cod-liver oil 3) supplemented with the other factors of the vitamin B complex in the form of autoclaved alkaline marmite. On such a diet, the rats show an initial rise in weight followed by a rapid decline culminating in convulsions and death. When in the convulsive state or on the verge of convulsions, the rats were given the dose of vitamin B_1. The effect of varying doses of the vitamin on the growth of rats is shown in Table VII.

Table VII. *Effect of vitamin B_1 on young rats**.

Vitamin B_1 dose per day	No. of rats	Duration of Exp. (days)	Average growth per week (g.)	σ
1·0	5	18–21	4·64	2·55
1·5	7	17–19	5·24	2·47
2·5	18	17–28	12·7	2·26
5·0	20	14–35	13·94	2·85
6·0	4	10–14	17·5	2·88
10·0	7	21–28	16·34	3·85

* Tests by J. R. O'Brien. σ = Standard deviation.

The results indicate that doses of vitamin B_1 of the order of 1γ suffice to maintain the young rat; after 2–3 weeks on a 1γ dose of vitamin B_1, the rats tend to weaken and to become moribund. Doses of 2·5–5γ are, however, adequate to promote practically normal growth in the young rat. Continued daily dosing of the rats leads to regular growth (Fig. 2). From Table VII, it is evident that a daily dose of 2·5–5γ of crystalline vitamin B_1 is necessary to promote growth up to maximum weight in rats supplied with the other factors of the vitamin B complex under our experimental conditions. It is also clear that doses in excess of this amount have relatively little extra growth-promoting effect.

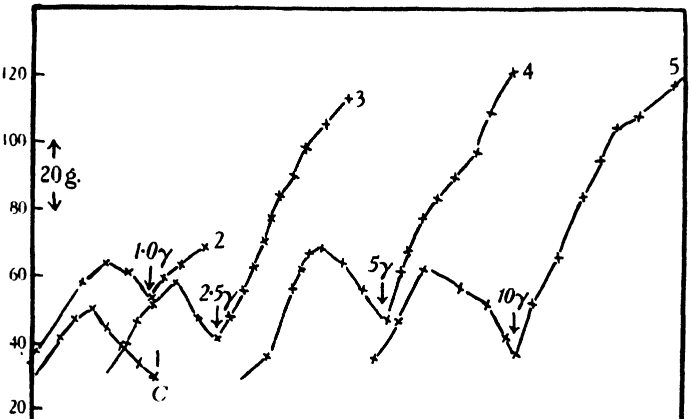

Fig. 2. This shows the effect of varying amounts of crystalline vitamin B_1 hydrochloride upon the growth of young rats of the same sex. Curve 1 shows the rise and decline of weight of the control rat which went into convulsions and died at the point C. Curves 1, 2 and 3 are weight curves for rats of the same litter, 4 and 5 for rats of another litter to which vitamin B_1 was administered at the time marked by the arrow. The control of these two latter behaved like that of 2 and 3.

These figures mean that 1·3 pigeon doses (1·1 international unit) suffices for nearly maximum growth and 2·6 pigeon doses produce improvement after 90 g. weight. These figures are in good agreement with the values of Reader [1930] who usually gave 2–3 pigeon doses to each rat to get normal growth. The lower estimate of 1γ for healthy growth in young rats (by Ohdake [1934]) does not necessarily indicate greater activity of his preparation as compared with ours, because the diet was different and reference to the curves shows that 1γ did not maintain growth well beyond 80–90 g. Ohdake's estimate for pigeons agrees substantially with our own.

Vitamin B_2 concentrates prepared from lead acetate precipitates.

In some cases, with complete success, we have substituted for alkaline autoclaved marmite a vitamin B_2 concentrate prepared from the lead acetate precipitates (a by-product in our large scale process [Kinnersley *et al.*, 1933]) by hydrolysis with acid. The vitamin B_2 complex was shown to be stable to acid by Chick and Roscoe [1929] and Narayanan and Drummond [1930].

Preparation. 600 g. moist lead acetate precipitate [Kinnersley *et al.*, 1933] are treated with 600 ml. H_2O and 300 ml. 20% sulphuric acid. The whole is boiled in a 1500 ml. beaker for 1½ hours with stirring. It is cooled and filtered from the lead sulphate. 20 % NaOH is then added to p_H 3·0 and the mixture is treated with H_2S and filtered. It is usually stored in the dark in cold store until required; any sodium sulphate crystallising out is removed. Before using, H_2S is removed by boiling. The usual volume is 900 ml. for 600 g. precipitate (≡10 kg. original yeast).

1 ml. of this vitamin B concentrate gives maximum effects, 0·5 ml. suffices as a source of all B_2-factors. This concentrate has been both mixed with the diet and given by mouth with identical results. Together with crystalline vitamin B_1, it has cured 23 rats of the dermatitis symptoms of vitamin B_2 deficiency. This concentrate is now being used in attempts to elucidate the problem of factor B_{4a}.

The problem of vitamin B_4.

The very definite results obtained by addition of pure crystalline vitamin B_1 alone raise acutely the question of the meaning of the previous work upon vitamin B_4. The following alternative explanations are possible: (1) Vitamin B_1 in excess can act as a substitute for vitamin B_4. (2) Vitamin B_1 must be present either in the diet or in the rat, *i.e.* by storage. So far as can be ascertained, no change has been made in the experimental diet except for possible variations in the marmite; to the breeding rats, smaller amounts of liver have been given, otherwise the diet has been as before, mixed corn, milk and lettuce twice weekly. Of course, there is no guarantee that climatic conditions have not influenced the composition of the corn *etc.* in some unknown way. (3) The explanation of the previous experiments [Reader, 1929; 1930] must have been in error. If we examine carefully the evidence for vitamin B_4 presented by Reader, we find in reality that two vitamin B_4 factors have been proposed. B_{4a}, the original, was a factor necessary for the growth of young rats; like the flavins, it was precipitated by mercuric sulphate. Believing that no change had been made in the factor studied, a reasonable view at the time, Reader [1930] changed the test and finally worked with a curative test for adult rats. The factor B_{4b} so studied was found in the same crude acid charcoal concentrates as B_{4a}. There is however no real guarantee that the factors B_{4a} and B_{4b} were identical. Considering the factor B_{4a}, the important point of the original work was that some factor other than vitamins B_1 and B_2 (as then understood) was essential for the rat. This point is abundantly supported by recent work; many investigators have recognised a need for a B_4-factor among whom may be quoted Moore *et al.* [1932], Halliday [1934] (rat), Keenan *et al.* [1933] (young chickens).

It is now generally believed that flavin is part of the original vitamin B_2 [György *et al.* 1934; György, 1934; Chick and Copping, 1934]; but it is not excluded that the factor B_{4a} might have been some manifestation of flavin and factor Y either separately or together; especially as these are found in crude vitamin B_4 concentrates[1]. The explanation of the factor B_{4b} is more obscure. Vitamin B_1 concentrates were originally obtained which failed both to cure the special symptoms and to increase the weight of rats. Such concentrates cannot now be prepared. The ataxic symptoms described by Reader in the adult rat (not the young rat) have been reproduced and cured by crystalline vitamin B_1 [O'Brien, 1934]. But the condition of pink feet has been of late uniformly absent. This may be a deciding factor; until it can be reproduced, a considered judgment upon the problem of factor B_{4b} must be suspended. It may be noted that Halliday described ataxic symptoms in adult rats upon milk diets which were attributed to vitamin B_4 deficiency. The pink paws are suggestive of some features of the egg-white syndrome [Boas-Fixsen, 1931]. We cannot exclude the possibility that the symptoms had a toxic origin and that factor B_{4b} may be an antitoxic agent; though we are loth to complicate the problem with such a view at the present stage.

SUMMARY.

The information in this and the accompanying paper by Holiday [1935] can be summarised in tabular form (Table VIII).

Table VIII.

Method of test	Our HCl	Windaus II	Van Veen I	Van Veen II
Pigeon (day dose)	1·96γ	1·64γ	2·5γ	1·9γ
Catatorulin test	10γ	9·9γ	11·5γ	15γ
ϵ/c spectroscopic measurement (Holiday)	45	45·6	39·3	40·4
Colour test	10γ	9·6γ	12·4γ	12γ

1. Vitamin B_1 hydrochlorides from different sources are shown to be identical by various methods of test. An average activity of 380–490 international units/g., average 437, has been found. Analyses agree best with the formula $C_{12}H_{16}ON_4S_3.2HCl$, but they are not quite consistent with this.
2. One nitrate and two sulphates of vitamin B_1 have been prepared with distinct and sharp melting-points.

We are indebted to the Medical Research Council for personal grants and for grants for expenses, and to M. Kempson and R. W. Wakelin for skilful assistance.

---

[1] György's vitamin B_6 is here considered to be identical with factor Y.

APPENDIX II.

Notes upon the catatorulin test for vitamin B_1 by R. A. Peters.

In this test, the power of vitamin B_1 to restore a specific *in vitro* respiration in avitaminous brain tissue is used. Experience with the method of Passmore *et al.* [1933] has led to the introduction of changes. Working with lactate only, the differences between $0{\cdot}3\gamma$ and 1γ vitamin B_1 are often obscured by the variation in duplicate samples. It is better to take advantage of the magnification in the catatorulin effect induced (*a*) by the use of pyrophosphate [Peters and Sinclair, 1933] and (*b*) by warm mincing [Peters *et al.*, 1935]. The latter requires considerable modification of the empirical equation, previously suggested. Details of procedure must be controlled at each point, otherwise unsatisfactory duplicates are obtained.

Procedure. Pigeons are cured at least once for periods over two days with a known or experimental sample of vitamin B_1. They are rendered more free from vitamin B_1 in this way. When symptoms reappear, the head is removed by guillotine, excess blood allowed to drain from the head upon filter-paper for 2–3 mins. The brain is then exposed by cautious excision of the top of the skull. The excised brain is placed upon a glass water-jacketed funnel (37° ± 2°) and the required parts, usually cerebrum, optic lobes and lower parts, minced with a bone spatula for 2–3 mins. and thoroughly mixed. Quantities of about 100 mg. are selected and placed successively in each tared bottle containing the Ringer-lactate-pyrophosphate solution. It is so arranged that one half of the bottles are filled before the other half. In this way, differences occurring as the tissue stands are minimised. The tissue is allowed to remain without disturbance in a small ball; the bottles are then re-weighed. When the weighing is complete, the tissue is divided into small fragments with a glass rod or crusher; care is taken to remove minimum amounts of fluid upon withdrawing the crusher. The divided tissue is allowed to stand for 1–2 mins. and addition of vitamin B_1 is then made. The vitamin B_1 is prepared by evaporation to dryness of an acid alcoholic solution in a small tube *in vacuo*; the dry vitamin is dissolved in the Ringer-phosphate-lactate-pyrophosphate[1] medium.

Bottles are then twice evacuated to 70 mm. and filled with oxygen; duplicates are evacuated in different batches again to control changes occurring upon standing. As each batch is filled with oxygen the taps are turned and the apparatus briefly shaken to saturate the Ringer with oxygen. The apparatus are all together quickly placed in the bath and shaken for 12 mins. before taking the first reading.

Readings can be taken at half-hour periods as before. In some cases, the first period has been 15 mins. and the subsequent readings for half-hourly periods.

Exp. 761 shows an experiment with pyrophosphate, the values being the mean of duplicates. The figures represent O_2 uptakes (μl.).

	Period hrs.				
Period ...	1	2	3	4	5
Vitamin	0–¼	¼–¾	¾–1¼	1¼–1¾	1¾–2¼
Nil	2060	1650	1360	1045	850
0·5γ	2350	2175	1900	1645	1460
1·0γ	2400	2300	2040	1860	1645
2·0γ	2410	2250	2100	1870	1695

Within the first hour, ¼–1¼, the differences are of the same order as formerly. We can calculate *V* from the Michaelis equation originally given by Passmore *et al.* [1933], and, as in this case, we often get fair agreement.

	v	*V*
For 0·0γ	1505	2260
0·5γ	2037	2330
1·0γ	2170	2350

During the second hour, pyrophosphate gives a largely increased vitamin effect, *i.e.* 66 % over the control for 1γ vitamin as compared with 44 % in the first hour. This increase varies to some extent with the condition of the tissue. The reactions are complicated and do not lend themselves at present to simple conceptions (*cf.* Peters *et al.* [1935] for a partial analysis of this). I believe it best to use a frankly empirical equation to fit individual cases. In Exp. 761 and some others, the points: 0·0, 0·5γ and 1·0γ are fitted approximately by the Michaelis equation if $kc=30$ and $R=20$.

---

[1] In some cases, Na pyruvate, 1 mg./3 ml. has been added, but it is not certain that this is an mprovement.

For the second hour, $kc=30$, $R=20$.

	v	V
0·0γ	950	2370
0·5γ	1550	2220
1·0γ	1750	2190

1γ as in the original work evidently gives approximately maximum effects so that the curve is discontinuous after 1γ, *i.e.* $2\gamma \equiv 1\gamma$.

In the cases which have been investigated, the approximate answer is not usually in any doubt. With pyrophosphate and warm mincing a quite satisfactory comparison of activity can often be obtained with the mean of duplicate values, owing to the much larger relative change in the oxygen uptake for different vitamin concentrations. I regard this as a most promising method of comparing the strengths of vitamin solutions, though more work is required to determine the most suitable equation for the new conditions.

LXXXII. IMPROVED YIELDS OF VITAMIN B_1.

BY HENRY WULFF KINNERSLEY, JOHN RICHARD O'BRIEN AND RUDOLPH ALBERT PETERS.

From the Department of Biochemistry, Oxford.

(*Received February 1st, 1935.*)

THE yields previously reported [Kinnersley *et al.*, 1933] have now been improved and some changes introduced. By using a special yeast supplied by the Distillers Company Ltd., about four times the amount of crystals are obtained from a given amount of yeast; 60 mg. pure hydrochloride may be expected from 50 kg. moist yeast (10 kg. as dry). It is an improvement to adsorb on charcoal at p_H 6·5 as the vitamin seems less liable to damage at this p_H value. The special yeast does not give a clear filtrate on centrifuging after the initial boiling. This can be clarified by the use of more lead acetate, at least double the amount previously recommended. It is apt to filter rather slowly at the baryta stage. The phosphotungstate stage works with precision; we notice that others have confirmed its value [Williams *et al.*, 1934]; the formaldehyde-azo-test is here especially useful and we place increasing reliance upon it [Kinnersley and Peters, 1934].

In the final stages of crystallisation, after removing the bulk of the crystals with acid alcohol (HCl, p_H 3), containing about 10 mg. of crystals in each ml., the remaining vitamin may be obtained as crystals by concentrating the filtrates to about half the volume and adding light petroleum (B.P. 40–60°) to the hot solution to faint cloudiness and cooling. Some further 15 % yield may thus be obtained.

As previously recorded (and as confirmed by Williams *et al.* [1934]), loss occurs at the gold stage, presumably owing to oxidation. We have tried to eliminate this by addition of cyanide but have obtained no certain improvement; in some experiments cyanide decreased the yield. Exp. 1 is an example of several experiments of this type.

Exp. 1. *The precipitation of the activity by gold chloride in presence of KCN.* The alcohol was removed *in vacuo* from a volume of the 99 % alcohol solution equivalent to ½ cwt. yeast (20,000 doses); 15 ml. of water were added and about 3 ml. of 10 % gold chloride and 1 ml. 10 % KCN alternately and in small and proportionate volumes at a time; the 30 ml. to be centrifuged were meanwhile cooled in ice. After a few minutes the precipitate was centrifuged off and without being washed was suspended in 15 ml. $N/200$ HCl, and H_2S was passed through for a period of 1 to 2 hours. The sulphide precipitate was filtered under micro-conditions and the filtrate concentrated in a small evaporating basin on the water-bath with 1 drop of 10 % $BaCl_2$ to about 0·5 ml. or less. During the last stages, the side of the basin was washed with alcohol, with which solvent the residue was finally removed into a small 5 ml. tared tube. In this tube most of the water was removed by heating and shaking in the bath—any inactive precipitates were centrifuged off and the solution was allowed to crystallise in the cold chamber for 24 hours or longer.

Equal amounts representing 25 kg. yeast were worked up with and without KCN. The yields were, with KCN: 21·3, 25·6, 30·5; without KCN: 35 mg.

The gold stage seems indispensable for crystallisation; loss is best avoided by minimum times of precipitation (5 mins.) and the use of cooling. We have been unable to convince ourselves that the passage of nitrogen is definitely helpful.

Table I gives the present yields. It must be realised that there are also proportionately increased yields of cruder vitamin B_1 present in the 50 % alcoholic extracts of charcoal which we find very useful in other work.

Table I. *Vitamin B_1 yields from special baker's yeast (moist).*

The amounts of vitamin hydrochloride present unless otherwise stated are judged by colour test in which $2\gamma = 1$ dose vitamin.

SUMMARY.

Improvements in the yield of pure crystalline vitamin B_1 hydrochloride are described.

We wish to thank the Medical Research Council for personal grants and for a grant for expenses. We are also indebted to the Distillers Company Ltd. for the facilities provided. We also thank T. Clarke, T. T. Cox, M. Kempson, W. T. Turner and R. W. Wakelin for skilful assistance.

LXXXIII. NOTE ON THE ULTRAVIOLET ABSORPTION OF CRYSTALLINE PREPARATIONS OF VITAMIN B_1.

By ENSOR ROSLYN HOLIDAY.

From the Medical Unit and Physiological Laboratories, the London Hospital and the Department of Biochemistry, Oxford.

(*Received February 1st, 1935.*)

Since Peters and Philpot [1933] stated that two samples of crystalline vitamin B_1 prepared at Oxford showed absorption maxima at 247 $m\mu$, whereas other workers [Heyroth and Loufbarrow, 1931] had correlated vitamin B_1 activity with absorption about 260 $m\mu$ it seemed doubtful whether any relation existed between absorption in the ultraviolet region of the spectrum of vitamin B_1 preparations and their biological activity.

Subsequently the opportunity occurred of examining several crystalline samples of vitamin B_1 prepared independently in three different laboratories, namely two samples from Prof. Peters, two from Prof. Windaus, and two from Dr Van Veen to whom grateful acknowledgment is made for the opportunity of making the comparison.

The object of the investigation was to discover what differences, if any, in the ultraviolet absorption existed between the samples of vitamin B_1 at hand when examined under similar conditions. The observation of Peters and Philpot [1933] that on rendering an acid solution of vitamin B_1 alkaline there was a shift of the maximum absorption to shorter wave-lengths and the appearance of a new and labile maximum (330–340 $m\mu$) suggested a basis of comparison. Since comparison of the changes of absorption in samples of unknown constitution obtained by varying p_H is likely to be more sensitive to differences in composition than a single determination at a given p_H, absorption measurements were made on all six samples in $N/200$ HCl at successive time intervals after bringing to a p_H between 11·0 and 12·0, and then subsequently after reacidification.

The effect on the absorption of varying the solvent was also tried.

Experimental.

The absorption measurements were made with a Hilger quartz E 316 spectrograph with Spekker photometer [Twyman, 1931; Twyman and Allsopp, 1934], using a condensed spark between tungsten steel electrodes as light source.

A weighed amount of each sample was originally dissolved in 75 % alcohol containing $N/200$ HCl and examined in a suitable layer thickness (0·5–2·0 cm.). The solution was diluted with 75 % acid alcohol to give a suitable density value in a layer of 5 cm. thickness and measured again. It was found that over this small range of dilution (22 to 10 times) Beer's law is followed within the limits of determination (± 2 %).

The 5 cm. cell was of standard Hilger type with centre filling funnel. For the determination of the alkali change a suitable volume (obtained by trial) of *N* NaOH was added through the funnel and the tube shaken for a few seconds, the thumb occluding the funnel opening, the enclosed bubble acting as mixer. The absorption was measured at once and then at intervals of 5 mins.

The time taken to expose a plate with the method here used is about 3 mins., and from the results of succeeding measurements it was evident that during this time some change in absorption had taken place. The absorption curves of the alkaline solutions are therefore mixed curves and cannot be taken as having accurate quantitative significance. Nevertheless, comparison of the curves with those obtained by Peters and Philpot [1933], who used a method requiring only 5–15 secs. exposure [Philpot and Schuster, 1933], shows quite good agreement.

RESULTS.

The results of the determinations are grouped in Table I, which shows the values obtained for the six samples in *N*/200 HCl in 75 % alcohol. The extinction coefficient has its usual meaning and *c* is in g. per litre. In order that the extinction coefficients of the sulphates and hydrochlorides should be comparable, they have been reduced to correspond to concentration of free base. The close correspondence between 61 A (15) and 64 (19) and Windaus II is very remarkable, and after reducing to free base value this is extended to 26 (59). The discrepancy in 26 (52) is discussed by Kinnersley *et al.* [1935]. The samples Van Veen I and II and Windaus I are also very similar and differ from the former group in having a markedly lower extinction coefficient and a maximum at λ 245 instead of λ 247 *mμ*.

1–4 Prepared by Kinnersley *et al.* [1935].
* Quoted from Peters and Philpot [1933].
† Determination by Prof. Pohl, private communication by Prof. Windaus.

Fig. 1 shows the absorption curves of 26 (59), Windaus II and Van Veen II in *N*/200 HCl in 75 % alcohol.

All six examples showed the alkali change of Peters and Philpot. As stated above, the method employed is really too slow for the making of measurements of rates of change occupying only about 15 mins. It is not surprising therefore that no difference in this respect was noticeable among the six samples.

The solvent was found to have great influence upon the absorption. Fig. 2 shows different absorption curves obtained with the same sample of vitamin. If the vitamin is dissolved in neutral 80 % alcohol and then acidified, it does not show the same absorption as when dissolved originally in acid alcohol. The same applies to aqueous solutions.

It will be noted that in neutral alcoholic solution the vitamin shows two well-defined bands at 234 and 268 $m\mu$. These correspond very closely with the bands found by Heyroth and Loufbarrow [1934] in some specimens of vitamin B_1 [see also Smakula, 1935]. In simple distilled water the absorption curves obtained with the vitamin are poorly reproducible. The reason for this was traced to the fact that between p_H 5·5 and 7·0 the vitamin is extremely sensitive to change in hydrion concentration, and the slight variations in the p_H of the distilled water used were sufficient to cause marked changes in the absorption curve. All curves obtained under these conditions are mixtures of curves 2 and 3, Fig. 2. The importance of measuring the absorption of the vitamin under standard conditions of hydrion concentration is therefore obvious.

Fig. 2. Vitamin B_1 hydrochloride. 1 —•—•— Dissolved originally in acid alcohol; 2 - - - - 80 % alcohol acidified; 3 ——— 80 % alcohol.

Discussion.

It appears that the purest samples of crystalline vitamin B_1 in acid alcohol all show selective absorption with a maximum at 245–247 $m\mu$. That others should have correlated vitamin B_1 activity with absorption at 260 $m\mu$ is difficult to explain. In this regard Prof. Windaus is now in agreement that his specimens show a maximum at 247 $m\mu$ (private communication to Prof. Peters) as against a previously published maximum at 260 $m\mu$.

The marked influence of hydrion concentration on the absorption of vitamin B_1 has no doubt been a source of confusion. There is the additional possibility that in less pure samples the impurities not only may have maxima about 260 $m\mu$, but may also alter the absorption of the vitamin.

It also appears that vitamin B_1 preparations of highest activity give very similar absorption curves. The extinction coefficients, the behaviour of the absorption on changing the hydrion concentration and the maxima of absorption are almost identical.

It is therefore probable that the absorption measured is that of the vitamin B_1 molecule, and that in the three laboratories from which the above samples are derived one and the same entity is being used.

LXXXIV. THE WATER-SOLUBLE B-VITAMINS.

IV. THE COMPONENTS OF VITAMIN B_2.

By HARRIETTE CHICK, ALICE MARY COPPING[1]
AND CONSTANCE ELIZABETH EDGAR.[2]

From the Division of Nutrition, Lister Institute, London.

(*Received January 30th, 1935.*)

Note. Vitamin B_2 may be defined as the heat-stable constituent of the vitamin B complex which must be added to diets containing all other dietary essentials, including the antineuritic vitamin B_1, in order to maintain growth and health in the rat and prevent occurrence of dermatitis ("rat pellagra").

THE recent isolation of lyochromes, water-soluble pigments with characteristic yellow green fluorescence, by Ellinger and Koschara [1933] and by Kuhn *et al.* [1933, 1, 2, 3] and the discovery that these pigments are present in materials possessing the biological attributes of vitamin B_2 have given a new impetus to the study of this vitamin. A series of such pigments, having certain well-defined physical and chemical properties in common, has been isolated in pure form from many substances rich in vitamin B_2, *viz.* whey, egg-white, yeast, liver, kidney [Ellinger and Koschara, 1933; Kuhn *et al.*, 1933, 1, 2, 3; Warburg and Christian, 1932; 1933; Karrer *et al.*, 1934].

At first some of these pigments, when administered even in very small doses, were thought to possess the whole nutritive properties of vitamin B_2. Later, however, as purer specimens were available for testing, it became apparent that neither ovoflavin nor lactoflavin nor hepatoflavin [Kuhn *et al.*, 1933, 2, 3; Kuhn, Rudy and Wagner-Jauregg, 1933; György *et al.*, 1933; Euler *et al.*, 1934], when added with vitamin B_1 to a "-B" diet, could supply the full function of vitamin B_2, but that some further supplement was necessary; in other words, that what had hitherto been regarded as vitamin B_2 contained at least two constituents. In these experiments the vitamin B_1 was supplied as an alcoholic cereal extract [György *et al.*, 1934] or as an adsorbate on acid clay prepared from rice polishings by Jansen and Donath's method [Euler, Karrer and Alder, 1934].

The missing supplement for lactoflavin or ovoflavin was provided by the addition to the diet of a yeast extract, from which the B-vitamins or lyochromes had been adsorbed by treatment with fuller's earth [Kuhn *et al.*, 1933, 2; György *et al.*, 1933; Euler, Karrer and Malmberg, 1934] or when vitamin B_1 was supplied as a concentrate made from baker's yeast by the Peters process [György *et al.*, 1934]. The latter observation at first led György and his co-workers to the conclusion that the heat-labile "vitamin B_4" [Reader, 1929; 1930, 1] was the missing factor. "Vitamin B_4" is stated to accompany vitamin B_1 to the end stage of the Peters process, as ordinarily carried out [Reader, 1930, 2]. The conclusion that "vitamin B_4" was involved has, however, recently been abandoned by György [1934] in favour of the idea that the supplement needed by flavin, which is present in the Peters preparation, is a new heat-stable component of the vitamin B complex. This new vitamin György [1934] has called "vitamin

B_6" and has suggested that it may be identical with the "factor Y" described by Chick and Copping [1930, 2] and Roscoe [1930]. This vitamin B_6, together with the flavin, forms a combination having the full biological action formerly attributed to vitamin B_2.

The above forms a very brief summary of work published in a large number of small papers during the last two years. In most of these only scanty details were given of the animal tests which formed the basis of the conclusions drawn as to the relation of the flavins to vitamin B_2. The subject seemed to us to need fuller investigation and the following experiments were begun about a year ago, in the hope of elucidating the nutritive properties of flavin and its relation to the vitamin B complex, not only for maintaining growth, but possibly also for preventing and curing dermatitis in rats.

The lyochromes investigated by us included a specimen of pure lactoflavin D prepared from whey (analysis: C, 52·75, 52·69; H, 5·70, 5·84; N, 14·43, 14·38 %; M.P. 269–273° (uncorr.)) kindly provided by Prof. Ph. Ellinger, and one of pure hepatoflavin from liver (analysis: C, 55·01, 54·85; H, 5·53, 5·65; N, 14·33, 14·32 %; M.P. 275–280°) placed at our disposal by Dr Sydney Smith. These specimens agreed well, both in analysis and melting-point, with those isolated respectively by Kuhn *et al.* [1933, 3] (lactoflavin) and by Karrer *et al.* [1934] (hepatoflavin). We wish here gratefully to acknowledge these gifts. Without them this work would have been impossible.

METHODS.

Diets. The tests for vitamin B_2 were carried out by the methods usual in this laboratory [Chick and Roscoe, 1928]. Young rats, when weaned, received the usual "-B" diet (caseinogen 100, rice starch 300, cottonseed oil 75, salt mixture (McCollum's No. 185) 25, water 500). The diet was heated in a steamer for 3 hours at 100°, in order to cook the starch grains, so that "refection" might be prevented [see Roscoe, 1927]. Vitamins A, D and B_1 were administered separately to each rat daily by capillary pipette, A and D as 0·08 g. cod-liver oil and B_1 as 0·1 ml. ($\equiv$0·6 g. original yeast, dry weight) of a Peters concentrate prepared from brewer's yeast [Chick and Roscoe, 1929].

We have not found any advantage in the elaborate purification of the caseinogen previously adopted [see also Roscoe, 1933] and for most of the present work a commercial sample of "light white casein" was used. A few comparative tests were made with similar "-B" diets containing purified caseinogen, but again no difference was detected either in the extent to which growth was checked or in the incidence of dermatitis.

In some of the diets the rice starch was replaced by an impure sample of maize sugar (containing 85 % dextrose, 1 % ash and *ca.* 14 % maltose, dextrins and other impurities), such as is used in this country in the manufacture of beer. This change was made in order to see if a maize derivative (by analogy with human pellagra) might prove conducive to regular development of the specific skin disorders which at the time were occurring only rarely in our young rats on diets deficient in vitamin B_2. The use of sucrose in the basal diet in place of starch was found conducive to the development of dermatitis in rats deprived of vitamin B_2 by Hogan and Richardson [1934].

Growth tests. Growth frequently ceased immediately from the time the rats received the experimental basal diet; in other cases there was very slow but steady increase in weight for several weeks. The difference appeared to depend on the reserves of B-vitamins with which the young rats were endowed and it has been noted that rats from our colony have appeared to be less sensitive to lack of vitamin B_2 since a generous allowance of dried yeast has been included in the breeding diet. This change was introduced to produce young rats in a more satisfactory condition for work on vitamins A and D. We have therefore tried the effect, with good results, of limiting the B-vitamins, especially vitamin B_2, in the diet of the mothers of litters intended for vitamin B_2 work. No yeast is given during lactation, the mothers' diet consisting of mixed cereals, milk, raw cabbage and carrot, for the first 2 weeks, and for the third week of the "-B" experimental diet supplemented with vitamin B_1 as Jansen and Donath's acid clay adsorbate from rice polishings. If the weight increase of the litter appeared to be too severely checked, milk was given in addition during the latter period and the weaning postponed for a few days, until the weight of the young rats was 30–40 g. This procedure has been successful in producing rats much more sensitive to vitamin B_2 deficiency, showing more regular cessation of growth and a more regular and quicker development of skin disorders.

When the body weight was stationary the daily doses of flavin were administered, with and without the various supplements to be tested, and growth was observed for 3 or 4 weeks or longer.

Table I. *Incidence of dermatitis in young rats receiving a diet deprived of vitamin B_2 from the time of weaning, the mothers being also deprived of this vitamin during the last week of lactation.*

Vitamin B_1 administered separately to each rat as 0·1 ml. (≡0·5 g. yeast dry weight) of a "Peters concentrate" prepared from brewer's yeast.

Cure of dermatitis. The irregularity in the occurrence of dermatitis in rats deprived of vitamin B_2, for which no adequate explanation has been forthcoming, has hitherto been a hindrance to the study of this syndrome [see Roscoe, 1933; Hogan and Richardson, 1932]. We have now concluded that differences in the reserves of vitamin B_2 possessed by the young animals at the beginning of the experiment are the principal cause of this uncertainty. The substitution of impure maize sugar for starch in the basal diet has also seemed to encourage the regular incidence of dermatitis.

The skin disorders which have been observed by us in rats suffering from deficiency of vitamin B_2 (using this term in the sense defined at the beginning of this paper) have shown the following two types [Chick and Roscoe, 1928, p. 795; Chick and Copping, 1930, 1, p. 933; see also György, 1934]:

(*a*) A florid dermatitis, roughly symmetrical, in which there is redness, swelling and oedema of the skin of the extremities (ears, digits of the fore and hind paws) and sometimes also of the nose and corners of the mouth; this may spread later over the limbs and trunk with cracking and desquamation of the skin. This type of dermatitis corresponds to that usually called "rat pellagra" in the literature. It has recently been described as the "specific type" of dermatitis by György [1934].

(*b*) A general affection of the skin, without swelling or inflammation, in which there is shedding of the hair, the remaining locks becoming matted and bald patches sometimes occurring later, especially over the head and face and on the anterior surface of the fore paws. The eyes acquire a "spectacled" appearance from loss of the eyelashes and surrounding hair; the eyes are usually sunken and a bloody serous fluid exudes from the sore swollen eyelids, which may be stuck together, and also from the orifice of the nostrils. The urine is scanty and concentrated and dribbling occurs with consequent soiling and staining of the abdomen. These appearances agree well with the description given by György of his "non-specific" skin changes.

In the succeeding pages these two kinds of skin affection are referred to as types (*a*) and (*b*) respectively.

In our experience young rats receiving a diet deprived of vitamin B_2 (in the old sense) may develop either the (*a*) or (*b*) type of dermatitis or a combination of both sets of symptoms. The (*b*) condition is the more usual and generally occurs sooner in young rats deprived of vitamin B_2. The animals affected remain much undersized and appear to suffer constitutionally to a severe degree from the vitamin deprivation. When the florid (*a*) symptoms develop, they usually occur later in rats whose general condition is stronger; sometimes they are superposed on the (*b*) symptoms in animals who survive for some time after the latter have developed.

This generalisation is illustrated in Table I, which gives the history of two litters of rats, which developed dermatitis on a "-B_2" ration. Among 16 rats maintained for 9 weeks after weaning on the experimental diet, the generalised (*b*) skin symptoms were present in 13 and to a severe degree in 6 of these, of which 1 died. At the same date only 8 rats showed signs of "florid" (*a*) dermatitis and in 5 of these it was only slight or incipient and the general condition of the rats was relatively good.

RESULTS.

The effect of flavin was tested on rats whose growth had failed on a diet deprived of vitamin B_2 as well as on those suffering in addition from either form of skin trouble and on some in which there was a syndrome combined of both types.

Effect on growth.

The results collected in Table II show that doses of pure lactoflavin and hepatoflavin, of 20–50γ daily, certainly stimulated growth to a small extent (average weekly increase in weight 5–8 g.), in comparison with the previous performance of the rats on the "-B_2" diet. Smaller doses, 6–12γ, of hepatoflavin were less effective; there was no appreciable increase of weight over a period of 4–6 weeks in the case of 2 rats receiving 6γ, and in 5 out of 8 rats receiving 12γ daily. When, however, doses of 20–40γ flavin were supplemented by a small dose of an autoclaved yeast extract (A) (equivalent to 0·5 to 1·0 g. dried yeast) which showed no vitamin B_2 activity after two successive treatments with fuller's earth at p_H 1·0, a rate of growth was attained which approached the normal standard (12–14 g. weekly increase in weight). A small amount of a yeast extract (B) (equivalent to 0·5 g. dried yeast), in which all the known B-vitamins had been destroyed by autoclaving at 120° for 5 hours at p_H 9 (*ca.*), supplemented flavin equally well, and normal growth was also obtained. With smaller doses of hepatoflavin, the supplements appeared to be less effective and the degree of growth seemed to be limited by the size of the flavin dose (see Table II).

The minimum rat day dose of hepatoflavin which was necessary for "normal growth" was 12–20γ, a value somewhat higher than that found by other workers. György [1935] found 7–10γ lactoflavin adequate as a rat day dose; Euler, Karrer and Malmberg [1934] 5–10γ, but their criterion for growth was lower than that adopted by us.

Table II. *Effect of lactoflavin and hepatoflavin on rats whose growth had ceased on a diet deprived of vitamin B_2.*

Vitamin B_1 given as 0·1 ml. daily (≡ 0·5 g. dry yeast) of a concentrate prepared from brewer's yeast by Peters's method (see Chick and Roscoe [1929]; method modified according to Kinnersley *et al.* [1933]).

Supplement A. Extract of brewer's yeast deprived of B-vitamins by treatment with fuller's earth (dose ≡ 0·5 g. dry yeast).

Supplement B. Yeast extract deprived of B-vitamins by autoclaving 5 hours at 120° at p_H 9 (dose ≡ 0·5 g. dry yeast).

Flavin	Daily dose γ	Average weekly increase in weight over a period of 4–6 weeks				Nature of supplement
		(a) Flavin		(b) Flavin + supplement		
		g.	No. of rats	g.	No. of rats	
Lactoflavin	10	5·1	2	12·3	2	A 1 rat; B 1 rat

				13·8	5	B
				(c) Supplement only*		
				1·1	7	A

* Time of observation 2–10 weeks.

Effect on dermatitis.

Lactoflavin was found to be without any curative effect upon florid dermatitis ("rat pellagra"), a result confirming that obtained by György [1934]. On the contrary, the symptoms were frequently developed after the administration of flavin to rats whose growth had ceased on the "$-B_2$" diet, but which showed no sign of dermatitis. This was observed in 2 rats receiving 10–20γ of lactoflavin and in 6 rats receiving 12–50γ hepatoflavin (see Table III, rats 98, 141).

Of 9 rats showing the (*b*) group of symptoms in various degrees of severity, the administration of flavin was without any effect in six cases, the result was doubtful in one case, there was slight improvement in one and a most dramatic cure was observed in one severe case (rat 147, Table III) after administration of 24γ hepatoflavin daily. Only in 1 rat showing no skin affection did the (*b*) symptoms develop in slight degree after administration of flavin and in 1 rat slight symptoms became more aggravated. These 2 rats received 20 and 10γ lactoflavin respectively daily.

With one or two exceptions therefore, in these experiments, flavin showed no curative effects on either of the two types of skin disorder.[1] When, however, supplement A or B was given in addition, swift and regular cure of the skin condition accompanied the resumption of growth. There was little difference whether the skin lesions were of the (*a*) or (*b*) type, or a combination of both. Some typical histories of such cures, which included observations on 22 rats suffering from type (*b*) and on 7 rats showing the florid type (*a*), are summarised in Table III.

---

[1] See footnote, p. 730.

Table III. *Effect of pure lactoflavin with and without supplements on the dermatitis developed in young rats deprived of vitamin B_2.*

Supplement A = Autoclaved yeast extract, treated with fuller's earth at p_H 1·0 to remove vitamin B_2.
,, AC = Supplement A after dialysis.
,, AD = Dialysate from supplement A.
,, B = Yeast extract, autoclaved at 120° for 5 hours at p_H 9–10 to destroy all known B-vitamins.

Diet St. contained carbohydrate as rice starch (60 % on dry wt.); diet MS as maize sugar (60 %).
(For descriptions of (*a*) and (*b*) types of skin affection, see pp. 724, 725).

Influence of the composition of the basal diet upon the development and cure of dermatitis.

(*a*) *Type of carbohydrate.* Whether addition of flavin hastened or stimulated the development of "florid" dermatitis ("rat pellagra") seemed to be related to the nature of the carbohydrate in the "-B_2" basal diet. Among 24 rats on which tests were made with daily doses of unsupplemented flavin, 12 were receiving their carbohydrate in the form of rice starch and 12 as maize sugar. The 8 rats which developed florid dermatitis after dosing with flavin included 7 of the latter group and only 1 of the former.

The administration of flavin, as contained in a small daily dose (5 g.) of raw egg-white, to 5 young rats which had ceased to grow on a "-B_2" ration, while showing no skin affection, caused development of a slight degree of florid dermatitis in 3 receiving the maize sugar diet but restored growth without any effect on the skin in 2 receiving the rice starch diet.

(*b*) *Source and dose of vitamin B_1.* A series of experiments in many ways similar to those described above has recently been carried out by György at Cambridge [György, 1935] and these we have been permitted to observe. In György's experiments the florid type of dermatitis was regularly developed on a "-B_2" diet, in which vitamin B_1 was given in pure crystalline form together with flavin, and was as regularly cured when the vitamin B_1 dose was changed to a Peters concentrate from baker's yeast, given in a relatively large dose (daily rat dose 1–2 ml. equivalent to 10–20 g. fresh, or *ca.* 3–6 g. dry, yeast).

We, on the other hand, had never detected the slightest curative or preventive effect for rat dermatitis in Peters's vitamin B_1 concentrate prepared in our laboratory from brewer's yeast (see Chick and Roscoe [1929], method modified according to Kinnersley *et al.* [1933]), but our rat daily dose (always controlled in separate trials for adequacy in vitamin B_1) was much smaller when reckoned on the basis of the original yeast from which the concentrate was prepared (*i.e.* equivalent to 0·6 g. dry yeast). For this reason alone it might be assumed to carry only about 1/5–1/10 of the adherent yeast "impurity" given in György's dose. It therefore seemed probable that Peters's concentrate, as used by him, might carry an adequate supply of the necessary supplement for flavin. By the kind co-operation of Dr György we have been enabled to test this assumption.

Two rats, 169 and 205, were chosen which had ceased to grow on our "-B_2" diet; both showed severe symptoms of the type (*b*) and one (169) of the florid dermatitis, type (*a*), also. In place of their previous vitamin B_1 addition they received the dose advised by György of his own Peters's vitamin B_1 concentrate (2 ml. $\equiv$ *ca.* 6 g. dry yeast), together with 12γ hepatoflavin. In both cases growth was immediately restored (average weekly increase in weight 18 and 17 g. respectively) and there was swift and complete cure of the skin lesions. For comparison, the effect of a much increased dose (0·3 ml. $\equiv$ 1·8 g. dry yeast) of our Peters's vitamin B_1 preparation, together with 12γ hepatoflavin was tried on 2 litter-mates (rats 167 and 203) of the above rats, which showed a comparable condition of vitamin B_2 deficiency. The effect on growth and dermatitis was very slight in comparison with that observed in rats 169 and 205 and about comparable with that observed when a much reduced dose was given (0·5 ml. $\equiv$ *ca.* 1·5 g. dry yeast) of György's preparation (rat 203). These results are summarised in Table IV.

György [1934; 1935] has interpreted these results as showing a separate specific action for the two types of dermatitis to be possessed by the two con-

Table IV. *Influence of vitamin B_1 ration.*

Diet St. contained carbohydrate as rice starch (60 % on dry wt.); diet MS as maize sugar (60 %).

stituents of vitamin B_2. Thus "vitamin B_6" (as contained in vitamin B_1 preparations made from yeast by the Peters process) has a definite action in curing the florid (or "specific") dermatitis and in counteracting the influence of flavin in producing this type. Flavin, on the other hand, possesses a definite curative action for the generalised "non-specific" dermatitis. To maintain steady growth both constituents are required.

We also have found the addition of flavin to a diet deficient in vitamin B_2 frequently conducive to the development of the florid type of dermatitis or to its aggravation when present, and we have found further that this action in some way depends on the type of carbohydrate contained in the basal diet. We conclude, however, that in combination with some dialysable, thermo- and alkali-stable substance contained in a yeast extract freed from all known B-vitamins, lacto- or hepato-flavin possesses curative properties for all forms of dermatitis and for the restoration of growth. The supplementary substance derived from yeast would appear to be absent from, or present in only negligible amount in, our Peters's vitamin B_1 concentrate and to be present in relative abundance in György's preparation. It is not possible to state whether this difference is to be explained by the differences in origin and method of preparation of the two products, ours from brewer's and his from baker's yeast, or whether it may not be due to the much larger dose given in his experiments, but the latter explanation appears at least probable.

We have observed the curative action recorded by György of unsupplemented flavin for the "non-specific" (*b*) skin symptoms, but rarely (Table III, rat 147), but we have noticed a definite effect in restoring growth which appears to be proportional to the dose of flavin given.[1]

In our trials with the supplementary material in the absence of flavin, we have obtained neither restoration of growth (see Table II *c*) nor consistent cure of either type of dermatitis. The action of a daily dose of supplement A (equivalent to 0·5 or 1·0 g. dry yeast) was tested over periods varying from 2 to 10 weeks on 7 rats showing skin affections in varying degree. Six of these rats showed the (*b*) type; in 1 of these the symptoms remained unchanged and in 5 definitely progressed. The (*a*) florid type was present to a slight degree in 5 of the rats and absent from 2; in 1 of the latter it developed and among the former the symptoms became worse in 1, remained unchanged in 2 and cleared up in 2.

Previous work by two of the present authors (undertaken to investigate the heat- and alkali-stability of vitamin B_2) showed complete failure of a yeast extract, after autoclaving at 120° for 5 hours at p_H 9·0 (*i.e.* supplement B), to influence dermatitis in rats deprived of vitamin B_2. In almost all the cases treated, the skin lesions were of the (*b*) type [Chick and Copping, 1930, 1; see also Roscoe, 1933]. One case is, however, quoted [Chick and Copping, 1930, 1, p. 934] in which the preparation showed a curative action for the florid type of dermatitis.

---

[1] *Note added February 26th, 1935.* Since the above was written we have observed more frequently a curative action of unsupplemented hepatoflavin for the (*b*) type of skin symptoms developed in rats deprived of vitamin B_2. Six rats, of body wt. 39–89 g., showing the (*b*) symptoms (4 in a severe degree) received daily 12 hepatoflavin; all showed some improvement, and 4 were completely cured, with a (subnormal) stimulation of growth. In 3 of the above rats the (*a*) florid type of dermatitis developed during this period.

When the supplementary material alone (vitamin B_6) was given in similar cases, the condition always deteriorated, nor have we observed any consistent curative action of vitamin B_6 for the florid (*a*) type when this was present, unless flavin was given also.

The above results thus contain suggestions that the two constituents of vitamin B_2 may sometimes function separately in the prevention and cure of the two different types of skin disorder, *viz.* flavin for the (*b*) type and the supplementary material for the (*a*) type. To this extent our conclusion confirms that arrived at by Dr György, but the general trend of our whole work indicates that for successful treatment of either condition, or of both when present together, and for maintenance or restoration of growth a combination of both the constituents of vitamin B_2 is necessary. All the above trials were, however, of the curative type and have the defects of this kind of experiment. It is probable that the relation between the two types of skin disorder and the two constituents of vitamin B_2 could be more satisfactorily investigated in prophylactic experiments made to observe the type of skin lesions developed when either flavin or the supplementary material is alone added to the basal "$-B_2$" diet from the time of weaning. Such experiments are now in progress.

Relation of the supplementary substance to the "factor Y" of Chick and Copping [1930, 2].

The facts recorded in the present paper may be summarised in the statements:

(*a*) that flavin is one constituent of vitamin B_2, as previously defined (p. 722), and

(*b*) that the second supplementary constituent is a water-soluble, dialysable, heat- and alkali-stable substance contained in yeast extract.

Vitamin B_2 as contained in natural foods (yeast, whey, liver, egg-yolk) would appear to be an association of these two constituents. In egg-white, however, the supplementary substance appears to be present in relatively small amounts.

In previous observations [Chick and Copping, 1930, 2; Roscoe, 1930] on the growth of rats maintained over a long period on synthetic diets in which the vitamin B_2 was derived from egg-white, and vitamin B_1 given as a minimum dose of a Peters concentrate from yeast, or as Jansen and Donath's adsorbate from rice polishings, a gradual failure of growth always occurred. This could be checked by substituting for the egg-white another natural source of vitamin B_2 or by addition of a yeast extract freed from known B-vitamins by prolonged autoclaving in alkaline solution. The required supplement was present in yeast, liver and egg-yolk, but relatively deficient in egg-white; it was heat- and alkali-stable and was provisionally called "factor Y". Some small amount of this factor was evidently present in our Peters's vitamin B_1 concentrate from brewer's yeast, for when large doses were used they supplemented the action of the vitamin B_2 from egg-white. "Factor Y" would thus appear to be identical with György's vitamin B_6, the supplementary substance needed by flavins in order to exercise the full function hitherto attributed to a single vitamin B_2. Until, however, the biological activity of the flavins was discovered [Kuhn *et. al.*, 1933] the status of our "factor Y" could not be more precisely defined.

Properties of vitamin B_6. Vitamin B_6 or "factor Y" is the most heat- and alkali-stable constituent of the B-group of vitamins; it can resist prolonged autoclaving in alkaline solution (p_H 9·0), *e.g.* in supplement B. For further investigation supplement A was chosen as providing the purer material, but the work has not as yet progressed very far. The activity is found present in the dialysate after dialysis through a cellophane membrane and is not removed by precipitation with lead acetate either at p_H 4·0 or 8·0, in this property affording a contrast with flavin.

Nomenclature of vitamin B_2 and its constituents.

Elvehjem and Koehn [1934], on the basis of experiments with chickens, have suggested that the term vitamin B_2 be reserved for the dermatitis ("pellagra")-preventing factor of vitamin B_2-containing materials. They found that flavins prepared from a liver extract were inactive, but that the fraction remaining after these were adsorbed by fuller's earth was highly active, in "prevention of pellagra". The material they desire to call vitamin B_2 would appear to correspond with our vitamin B_6 or "factor Y". This, from the investigation described in the present paper, is clearly only one constituent of vitamin B_2 as previously understood, and requires to be associated with flavin in order to show the full activity of that vitamin. It seems to us that the use of the term "vitamin B_2" to signify either the non-flavin or the flavin constituent of what in the past was known as vitamin B_2 can only cause confusion in the literature of this subject. The custom adopted by workers concerned primarily with the chemistry of the flavins of alluding to these pigments as "vitamin B_2" adds to the confusion [*e.g.* Kuhn and Weygand, 1934].

We would suggest that the term vitamin B_2 be retained for the association of (i) flavin and (ii) supplementary substance, that (i) be known simply as flavin, since it has been identified with a substance of known chemical constitution, and that (ii) be called vitamin B_6 until such time as its chemical nature and identity are established.

SUMMARY.

1. The results of experiments on rats described in this paper indicate that vitamin B_2, as previously defined, is composed of two constituents: (i) flavin, (ii) a supplementary substance contained in yeast extract.

2. The supplementary substance appears to be identical with the "factor Y" previously described by Chick and Copping [1930, 1], and with the "vitamin B_6" described by György [1934]. It is heat- and alkali-stable, can dialyse through a cellophane membrane, is not adsorbed by fuller's earth at p_H 1·0 or precipitated by lead acetate at p_H 8·0 or 4·0. It is present in small amount in the vitamin B_1 concentrate prepared from yeast by Peters's process and can be detected when large doses are given.

3. Pure hepatoflavin or lactoflavin, when added as a small daily dose (12–20γ) to a basal diet deprived of vitamin B_2, but containing vitamin B_1 (as a minimum daily dose of a concentrate prepared from brewer's yeast by Peters's process), was found to restore growth in rats to a small extent (increase of weight up to 6 g. weekly). In order to attain normal growth (10–12 g. weekly) a small daily dose of the supplementary material (equivalent to 0·5–1·0 g. dry yeast) was also necessary.

4. Flavin when given alone (in doses of 12–20γ daily) was found to be without effect upon the characteristic "florid" dermatitis, type (*a*), "rat pellagra", developed in young rats deprived of vitamin B_2; in some instances its administration appeared to encourage the development of this type of skin disorder in animals where it had not yet developed. In some animals suffering from the more generalised type of skin disorder, described as type (*b*) in this paper, flavin appeared to have a curative action; in others there was no effect.

5. The supplementary material, when given alone (in doses equivalent to 0·5–1·0 g. dry yeast), had no effect in restoring growth, while the (*b*) type of skin disorder, if present, progressed without any check. Upon the florid (*a*) type

of dermatitis, there appeared sometimes to be a slight curative effect, but the results were irregular and inconclusive.

6. When flavin and the supplementary material (in the above doses) were given together, there was a speedy cure of either the (*a*) or (*b*) type of skin disorder, or of both, in cases where there was a combined syndrome, and normal growth was immediately restored.

7. It is suggested, in order to prevent confusion in the literature of the subject, that the term *vitamin* B_2 be retained to signify the two factors in association, that the one constituent be termed simply *flavin*, and the second, supplementary, substance be called *vitamin* B_6, as suggested by György [1934].

In conclusion we wish to express our thanks to Sir Charles Martin for his interest and kindly criticism and to Dr P. György for providing us with materials used for experiments summarised in Table IV, and for his friendly co-operation. Our thanks are also due to the Corn Products, Ltd. for supplying the information regarding the sample of maize sugar used in the basal diet. Our indebtedness to Dr Ph. Ellinger and Dr S. Smith for the samples of pure flavin has already been expressed.

NOTE ON THE INFLUENCE OF LIGHT UPON VITAMIN B_2.

Pure flavin has been shown to be sensitive to visible light, the change being accompanied by loss of biological properties [György *et al.*, 1933]. Many observers in the past have reported destruction of vitamin B_2 in yeast and yeast extracts by exposure to ultra-violet radiation from a quartz mercury arc; and this method has been used to free yeast extracts from vitamin B_2 in the preparation of vitamin B_1 concentrates [Hogan and Hunter, 1928; Hogan and Richardson, 1932]. We, however, found partial destruction of both B-vitamins to occur when a yeast extract was exposed to ultra-violet radiation [Chick and Roscoe, 1929]. It is curious that during many years of vitamin B_2 investigation, we, in common with other workers, should have had no suspicion that this vitamin was sensitive to visible light. The materials used were subject to no special precaution, except that, as a routine, they remained in a dark refrigerator except when being handled. It is probable that, being chiefly yeast products of a brown colour, they were protected by this circumstance. Vitamin B_2 preparations from egg-white [Chick, Copping and Roscoe, 1930] are greenish yellow in colour and here sensitiveness of the vitamin to visible light was demonstrated in the following manner in some recent experiments.

A specimen (EW I) prepared in the ordinary way was found to be unusually poor in vitamin B_2 action and it was then realised that, owing to a change in arrangements, the preparation had been carried out in the month of July on a sunny bench under a window facing south-west. Ordinarily such preparations had been made in a north room and evaporated in a dark cupboard. Another preparation (EW II) was then made, in which the whole process, as far as possible, took place in the dark; this preparation proved to be unusually potent in vitamin B_2 action. The potency of EW I was much enhanced when a supplementary dose (20γ daily) of pure hepatoflavin was given; flavin, on the other hand, in no way enhanced the action of EW II. Addition of Supplement B (alkaline autoclaved yeast extract) increased the growth of rats receiving EW II, but did not assist the action of EW I. These facts indicated that it was the flavin constituent of the vitamin B_2 in EW I that had been destroyed by the sunlight, and that the growth-promoting power of this preparation, even when supplemented by Supplement B, was limited by the small amount of undestroyed flavin present.

LXXXV. EFFECT OF DEFICIENCY OF VITAMIN B COMPLEX ON THE "REDOX" SYSTEM IN THE EYE-LENS.

By SURENDRA NATH RAY,[1] PAUL GYÖRGY AND LESLIE JULIUS HARRIS.[2]

From the Nutritional Laboratory, Medical Research Council and University of Cambridge, and Department of Physiology, University of Cambridge.

(*Received January 31st, 1935.*)

Previous papers from the Nutritional Laboratory have demonstrated the presence of vitamin C in the lens of the eye [Birch and Dann, 1933; 1934] and this result has since been corroborated by many others [Euler and Martius, 1933; Müller, 1933]. Euler and Martius also made the further interesting observation that, in cataract in man, ascorbic acid could not be detected in the lens. At about the same time Langston and Day [1933] reported that they had been able to produce cataract in rats by diets deficient in vitamin B_2. These two findings suggested that there might be some interrelation between the vitamin B complex and ascorbic acid and other redox systems in the metabolism of the lens, and the present investigation was undertaken with the object of testing this possibility.

The procedure adopted was to keep groups of rats on diets lacking in one or more of the various vitamins of the B group. After a certain time, when the rats had developed lesions characteristic of the particular deficiency, they were killed and their lenses examined for vitamin C by titration against standard 2:6-dichlorophenolindophenol. In certain cases the lenses of animals cured by the administration of the appropriate vitamins were also examined.

Experimental.

The animals were usually killed by coal gas and their eye-balls removed without delay. The eye-balls were carefully incised with a sharp scalpel and the lenses were gently pressed out. To remove the aqueous and vitreous humours surrounding them, the lenses were rolled on a piece of filter-paper. With the application of a little pressure, the softer material could be rubbed away, leaving the harder portion behind. This was used for the estimation of vitamin C.

The small size of the eye-lens made it difficult to estimate the amount of vitamin C by direct titration. For this reason a modification of the micro-titration method of Birch *et al.* [1933] was used. The lenses from the eyes of one rat were weighed and ground up with 0·2 ml. of 20 % trichloroacetic acid and a little washed sand, and the resulting mixture was made up to 1 ml. The solution was centrifuged and an aliquot part (0·3 ml.) of the supernatant liquid was added to a known volume (0·05 ml.) of 2:6-dichlorophenolindophenol solution. The excess of the dye was then back-titrated by a solution of pure ascorbic acid (a solution of 5 mg. of the acid in 100 ml. of 10 % acetic acid solution being generally employed). The dye solution (a 0·1 % solution by weight was usually taken) alone was next titrated against the ascorbic acid solution and the difference gave the amount of ascorbic acid present in the lens extract. With a little practice and when working with lenses from a single normal rat, duplicate results agreed to within 10 %.

---

[2] Member of Scientific Staff, Medical Research Council.

The following two diets were generally used and will be referred to in the text as diets 1 and 4:

Diet 1	
Extracted caseinogen ...	18
Salt mixture	4
Cod-liver oil	1
Butter-fat	9
Rice starch	68

Diet 4	
Glaxo caseinogen A.B. ...	18
Salt mixture	4
Cod-liver oil	1
Butter-fat	9
Cane sugar	66
Agar	2
Irradiated yeast 0·1 g. daily	

Diet 4 is partially deficient in vitamin B complex, and diet 1 is vitamin B-free. In the case of rats on diet 1, the B vitamins were supplied, when necessary, in the following forms: vitamin B_1 as solutions of pure crystalline B_1 (3 pigeon doses a day), vitamin B_2 complex as pure crystalline flavin *plus* "Peters's eluate" [Kinnersley *et al.*, 1933] for antipellagra factor. No supplements were generally used with diet 4, the irradiated yeast being prepared by exposure of dried yeast in thin layers to a mercury-vapour lamp for 24 hours. Fuller experimental details regarding the preparation of experimental animals are given in an accompanying paper [György, 1935, 2]. Adult rats kept on the stock basal diet used in the Nutritional Laboratory (brown bread, milk, green vegetables, with meat and liver once a week) were taken as normal controls.

Results.

The indophenol-reducing capacities (expressed in terms of concentration of ascorbic acid) of the lenses of rats on normal diet, on diet 4 and on diet 1 (supplemented by certain vitamins of the B group) are given in Table I.

Table I.

It will thus be seen that although there is a large quantity of reducing agent (vitamin C) in the lens of the normal rat, the amount present in the lens of a rat kept either on diet 1 or 4 is very low. But in addition it was found in the case of some of the rats kept on diet 4, that when the extract of the lens was added to a measured volume of 2:6-dichlorophenolindophenol, the resulting solution required a larger volume of ascorbic acid solution for complete decoloration than that necessary in control tests for the decoloration of the dye solution alone. This points to the presence of some oxidising substance in these lens. A few such results are given in Table II.

Table II.

No. of rat	Wt. of eye-lens (g.)	Amount of ascorbic acid in mg. oxidised by 1 g. of eye-lens
20	0·037	0·40
21	0·030	0·17
22	0·033	0·25

Significance of the diminished reduction titre.

This diminution of the indophenol-reducing agency almost to vanishing point in the lens of the rat may occasion surprise, since previous experience has shown conclusively that the rat is able to synthesise its own vitamin C [Parsons, 1920; Harris and Ray, 1933]. On the other hand other tissues, such as liver or kidney, from these same animals were found on examination to contain normal amounts of vitamin C. This might suggest either that the lens has a mechanism for synthesising vitamin C different from that present in liver or kidney, or that the vitamin C is not synthesised in the eye-lens but is supplied from elsewhere in the body and that the mechanism of this supply may break down in animals restricted to these special diets. An objection to the last theory may however be raised in the fact that when high doses of vitamin C (50 mg.) were injected into a rat kept on diet 4 its eye-lens showed a slight increase in concentration (about 0·15–0·20 mg./g.) of ascorbic acid. A third and more plausible theory is that the ascorbic acid in the lens forms, with some oxidising agent, part of a complex oxidation-reduction system. By the titration method we are examining only the amount of ascorbic acid in the reduced condition. It may be supposed that when animals are subjected to these special diets, the amount of oxidising substances in the eye-lens increases, thereby converting an equivalent amount of ascorbic acid into some oxidised product. Thus although the amount of total ascorbic acid (reduced + oxidised) may remain the same, it is evident that the titre would fall, thereby giving a false impression of a diminution in the amount of vitamin C. It must be pointed out however that under normal conditions the reducing titre for the lens (ox) is in fact equal to the vitamin C content as determined biologically [Birch and Dann, 1934]. Further work to elucidate these points is now being carried out.

Influence of individual dietetic factors.

The exact dietetic origin of this fall in the total reducing capacity of the eye-lens remains obscure. That inanition is not the cause is shown in Table III. The animals in these experiments were kept on a diet deficient in "vitamin H" [György, 1931; 1935, 1]. Besides loss of weight, they had all developed lesions characteristic of this deficiency. Yet it will be seen that the vitamin C content of the lens is quite normal.

Table III.

No. of rat	Initial wt. (g.)	Final wt. (g.)	Wt. of eye-lens (g.)	Concentration of ascorbic acid in mg./g.
23	76	69	0·040	0·53
24	73	48	0·040	0·45
25	69	57	0·015	0·44
26	73	58	0·026	0·48
27	89	77	0·022	0·49
28	71	55	0·025	0·48

These results demonstrate at the same time that "vitamin H" deficiency is not the cause of this diminution in reducing capacity. Nor does a deficiency of either flavin or the antipellagra factor appear to be responsible; for, as shown in Table I, even when these vitamins are supplied in the diet (Rats 7–12, 18), there is no improvement in the amount of vitamin C. The results with rats 7–12 and 19 also seem to rule out the possibility of vitamin B_1 deficiency being the cause. This conclusion is further brought out in Table IV where the experimental rats were kept on a diet deficient in vitamin B_1 only (alkaline autoclaved marmite being used to provide vitamin B_2 complex). All the rats exhibited advanced polyneuritic symptoms.

Table IV.

No. of rat	Wt. of eye-lens (g.)	Concentration of ascorbic acid in mg./g.
29	0·017	0·31
30	0·018	0·30
31	0·021	0·32
32	0·020	0·20
33	0·017	0·29*
34	0·020	0·27*

* Cured by administration of 1·5 pigeon doses of crystalline vitamin B_1 solution.

It will be noticed that the concentration of the reducing agent in the lens is fairly high and further that no change results when a cure is effected by an injection of vitamin B_1.

A few lenses from vitamin A-deficient rats, kindly provided by Dr W. J. Dann, were also examined, and they were also found to contain normal amounts of reducing factor.

The results seem to show that this peculiar metabolic disorder in the lens of rats subjected to certain diets is probably due to deficiency of some factor which is not identical either with vitamins B_1, B_2 (flavin or antipellagra factor), "H" or A. We have no evidence as yet as to the probable nature of this factor, but while testing several natural foodstuffs, we found raw egg-white to be a potent source of it. Liver extracts as well as fresh liver were also tested but were found to give rather irregular results. The reason for this is not known. The results are shown in Table V.

Table V shows that raw egg-white, administered in daily doses of 5 ml. possesses strong prophylactic as well as curative action. Smaller doses, 3 and 2 ml. per day, were also tried but the results then were not so clear-cut and gave rather variable values. It may also be pointed out that rats nos. 35–38 were suffering from acute dermatitis owing to deprivation of the antipellagra factor, yet the high reducing capacity of the lens emphasises the the non-identity of the antipellagra and eye factors.

Table V.

No. of rat	Wt. of eye-lens (g.)	Conc. of ascorbic acid in mg./g.	Diet used
35	0·030	0·39	Diet 1 + 5 ml. egg-white daily + vit. B_1
36	0·031	0·32	,, + ,, ,, + ,,
37	0·038	0·28	,, + ,, ,, + ,,
38	0·029	0·23	,, + ,, ,, + ,,
39	0·034	0·37	,, + ,, ,, + ,, + haddock (antipellagra factor)
40	0·028	0·43	,, + 5 ml. egg-white daily + vit. B_1 + Peters's eluate
41	0·034	0·22	Diet 4 + 5 ml. egg-white daily for the last 15 days
42	0·036	0·30	,, + ,, ,, ,,
43	0·021	0·25	Diet 1 + 2 g. liver daily
44	0·041	0·00	,, + ,, ,,
45	0·035	0·37	,, + B_1 + flavin + 2 ml. liver extract daily
46	0·047	0·11	,, + ,, + flavin + 2 ml. liver extract daily + Peters's eluate
47	0·047	0·20	,, + ,, + flavin + 2 ml. liver extract daily + Peters's eluate

It is as yet too early to suggest whether this diminution of the reducing power of the lens is due to some new vitamin. The nature of the factor present in raw egg-white is being investigated. We also hope to publish at a later date an account of the histological changes, if any, in the lens of the eye due to deprivation of this factor.

Vitamin C.

The vitamin C content of the eye-lens of guinea-pigs, both normal and scorbutic, has also been examined. As may be imagined, the vitamin C in the lens appears to depend upon the amount given in the food but curiously enough quite an appreciable amount of the vitamin (about 0·2 mg./g.) is held back tenaciously by the eye-lens, even when the animal has died from acute scurvy. The effect of chronic scurvy as well as combined deficiency of vitamins B and C is under investigation, and fuller details will be published later.

Oxidising agent present in blood.

According to van Eekelen *et al.* [1933; see also Emmerie and van Eekelen, 1934] vitamin C is present in a reversibly oxidised form in the blood. Direct titrations of trichloroacetic acid extracts of the blood of normal animals against 2:6-dichlorophenolindophenol, indeed, fail to show any reduction. With guinea-pigs or human beings given large doses of vitamin C, extracts of blood show small reducing values which however are almost negligible compared with the amount of vitamin C ingested. Nevertheless when extracts of normal blood were examined by the new back-titration method, the presence of some oxidising agent, of the same nature as that occasionally seen in the lens of rats fed on deficient diets (p. 737), was encountered. This finding suggests that there may be some agency present in blood which is capable of oxidising ascorbic acid, possibly into the reversibly oxidised form. If the amount of ascorbic acid ingested is very great, it is evident that after it has reduced the whole of the oxidising agent in the blood, some of the ascorbic acid may still remain and this surplus will give a net reducing value to the blood. Conversely, an increased concentration of the oxidising agent may be expected to be found in scorbutic animals. Only a few experiments have been performed in this direction and though the results seem to confirm this theory, much additional work is required before anything more definite can be said.

The results are summarised in Table VI.

Table VI.

No. of rat	Nature of animal	Wt. of blood taken (g.)	Amount of ascorbic acid in mg. capable of being oxidised by 1 g. of whole blood
48	Normal	8·65	0·019
49	,,	4·75	0·026
50	Diet 4	3·30	0·022
No. of guinea-pig			
G1	Normal	9·40	0·00
G2	19 days on scorbutic basal diet	8·55	0·039

SUMMARY.

1. A new technique for estimating vitamin C by a method of back-titration is described. By its means the indophenol-reducing capacity of the lens from a single normal rat can readily be estimated, the error of determination being within ± 10 %.

2. The indophenol-reducing capacity of the eye-lens as determined by this method is greatly diminished in rats which have been subjected to certain experimental diets lacking in various constituents of the vitamin B complex. In extreme cases, extracts of the lens, instead of showing a reducing capacity, actually oxidise ascorbic acid. The cause of the abnormality does not appear to be due to deficiency of vitamins B_1, B_2 (either flavin or antipellagra factor), "H" or A. It is however too early to say whether a new vitamin is involved.

3. Raw egg-white possesses marked prophylactic and curative action in this disorder.

4. The blood of normal and of deficient animals contains an oxidising agency similar to that found under certain conditions in the lens.

LXXXVI. INVESTIGATIONS ON THE VITAMIN B_2 COMPLEX.

I. THE DIFFERENTIATION OF LACTOFLAVIN AND THE "RAT ANTIPELLAGRA" FACTOR.

By PAUL GYÖRGY.

From the Physiological and Nutritional Laboratories, Cambridge.

(*Received January 31st, 1935.*)

By the end of 1932 three separate components had been distinguished in the vitamin B complex as needed by the rat: (1) vitamin B_1, the antineuritic factor; (2) vitamin B_4, the absence of which was said to be associated also with symptoms of nervous lesions such as disturbances of co-ordination and ataxia; and finally (3) vitamin B_2, the antipellagra factor. In contrast with the first two, the relatively high thermostability of vitamin B_2 had been noted as its special characteristic. All the three factors mentioned display growth-promoting properties under suitable circumstances. Some have held that vitamin B_2 is divisible into two further factors [Sure *et al.*, 1931; Thatcher *et al.*, 1931; Gurin *et al.*, 1931], or at least that this is probably the case [Sherman and Sandels, 1929; 1931]. In this fractionation of vitamin B_2, one factor is alleged to be predominantly growth-promoting, the other being the antipellagra factor. However, none of the supporters of this theory has been able to bring forward convincing proof of his views. Roscoe, on the grounds of her wide experience, recently stated [1933, 2] that "no support was found for the theory postulating the existence of separate dietary factors respectively for preventing and curing dermatitis and for promoting growth".

Chick and Copping [1930] showed that an alkali- and heat-stable, water-soluble, growth-promoting factor, called by them factor Y, probably existed, but no experimental work has yet determined its precise position in the vitamin B complex.

The biological analysis of vitamin B_2 was attended with great difficulties. Almost all workers were agreed that the specific symptoms peculiar to vitamin B_2 deficiency, as first described by Goldberger and Lillie [1926], and regarded by them as analogous with pellagra in man, only appeared irregularly in rats [*cf.* Medical Res. Council, 1932, p. 151]. In another recent paper Roscoe [1933, 1] gives "data concerning the incidence of dermatitis among the vitamin B_2-deficient animals observed in the Nutritional Laboratory of the Lister Institute during the past seven years". Skin changes were noted in only 108 out of a total of 191 rats. The average time taken for symptoms to develop was 10 weeks. Roscoe employed the usual vitamin B-free, synthetic diet, supplemented by vitamin B_1 $(+B_4)$ in the form of a concentrate from brewers' yeast prepared according to Peters [*cf.* the new directions of Kinnersley *et al.*, 1933]. Other authors used an alcoholic extract of maize [Goldberger and Lillie, 1926], or of wheat [Bourquin and Sherman, 1931] as the source of vitamin B_1. Dried yeast irradiated with ultra-violet light and liver extracts similarly irradiated [Hogan and Richardson, 1932, 1, 2; 1933] or irradiated rice polishings [Thatcher *et al.*, 1931] are said to be equally suitable forms in which vitamin B_1 may be given in experiments on vitamin B_2. With these dietetic modifications, and using alcoholic extracts of maize and wheat, the percentage of rats deprived of vitamin B_2 which show pellagra-like dermatitis reaches a satisfactorily high level; but even these experimental methods do not yield uniform results.

The object of our own investigations was the study of the skin changes, and the work of Sherman and Sandels, which appeared about the time we were beginning our experiments, suggested to us that this object could be most rapidly and easily attained by the use of the diet described by Bourquin and Sherman [1931].

These experiments have been reported in several papers in association with Kuhn and Wagner-Jauregg [1933; 1934]. In addition to a number of minor observations, they yielded two new and important pieces of information. (1) Vitamin B_2 is in fact not a single substance but may be subdivided into two subsidiary components; and (2) it was possible chemically to identify one of these subsidiary factors, which was first prepared in crystalline form from milk. This natural dyestuff, called lactoflavin, corresponds to the coloured component of the "yellow oxidation ferment" of Warburg and Christian [1932, 1, 2; 1933], and is present, under natural conditions, in foodstuffs, not only in the free state, but also in the form of Warburg's ferment, *i.e.* in combination with a protein carrier as a non-dialysable "flavoprotein" [György *et al.*, 1934, 3].

When the experimental diet of Bourquin and Sherman is used it is not possible to produce an increase in the weight of animals whose growth has become stationary merely by the addition of pure lactoflavin to the diet. The addition of some other factor (or factors) is found to be necessary. Our first active supplements to the basal diet of Bourquin and Sherman consisted of concentrates from yeast from which the flavins had been removed by adsorption on fullers' earth in acid solution. Such solutions by themselves were however completely inactive, and animals, after a slight initial gain in weight, generally remained at a constant weight for weeks on end. If lactoflavin were administered at this juncture there was a dramatic resumption of growth. The active yeast residue referred to above may be replaced by a concentrate of vitamins B_1+B_4 such as may be obtained by adsorption of purified concentrates from yeast on charcoal, and subsequent elution with alcohol containing hydrochloric acid [Kinnersley *et al.*, 1933; György *et al.*, 1933, 1, 2; 1934]. Since however the results of these experiments were independent of the vitamin B_1, which was present in considerable amounts in the diet of Bourquin and Sherman (extract of wheat), we were inclined at first to correlate the indispensable supplementary substance with vitamin B_4.

In the isolation of lactoflavin, and its identification as one of the components of the vitamin B_2 complex, the growth rate was used exclusively as biological criterion and standard. The unit dose was defined according to the rules laid down by Chick and Roscoe [1927], as that quantity of lactoflavin which would give rise to a gain in weight of 10 g./week for at least 4 weeks. Under the experimental conditions mentioned (diet of Bourquin and Sherman *plus* flavin-free supplementary substance), 7–10 γ of lactoflavin were found to be equivalent to 1 rat day dose [György *et al.*, 1933, 1; 1934, 3]. On the other hand, in order to produce the full effect of lactoflavin, we required as supplementary factor a quantity of yeast concentrate, as prepared by Kinnersley *et al.*, equivalent to 5–15 g. of fresh bakers' yeast.

The growth-promoting action is only one property of vitamin B_2, which owes its peculiar position in the vitamin series to its supposed protective action against pellagra. To what extent lactoflavin also possesses this biological property is an important question to which the results already referred to give no answer, for, in our numerous original experiments, we failed to observe a single case of genuine, well-marked, pellagra-like dermatitis. Vitamin B_2 deficiency was expressed only as cessation of growth, followed later by a gradually progressive decrease in weight. Thus an important gap arose. The filling of this gap was the task to which the experiments now described were directed.[1]

In the meantime, the scope of the task had widened considerably. The precise nature of the "supplementary substance" which was present in the vitamins B_1+B_4 concentrates of Kinnersley *et al.* was to be submitted to a more exact analysis. Owing to the inconstant chemical composition, and therefore uncertain nature, of the wheat extract which served as the source of vitamin B_1 in the diet of Bourquin and Sherman, I preferred to employ for my other experiments the crystalline preparation of Windaus *et al.* [1931], or a highly purified vitamin B_1 product, of which 8–12 γ were equivalent to 1 pigeon day dose. I was supplied with both these preparations through the generosity of the I. G. Farbenindustrie, Elberfeld, Germany.

The distribution of vitamin B_2 in animal products has also been re-investigated [see György, 1935, 1], since, owing to the state of our knowledge at the time when our previous investigations were undertaken, the complex nature of vitamin B_2 could not then be taken into account [György *et al.*, 1934, 1]. Finally I have made a renewed attack on the problem of the photosensitivity of vitamin B_2 [György *et al.*, 1933, 2] or of its components, having regard, this time, to the pellagra-like skin changes [see György, 1935, 2].

EXPERIMENTAL.

A. *Use of the diet of Bourquin and Sherman for the production of pellagra-like dermatitis in rats.*

There were several possibilities which might account for the failure to produce pellagra-like skin changes in the experiments performed with Kuhn and Wagner-Jauregg. The relatively short duration of the preliminary depletion period, during which the animals received no supplements in addition to the diet of Bourquin and Sherman, has already been referred to in previous papers. The animals used for the experiments were very young, generally weighing 20–30 g. The weight frequently became stationary after 1 week only. After 4, or at the most 6 weeks, the animals became so weak that treatment with active B_2 concentrates could usually be no longer postponed. In order to demonstrate the essentially supplementary action of flavin, feeding with flavin-free solutions was begun early, usually in the 3rd to 6th week of the experiment. This was done on the assumption that flavin was the actual pellagra-preventing substance. If this assumption were incorrect, and if the pellagra-preventing substance were contained instead in the supplementary factor, then the absence of pellagra-like dermatitis would be the logical result of this experiment. Finally the possibility has to be discussed whether alcoholic wheat extracts vary in pellagra-preventing activity, so that some of them may be able alone to prevent the development of pellagra.

The experiments performed to clear up this possibility gave positive answers to all the questions which have been considered.

Fifteen rats, ranging in weight from 30 to 40 g., were put on a Bourquin-Sherman diet; five of these received no further supplements, five received 10 γ

---

[1] A preliminary communication appeared in *Nature*, **133**, 498, March 31st, 1934.

each of lactoflavin daily, and the remaining five animals each received 1 ml. of a solution of vitamins B_1+B_4 [Kinnersley *et al.*, 1933] equivalent to 10 g. of fresh bakers' yeast. After 5–8 weeks, two animals of the first and three of the second group showed definite pellagra-like manifestations of the skin, while the third group remained free from symptoms, their weight however remaining stationary in common with the rats of the other two groups. It chanced that the supply of maize-starch impregnated with alcoholic extract of wheat ran out at this stage of the experiment and a new sample had to be used. The result was a gradual disappearance of the pellagra-like skin changes. In addition, the group of animals treated with supplements of lactoflavin displayed an increase in weight side by side with the improvement in the skin symptoms (Fig. 1). The weight of the animals receiving no lactoflavin remained stationary. It must therefore be concluded that the alcoholic wheat extract used later in the experiment, in contrast to the extract used previously, contained a amount of pellagra-preventing substance which was sufficient to bring about the disappearance of the pellagra-like dermatitis. At the same time another unexpected conclusion probably follows from this observation, namely that lactoflavin is not the pellagra-preventing substance, but that under certain circumstances, large amounts of the pellagra-preventive factor may be present in an alcoholic wheat extract, and that it is also present apparently in the alcohol eluate from charcoal prepared from bakers' yeast [Kinnersley *et al.*, 1933]. Pellagra was cured in all these animals in 7 weeks. The use of untreated rice-starch in place of the maize-starch loaded with alcoholic wheat extract, and the use of a solution prepared from crystalline vitamin B_1 (from the picrolonate) as a source of vitamin B_1 (3 pigeon day doses daily) brought about another immediate cessation of growth of the animals, followed by progressive loss of weight, and after 3–4 weeks, an acute exacerbation of "rat pellagra". This subsequent period gave a further setback to the conclusions which had previously been drawn.

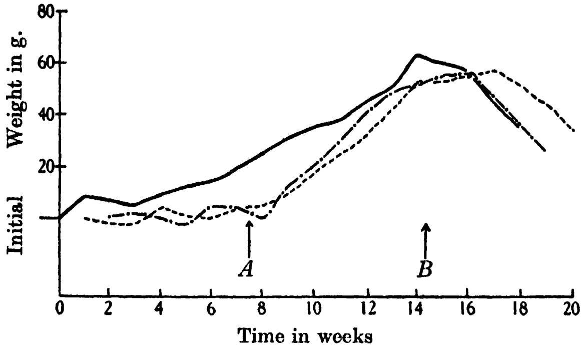

Fig. 1. The weight curves of three rats which received 10γ lactoflavin daily in addition to the diet of Bourquin and Sherman. At *A* the alcoholic extract of whole wheat was replaced by a new sample, and this in its turn was replaced at *B* by a crystalline preparation of B_1. All the animals showed symptoms of pellagra at the end of the experiment.

The results of the experiments just described show that, with a suitable wheat extract, the diet of Bourquin and Sherman may be employed with advantage in experiments on "pellagra". The uncontrollable variations in the contents of "pellagra-preventive" factor (probably depending on the type of wheat used and on the composition of the alcoholic wheat extract) constitute a very disturbing element of uncertainty which may under certain circumstances completely prevent the carrying out of the desired experiments. Accordingly it is recommended that if a crystalline, or similarly well-characterised and highly purified preparation of vitamin B_1, can be obtained the diet of Bourquin and Sherman should be dispensed with in experiments of which the purpose is the study of pellagra-like dermatitis. In addition to this, it must be borne in mind that yet other unknown components of the vitamin B complex may be present in the alcoholic wheat-extract. Thus work on the vitamin B complex, and on the B_2-group in particular, may be made to give quite illusory results.

B. *Use of highly purified or crystalline vitamin B_1 in the analysis of the vitamin B_2 complex.*

By the use of crystalline vitamin B_1 in a diet otherwise free from representatives of the vitamin B group, the analysis of the vitamin B_2 complex became more exact. This advance possesses a certain disadvantage from the biological point of view. For the study of the symptoms of deficiency of any particular component of the vitamin B_2 complex, all the other members of this group must be present in the experiment. It is known from numerous experiences in the study of vitamins that the appearance of the uncomplicated pure, specific, deficiency disease can only be assured if this condition is fulfilled. It is highly probable that the diet of Bourquin and Sherman comes nearer to satisfying this condition than a pure, or highly purified preparation of vitamin B_1. Nevertheless this disadvantage should not be over-estimated, and the attempt at analysing the vitamin B_2 complex should be undertaken by a clear, comprehensive method. The isolation of lactoflavin, with the help of the diet of Bourquin and Sherman, represents an important achievement for the new biological analysis. We now have at our disposal, in the form of crystalline preparations, both vitamin B_1 and lactoflavin. It remained to be shown in separate experiments whether the charcoal eluate obtained from bakers' yeast by the method of Peters was also capable of fulfilling the rôle of supplementary factor in these modified experiments.

The basal diet was constituted as follows:

Caseinogen AB "Glaxo"	18
Rice-starch	68
Butter fat	9
Cod-liver oil	1
Salt mixture (B.D.H.)	4

Caseinogen AB "Glaxo" extracted with alcohol was used in the later experiments, but no definite biological differences could be detected, in these experiments, between the two specimens of caseinogen.

The experimental animals employed were albino and piebald rats of various weights. In the earliest experiments the weights ranged chiefly from 35 to 50 g. The stock diet for one group of rats consisted of milk, bread and wheat kernels, with meat and cabbage once weekly. The majority of the rats were descended from a single stock reared on the following regulation stock diet in use at the Nutritional Laboratory:

Monday.	Bread, milk, cabbage and mixed corn.
Tuesday.	Bread, milk, liver.
Wednesday.	Boiled wheat, milk, yeast and cabbage.
Thursday.	Bread, milk, meat and mixed corn.
Friday.	Bread, milk and carrots.
Saturday.	Bread, milk, cabbage and mixed corn.
Sunday.	Bread, milk and carrots.

Lettuce twice a week when obtainable.

The change in the stock diet was without detectable influence on the time of appearance of pellagra-like skin changes, on their intensity or on the absence of growth which occurs with an experimental diet free from vitamin B_2 complex. Differences in sex or in pigmentation (albino or black-and-white) were also found to be of no significance in these investigations.

In addition to the experimental diet the rats received vitamin B_1, at first in the form of a crystalline preparation (from vitamin B_1 picrolonate) in doses of 3–4 pigeon day doses dissolved in 2 ml. of water daily (Sundays excepted). A lengthy series of experiments showed that a highly purified vitamin B_1 concentrate, 1 pigeon day dose of which was equal to about 8–12 γ of the dry residue, performed the same function as the pure picrolonate. The latter substance, which is more easily prepared, was therefore used in preference. Henceforth every new experimental result was invariably controlled with the crystalline preparation serving as the source of vitamin B_1.

The first task was the repetition of the results previously obtained with the diet of Bourquin and Sherman. The most urgent question was whether the character of lactoflavin, as a component of the vitamin B_2 complex, could be brought out by the modified experimental method also.

To this end the animals were given, together with the preparation of vitamin B_1, Peters's eluate [Kinnersley *et al.*, 1933] from bakers' yeast, such as had already proved of value as a supplementary factor when the diet of Bourquin and Sherman was being used [György *et al.*, 1934, 3]. 1 ml. of a solution, equivalent to 10 g. of fresh bakers' yeast, was given daily (again Sundays excepted). Despite these supplements however the growth of the animals remained almost completely stationary, apart from a slight increase in the first weeks of the experiment. If, after a longer or shorter preliminary period, the animals are given lactoflavin, a striking increase in weight at once sets in which persists with practically no diminution for 4–6 weeks. If the order of the experiment be now reversed and the animals be fed first with vitamin B_1 *plus* lactoflavin, growth will remain stationary in precisely the same way. In fact the inhibition of growth in this case is generally most impressive and is as a rule absolute. In this experiment the subsequent administration of Peters's eluate causes as sudden a resumption of growth as did that of lactoflavin with the animals which were given vitamin B_1 *plus* Peters's eluate in the first place and lactoflavin subsequently. The change in the order of the experiment does not affect the result, at all events so far as the resumption of growth is concerned (Fig. 2).

Thus the information obtained in previous researches [György, Kuhn and Wagner-Jauregg, 1933; 1934] was confirmed once more with the aid of this clear and simplified experimental technique. Vitamin B_2 therefore may be subdivided into two subsidiary factors: (*a*) the crystalline, well-defined lactoflavin and (*b*) the "supplementary factor" (or perhaps supplementary factors) contained in Peters's "charcoal eluate" from bakers' yeast. Growth can only be brought about by the combined actions of both these components, independently of the order in which they are exhibited.

This result is of critical importance, the key as it were to all further attempts at analysing the vitamin B_2 complex. It was confirmed by numerous subsequent experiments. Of these eleven were devoted exclusively to this purpose. In seven of these the animals received Peters's eluate in addition to vitamin B_1 in the preliminary stage. In four others they received lactoflavin only in addition to vitamin B_1. Lactoflavin was given in doses of 7–10 γ daily, and Peters's eluate in amounts equivalent to 10 g. fresh bakers' yeast. The average weekly gain in weight for the eleven experiments was 11 g. in an experimental period of 4 weeks, and 10 g. in a period lasting 6 weeks. It should be emphasised that the variations in the values obtained for individual animals were very slight. Increasing the quantity of lactoflavin to 20 γ or of yeast eluate to the equivalent of 20 g. fresh bakers' yeast did not increase the rate of growth to any notable extent. On the other hand, reduction of the doses, whether of lactoflavin or of yeast eluate, led to an insufficient acceleration of growth.

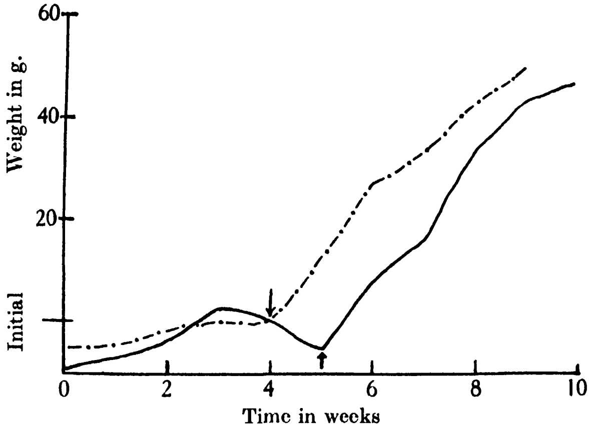

Fig. 2. Apart from the basal diet both animals received 3 pigeon doses daily of vitamin B_1. In addition to this the animal —— received 10γ lactoflavin, and the animal —·— 1 ml. Peters's eluate daily (equivalent to 10 g. of fresh bakers' yeast). At ↑ the animal —— was given 1 ml. of Peters's eluate also, and at ↓ the animal —·— 10γ lactoflavin. An increase in weight was only produced by the combined administration of vit. B_1 + lactoflavin + Peters's eluate.

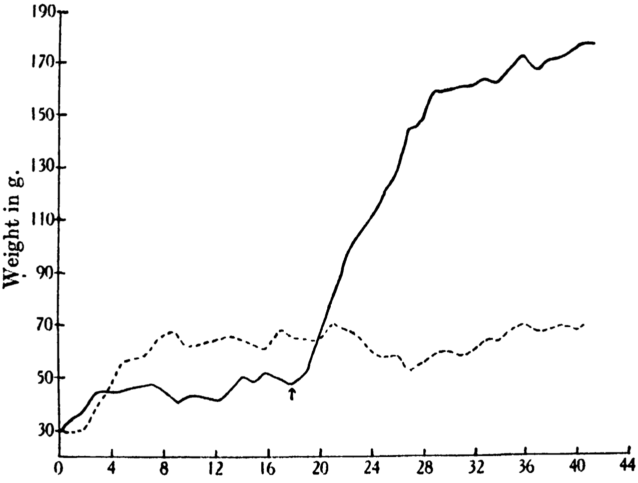

Fig. 3. The weight-curves of two animals which, apart from the basal diet, received at first only vitamin B_1 + Peters's eluate. At ↑ the animal —— was given 10γ lactoflavin daily in addition. The doses of Peters's eluate and lactoflavin were doubled in the 32nd week.

The daily requirements established in this case hold good only for the experiment described. It is quite possible, for example, as Euler *et al.* [1934] have recently emphasised, that the daily requirement for lactoflavin may be lowered if the animals are given all the other components of the vitamin B_2 complex at the same time, or at all events if they are given them in a more favourable combination than in the above experiment. In this respect Peters's yeast eluate does not fulfil the highest requirements as a supplement to lactoflavin. This may clearly be seen from the fact that animals receiving vitamin B_1, lactoflavin and Peters's eluate maintain the normal rate of growth only up to a body weight of 150–170 g. Growth cannot be pushed beyond these limits even by increasing the doses of lactoflavin and yeast eluate. The curve reproduced (Fig. 3) is particularly instructive in this respect.

Crystalline lactoflavin may also be replaced by egg-white.

Animals receiving 3–5 ml. daily of raw egg-white in addition to a basal diet *plus* purified vitamin B_1 react in the same manner as in the experiments with vitamin B_1 and crystalline lactoflavin. Growth remains at a complete standstill and shows no change for weeks on end. Feeding with Peters's preparation at this point promptly brings about the expected increase in weight (Fig. 4). Up to the present we have been unable to find any definite differences between the reactions of animals receiving crystalline lactoflavin and those in receipt of raw egg-white as the source of lactoflavin. The amount of Peters's eluate required in this experiment was again equivalent to 10 g. of fresh bakers' yeast. A dose of 3 ml. of egg-white as the source of lactoflavin is sufficient to maintain the growth at the standard rate. An increase in the dose of egg-white to 5–10 ml. produced no additional increase in growth, nor did an increase in the dose of lactoflavin from 7–10 γ to 20 γ.

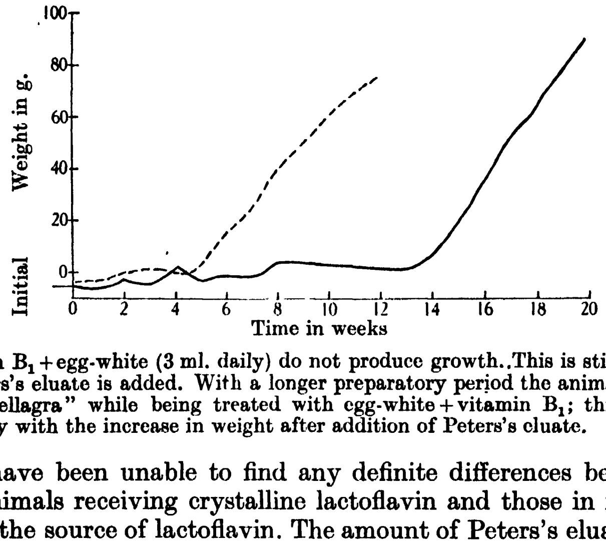

Fig. 4. Vitamin B_1 + egg-white (3 ml. daily) do not produce growth. This is stimulated immediately Peters's eluate is added. With a longer preparatory period the animal —— displayed typical "pellagra" while being treated with egg-white + vitamin B_1; this rapidly healed coincidently with the increase in weight after addition of Peters's eluate.

The experiments which have just been described possess special significance with regard to the question of the existence of vitamin B_4 [Reader, 1929; 1930, 1, 2]. It is worthy of note that rats receiving crystalline vitamin B_1 (3–4 pigeon doses daily) and no further addition of vitamins (with the possible exception of crystalline lactoflavin only) do not exhibit any symptoms which can be taken as specific of vitamin B_4 deficiency (Reader), even in experiments extending over as long as 10–15 weeks and more. Nervous manifestations typical of this condition in particular were absent, such as ataxia, loss of co-ordination and spastic gait.[1]

---

[1] The nature of the symptoms held to be due to vitamin B_4 deficiency is discussed in a separate paper by Birch and György in press.

C. *Pellagra-like dermatitis*[1] *and the vitamin B_2 complex.*

The incidental observations made in the experiments with the diet of Bourquin and Sherman, that pellagra-like dermatitis was dependent not on the absence of lactoflavin but on that of the "supplementary factor", was convincingly confirmed by a further extensive series of experiments with the modified technique. In a group of over fifty rats which received purified vitamin B_1 and Peters's eluate in quantities equivalent to 10 g. fresh bakers' yeast, not a single case of skin changes of a pellagra-like character was observed. This negative result cannot be explained by the shortness of the period during which the animals were under observation, for a large number (24) of the experimental animals were treated with vitamin B_1 and Peters's eluate for at least 12 weeks. At the same time the growth curve, after an initial but definite rise, took a horizontal, or a moderately rising course (*cf.* as example Fig. 3). The relevant figures are given in the following table:

No.	Weeks	Increase in wt. (g.)	No.	Weeks	Increase in wt. (g.)
1	19	21	13	16	18
2 +	15	16*	14 +	14	7*
3	20	40	15 +	27	79
4	19	28†	16	23	63
5	20	13	17 +	26	44
6	20	35	18 +	13	10*
7	19	37	19	21	38
8	24	46	20	41	39
9 +	23	17	21 +	21	34
10 +	29	50	22 +	12	6
11 +	18	35*	23 +	20	39
12 +	26	27*	24 +	22	38

* Died. † 33 g. in first 5 weeks and – 5 g. in the remaining 14.

In about one half of the rats submitted to over 12 weeks' experimentation (*i.e.* in 13 marked + out of 24 in the above table) the deficiency of lactoflavin expressed itself in these experiments not only as stationary weight but in certain well-marked associated symptoms, the most important of which were changes in the skin and fur. These latter, however, were fundamentally distinct from the specific "pellagra-like" changes. They differ chiefly in being much less striking. In deficiency of lactoflavin (at least under the experimental conditions selected by us) a gradually progressive loss of hair occupies the foreground of the picture. It is localised to certain areas, such as the back between the shoulders, the lines joining the eyes and ears leaving a median comb of hair remaining in between and finally the chest. In many cases there may be observed on the uninflamed skin, in the midst of the scanty patches of fur, minute, almost punctate whitish-yellow scales. In advanced cases the eyes are sometimes surrounded by a spectacle-like loss of hair, while the eyelids are gummed together. The extremities and the ears invariably escape all changes whatsoever. If treatment, *i.e.* addition of lactoflavin, is not begun in time, the animals succumb to general exhaustion. The end is usually ushered in by meteorism (which is presumably an expression of intestinal atony), by dyspnoea (which is probably due to the last-named symptom and is reminiscent of the laboured breathing seen in pneumonia) and by blue discoloration of the extremities (circulatory failure?). The administration of lactoflavin at the appropriate time will avert this end with absolute certainty. With the resumption of growth all the other associated symptoms of lactoflavin deficiency begin to resolve.

---

[1] Throughout this series of papers the term "pellagra", as applied to rats, is used without prejudice as to its identity or non-identity with human pellagra.

While in lactoflavin deficiency the skin changes just described appear irregularly and are not very striking, in rats which received in addition to the basic diet vitamin B_1, or vitamin B_1 *plus* lactoflavin or egg-white, but not the "supplementary factor" contained in Peters's eluate, the skin disorders completely fill the picture. It is here that we encounter the specific symptom-complex of pellagra-like dermatitis first described by Goldberger and Lillie [1926]. This peculiar skin disorder appeared in every case provided the experiments were prolonged for a corresponding length of time. We already possess observations on 211 cases of this nature which we collected during 1934. Of these 55 have had the disease twice, *i.e.* having been successfully treated on the first occasion they again fell ill when submitted to the original conditions once more. The animals may be placed in six groups according to the supplements they received.

Group	Supplement	Total no. of animals	First symptom of "pellagra" after av. no. of weeks	Animals ill twice	First symptom of "pellagra" of second illness after av. no. of weeks
1	Crystalline vitamin B_1 (3–4 pigeon units daily)	10	6	1	7
2	Purified vitamin B_1 preparation (3–4 pigeon units daily)	12	7	3	8
3	Crystalline vitamin B_1 + lactoflavin (10γ daily)	31	6	8	6
4	Purified vitamin B_1 preparation + lactoflavin (10γ daily)	65	7	18	7
5	Purified vitamin B_1 preparation + 3 ml. egg-white daily	59	7	18	8
6	Purified vitamin B_1 preparation + 5 ml. egg-white daily	34	8	7	11
	Total	211	7	55	8

Thus with this experimental technique it has been possible to overcome the element of uncertainty which has hitherto prevailed in the experimental production of pellagra-like dermatitis. Differences in the supplements used did not affect the incidence of the clinical picture of pellagra-like dermatitis. Within narrow limits it was a matter of indifference whether the animals received only vitamin B_1 in addition to the basal diet, or vitamin B_1 *plus* lactoflavin (the latter in the form of crystalline lactoflavin, or as egg-white in doses of 3–5 ml. daily). It was found that the only factor of importance in this respect was the daily quantity of vitamin B_1 administered. If less than 3 pigeon day doses were given daily the appearance of pellagra-like dermatitis was often delayed. In a few cases, examples of which are shown in the accompanying curves (Fig. 5), spontaneous healing of the "pellagra" was observed while these subliminal doses of vitamin B_1 were being given, either with or without the simultaneous appearance of polyneuritic symptoms. But a subsequent increase in the dose of vitamin B_1 to 3–4 pigeon day doses daily brought out the pellagra-like dermatitis once more, at the same time suppressing the nervous symptoms. Thus it is an indispensable condition for the production of pellagra-like dermatitis that the animals be adequately supplied with vitamin B_1. Excessive doses of vitamin B_1, 6–8–10 pigeon day doses daily instead of 3–4, did not accelerate the development of the dermatitis, nor did they predispose towards its appearance. We are therefore unable to agree with Kellogg and Eddy [1933], who see a relationship between the development of pellagra-like dermatitis and a hypothetical toxic action on the part of vitamin B_1. It is also worthy of mention in this respect, that in our experiments excessive dosage with vitamin B_1 does not affect the weight curves of the animals. This must be taken as evidence on the one hand that the vitamin B_1 requirements of the animals were amply satisfied by 3–4 pigeon day doses, and on the other hand that the vitamin B_1 preparation employed was uniform in the biological sense.

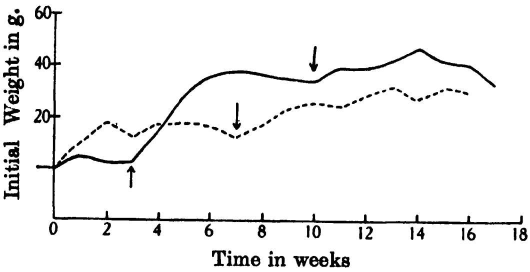

Fig. 5. Both animals received at first vitamin B_1 only (1·5 pigeon day doses daily); the animal —— from ↑ onwards, and the other rat - - - - - from the very commencement. One week before ↓ both rats showed definite signs of healing of the pellagra symptoms which had just recently appeared. Doubling of the dose of vitamin B_1 at ↓ produced an exacerbation of the pellagra symptoms.

We were unable to find any correlation between the season of the year when the experiments were performed, or between the initial weight of the experimental animals on the one hand and the development of "rat pellagra" on the other. The relation between the initial weight of the animals and the time taken to produce symptoms of "pellagra" is shown in the table below.

Initial body-weight (g.)	No. of exp. animals	First symptom of "pellagra" after av. no. of weeks	Animals ill twice	First symptom of "pellagra" of second illness after av. no. of weeks
26–35	21	7	—	—
36–45	51	7	1	13
46–55	35	7	—	—
56–65	17	6	2	8
66–75	21	7	5	7
76–85	17	9	7	10
86–95	18	9	14	9
96–105	16	6	13	6
106–115	7	7	6	7
116–125	4	7	3	8
126–135	4	6	4	6

The onset of the second illness in animals which have been successfully cured of a first attack of "pellagra" and are then re-submitted to the disease-producing conditions is determined by the intensity of the original therapeutic treatment. The reappearance of the disease may be considerably postponed by intensive treatment, which must be taken as evidence that the "pellagra-preventing factor" is capable of being stored in the body.

The skin manifestations met with when vitamin B_1 or B_1 *plus* lactoflavin (egg-white) are given may be distinguished readily and with certainty from those which appear when vitamin B_1 *plus* Peters's eluate are fed. The former symptoms are identical with the "pellagra-like" dermatitis of Goldberger and Lillie [1926], while the irregular skin manifestations of lactoflavin deficiency as seen with our experimental technique are chiefly of an unspecific nature.

The leading feature of "pellagra-like" dermatitis is the involvement of the most peripheral parts of the body. The disease begins with swelling and hyperaemia of the ears which is soon followed by the involvement of the fore and hind paws and the nasal region. The distribution is for the most part perfectly symmetrical but exceptions to this rule are met with occasionally. In the latter the symmetry is frequently, though not invariably, restored during the course of the illness. The second stage, which follows the swelling and hyperaemia, consists in the formation of crusts on the pinnae, which becoming thickened and indurated may develop into flower-like excrescences. Scabs form in the vicinity of the raw and inflamed nostrils, corresponding in their distribution to the follicular areas of the vibrissae, and also on the eyelids, which are gummed together in these cases. The vibrissae do not fall out. The paws undergo either a desquamation in small flakes or larger scales, or else their dorsal surfaces become markedly oedematous with a serous discharge, associated in many cases with gangrene of individual toes and secondary auto-amputation. Among the hairs on other parts of the body seborrhoeic scales or often only inspissated secretion are not infrequently found. The hair shows very little external alteration. In a few animals bleaching may be observed, hairs formerly black becoming grey. Ulceration of the buccal mucuous membrane, particularly the lower surface of the tongue, is a very common associated symptom. The pulse-rate per minute is normal (450–530); diarrhoea is a rare occurrence. If no specific treatment be undertaken the animals succumb, without exception, with progressive loss of weight which towards the end falls steeply.

The very striking differences in the characters of the skin manifestations afford the best proof that the disturbances of growth seen in lactoflavin deficiency on the one hand, and those met with during the administration of vitamin B_1, or B_1 *plus* lactoflavin (egg-white) on the other hand, do not depend on the same disturbances of metabolism. As we have already shown, administration of lactoflavin and of the "supplementary factor" in Peters's eluate both cause resumption of growth under suitable conditions. In the same way both lactoflavin and Peters's eluate bring about the disappearance of the skin manifestations in a short time.

The effect of lactoflavin in this respect runs parallel with the increase in growth and consists in disappearance of the fine whitish yellow scales and in shedding of the old hairs and their replacement by new ones of the normal density and gloss. This result is attained by 7–10 γ lactoflavin daily, whereas a manifold increase in the dose of Peters's eluate has no more effect on the skin changes than on growth, if the simultaneous administration of lactoflavin is withheld.

The healing of "pellagra-like" dermatitis under the influence of adequate doses of Peters's eluate begins with shedding of the vegetation on the ears, paws, nasal regions and eyelids. The ears when first freed from scabs are thickened and hyperaemic with ragged, irregular margins. In the vicinity of the eyes and nose, and in other parts of the body, the hair frequently comes out in tufts at the same time as the scabs and scales are shed, exposing bald areas until new hairs have reappeared. The transitory spectacle-like borders surrounding the eyes arise in this way. The last sign to disappear by which a case of healed "rat pellagra" may be recognised is the reddened, and later somewhat shiny, folded ears; finally, with sufficient treatment, even this residual symptom disappears.

In pellagra-like dermatitis developing during the administration of vitamin B_1 *plus* lactoflavin (10 γ daily), or vitamin B_1 *plus* egg-white (3–5 g. daily), administration of Peters's eluate in doses equivalent to 10 g. of fresh bakers' yeast will produce rapid healing of the skin changes with simultaneous increase in weight, equal to, or even exceeding, that demanded by the criterion (10 g. per week) (*cf. e.g.* Fig. 4). In very advanced cases the acceleration of growth in the first week of treatment may fall short of that anticipated, only to compensate for this delay in the 2–3 weeks following. The skin is generally restored to its normal condition after 3–4 weeks of treatment. Bleaching of the hairs, which may have arisen during the disease, generally persists after all the other symptoms have been successfully cured. With a dose of Peters's eluate equivalent to 5 g. of fresh bakers' yeast, the skin manifestations resolve in the same way, if somewhat more slowly, as with double this amount; but the increase in growth falls considerably short of the criterion. Still smaller doses leave even the skin manifestations unaffected. These subliminal doses may be of no avail even prophylactically. The symptoms however do not as a rule become intensified but exhibit considerable variations which in some instances may approach spontaneous healing. If the Peters's eluate be prepared from brewers' instead of from bakers' yeast, then doses equivalent to double the quantity of the original yeast will be necessary.

From the experiments described thus far, the fact emerges that the pellagra-preventing substance cannot be identical with lactoflavin but should be looked for in Peters's eluate. The correctness of this assumption is strongly confirmed by the following observations.

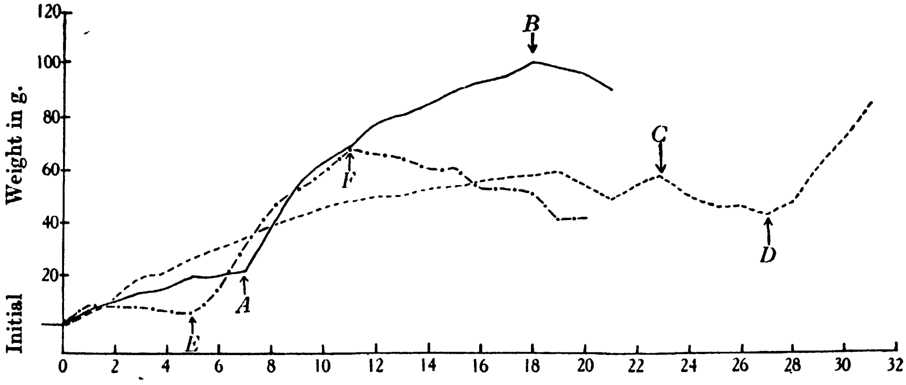

Fig. 6. The rat —— at first received vitamin B_1 + Peters's eluate only; at *A* lactoflavin was added, and at *B* Peters's eluate was omitted, *i.e.* administration of vitamin B_1 + lactoflavin only. Result: "pellagra". The rat ----- was treated at first with vitamin B_1 + lactoflavin and with doses of Peters's eluate insufficient to produce growth. At *C* this rat was given vitamin B_1 + lactoflavin only. Result: "pellagra" which was cured by Peters's eluate (*D*), this time in large doses. The rat —·— received at first vitamin B_1 + lactoflavin. Addition of Peters's eluate at *E* and again omitted at *F*. Result: "pellagra".

In animals which have suffered either from deficiency of lactoflavin or from "pellagra" and are being treated with vitamin B_1 *plus* lactoflavin *plus* "supplementary factor" (Peters's eluate), and no longer show any pathological skin changes, if then Peters's eluate be suddenly omitted, the specific skin manifestations of pellagra-like dermatitis will infallibly reappear sooner or later. A few examples from this extensive series of experiments are given in Fig. 6. On the other hand elimination of lactoflavin with continued administration of Peters's eluate does not lead to the development of "pellagra".

The conclusion is therefore irresistible that the "pellagra-preventing substance" is contained in the flavin-free, charcoal eluate of Peters, and that it is not identical with lactoflavin. When engaged in proving the growth-promoting properties of lactoflavin in our earlier experiments [György, Kuhn and Wagner-Jauregg, 1933; 1934] we made use of Peters's eluate as a "supplementary factor". We then expressed the opinion that the active principle to which the properties of Peters's eluate were due was vitamin B_4. In the specific vitamin B_4 deficiency disease, as described by Reader, nervous symptoms resembling polyneuritis are prominent, whereas in our experiment these symptoms were completely lacking, the picture being dominated by the pellagra-like dermatitis. Furthermore we succeeded in curing the pellagra-like dermatitis by using, instead of Peters's eluate, a yeast preparation (marmite) autoclaved for 4 hours at p_H 10 [György, 1934]. This finding cannot be reconciled with the fact that vitamin B_4 is highly sensitive to alkalis (Reader). In this respect we may refer to our earlier remarks (p. 748). In our preliminary communication, to avoid misunderstandings, we chose for the component of the vitamin B_2 complex, which was to be regarded as the pellagra-preventing substance, the provisional designation of vitamin B_6, leaving open the question of its identity with the Y-factor of Chick and Copping [1930], and with the pigeon-factor B_5. We propose to adhere to this designation for the time being and shall return to the problem of nomenclature later.

It follows from the experiments described above that no causal significance can be ascribed to lactoflavin, either in respect of the development or the cure of "pellagra-like" dermatitis. The appearance of "pellagra" was observed in 189 cases in which vitamin B_1 *plus* lactoflavin was given, but not a single case was seen when B_1 *plus* B_6 (Peters's eluate) only were given. Pellagra-like dermatitis developed in 22 animals which were given vitamin B_1 only, with no simultaneous administration of lactoflavin. In these cases the administration of vitamin B_6 alone, in the form of Peters's eluate (*cf.* Fig. 7), eventually brought about the cure of the pellagra-like skin manifestation, just as it did also in the case of those animals which developed "pellagra" when given vitamin B_1 *plus* lactoflavin. Nevertheless the two cases differ in two respects. There is, as might be expected, no resumption of growth in the absence of lactoflavin on the one hand, in spite of the administration of vitamin B_6, and on the other hand the skin changes take much longer to clear up than when B_6 is given in combination with lactoflavin; although the "pellagra" shows considerable improvement after 4 weeks, it is by no means healed. The symptoms of lactoflavin-deficiency, where this exists, remain in all their intensity. It should however be pointed out that with more prolonged treatment all the manifestations of pellagra will eventually disappear under the influence of vitamin B_6 (Peters's eluate) alone. In many cases

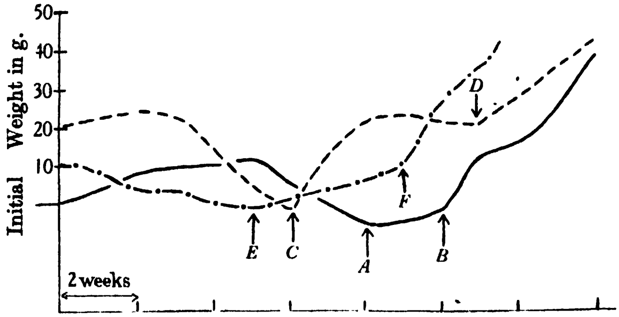

Fig. 7. The weight-curves of three rats which had developed "pellagra" with vitamin B_1 as the only supplement. At *A*, *C* and *E* addition of Peters's eluate, and at *B*, *D* and *F* of lactoflavin also.

where marked loss of weight has occurred before the beginning of treatment, administration of vitamin B_6 even without simultaneous administration of lactoflavin may cause a transitory stimulation of growth, but this increase comes to a stop after 1–2 weeks and can only be renewed by giving lactoflavin (Fig. 7). If feeding with lactoflavin is begun during a stage when the administration of vitamin B_6 has not yet completely cured the pellagra, the rapid improvement which sets in may be erroneously ascribed to the action of lactoflavin. The falsity of this conclusion has been finally proved by our experiments.

DISCUSSION.

Analysis of the vitamin B_2 complex into lactoflavin and a residual factor (or factors) constitutes the first step towards the successful analysis of this group of water-soluble vitamins. The growth-promoting action of lactoflavin and the presence of a lactoflavin-free "supplementary factor" which was necessary in order to demonstrate this growth-promoting action (György, Kuhn and Wagner-Jauregg) have been confirmed once more by the experiments described in this paper, in which a simplified and easily comprehensible technique was employed. There can be no doubt of the correctness of these findings, as they have since been confirmed by other workers, such as Euler *et al.* [1933; 1934], Chick and Copping [1934] and others.

The biological activity of lactoflavin was also recognised by Booher [1933; 1934], who claims, in a recently published paper, that a lactoflavin concentrate prepared by her stimulated growth in rats maintained on the diet of Bourquin and Sherman without any supplementary factor being present. This claim however rests upon the assumption that the lactoflavin prepared by Booher is comparable with the pure lactoflavin which was employed by us. A glance at the doses of the two preparations required is sufficient to invalidate this assumption. The daily requirement of Booher's preparation is 600γ, that of pure lactoflavin 7–10γ. It seems certain that the lactoflavin concentrate of Booher represents a heterogeneous mixture, which contains among other things the supplementary factor which we found it necessary to add to lactoflavin in our experiments.

The recent synthesis by Kuhn and Weygand [1934] of a lactoflavin which was biologically active under the usual conditions (*i.e.* in the presence of Peters's eluate as a supplementary factor) represents the climax of the series of researches which had as their object the isolation of lactoflavin as one of the components of the vitamin B_2 group.

The vitamin character of lactoflavin was first established by the growth test exclusively, while the relationship of lactoflavin to pellagra-like dermatitis, which according to the original definition, represented the real specific symptom of vitamin B_2 deficiency, was at first obscure. In the first place the technique originally employed failed to produce "pellagra". This essential condition was only satisfied after the experimental technique was modified. The utilisation of a crystalline or highly purified preparation of vitamin B_1 instead of an alcoholic extract of wheat as the source of this vitamin together with a diet otherwise free from vitamin B_1 led invariably to the development of "pellagra". In our experience with over 200 animals, the average time elapsing before the appearance of the specific skin manifestations was 7 weeks. Using this experimental technique it was found that lactoflavin had nothing to do with either the prevention or the cure of "pellagra-like dermatitis". The actual pellagra-preventing substance is the supplementary factor, or at all events a part of it, together with which lactoflavin is able to reveal its growth-promoting powers. A deficiency of this factor, which we had provisionally termed vitamin B_6, leads invariably to the appearance of "pellagra", even in the presence of lactoflavin.

The identification of the pellagra-preventing substance as one of the components of Peters's eluate also makes it possible to understand certain apparent discrepancies between our experimental results and the views held by Chick and her collaborators. Roscoe [1933, 1] observed pellagra-like dermatitis in about 50 % only of their experimental animals, and after an average experimental period of 10 weeks. In a personal communication Dr Chick states that the skin and manifestations were not generally severe in degree. Chick and Copping [1934] found that the action of lactoflavin upon the skin manifestations was a variable one. In many cases the "skin lesions" improved during the course of treatment with lactoflavin, while proving refractory in others. These results, which at first sight appear contradictory and irreconcilable with our own, are readily explicable in the light of our present knowldege. Chick and her collaborators employed Peters's eluate as the source of vitamin B_1 and thus continually supplied their rats with small quantities of pellagra-preventing substance in addition. Very often these quantities fell short of the threshold dose, as they were equivalent to only 0·6 g. of dried yeast, instead of 10 g. fresh yeast (equivalent to about 2 g. dried yeast). Further, brewers' yeast used by Chick is poorer in pellagra-preventing substance than bakers' yeast. At the same time, doses smaller than the therapeutic unit are effective prophylactically. It can therefore be understood why under these circumstances the appearance of pellagra in the experiments of Chick and her collaborators was inconstant, and that the symptoms of pellagra never reached the greatest intensity or developed in a short space of time. The slight therapeutic affect of lactoflavin occasionally observed by Chick and Copping [1934] also becomes easy to understand, since in our own experiments we have seen that lactoflavin occasionally accelerates the action of the "pellagra-preventing substance" and is thus apparently concerned in the healing process. On the other hand, the actual healing power is the property of the pellagra-preventing substance which was administered to the animals with the Peters's eluate.

Chick and Copping also suggest the identity of the supplementary factor (pellagra-preventing substance or vitamin B_6) with the factor Y previously described by them [1930]. This possibility was discussed also in a preliminary communication [György, 1934]. In view of the fact that Chick and Copping [1930] did not postulate any connection between the factor Y and the skin affections developed in absence of vitamin B_2, and that they did not take into account its character as supplementary substance within the vitamin B_2 complex, we thought it best, in order to avoid misunderstanding, to give the pellagra-preventing substance an entirely new designation.

The ultimate nomenclature of the vitamin B_2 complex will be a matter for the competent authorities to decide. We would urge that the generic term vitamin B_2 for the whole group be retained, and the individual components distinguished by special names. This question can be considered as already settled in the case of lactoflavin in the same way as the term ascorbic acid has been justified for vitamin C. For the time being the "pellagra-preventing substance" may be referred to as such, or as vitamin B_6, until its isolation has been accomplished, when it may receive its final designation. Elvehjem and Koehn [1934] have recently brought forward the proposal that the pellagra-preventing substance be termed vitamin B_2, and that lactoflavin be renamed, as they find that it has no connection with pellagra in chickens. In our opinion this proposal, if only from the point of view of the antecedent literature, would increase the confusion.

The systematic investigation of the vitamin B_2 complex does not form an end in itself. The clinician will view this analysis as only the first step essential for the better understanding of the relationship between the individual representatives of the vitamin B_2 complex and the corresponding specific diseases in man. Now that the separation of the pellagra-preventing substance (vitamin B_6) from lactoflavin has been accomplished, the problem of the prevention of human pellagra will have to be subjected to a new experimental investigation. In this respect nutritive products will be considered according to their content of vitamin B_6 and not as hitherto, according to their total vitamin B_2 content. Our experiments [György, 1935, 1] have already led to the noteworthy discovery that fish, the great value of which for the treatment of pellagra in man was expressly pointed out by Goldberger, is among the natural products richest in vitamin B_6. Thus the value of fish, *e.g.* herring, salmon *etc.* as a foodstuff is supported by this experimental finding.

Further research must be devoted to a close examination of the vitamin B_6 content of cereals, especially of maize, if only in view of the criticism of Aykroyd [1930] which was fully justified in the previous state of our knowledge. However, our ultimate object is the testing of concentrates rich in vitamin B_6 on cases of human pellagra; and experiments in this direction are already being contemplated. It will be the results of these experiments which will finally confirm or disprove Goldberger's theory, which regards human pellagra and rat pellagra (as well as "black-tongue" in dogs) as identical in nature.

In the absence of personal clinical experience of human pellagra I must refrain from taking up any definite point of view with regard to the identity of the clinical pictures in man and in the rat. On the other hand, I am struck by the resemblance of pellagra in rats to a peculiar disease of infancy, known as "pink disease" or acrodynia, which has only been recognised in the last 20 years. It would be of great value if the results of animal experimentation were applied to human pathology in this instance, especially as successes with the feeding of liver have recently been claimed in many quarters. One important clinical difference between pink disease and rat-pellagra is the absence of an increased pulse-rate in the animals, whereas in the disease of infants it is one of the most constant symptoms.

Although there are indications as to the part which the "pellagra-preventing factor" may play in human pathology, we are completely in the dark in the case of lactoflavin. The symptoms of lactoflavin deficiency in animals are not sufficiently striking or specific. Important information in this respect will probably only be obtained by empirical means.

The relation between the vitamin B_2 complex and Castle's so-called extrinsic factor (which, in combination with the intrinsic factor of the stomach, is responsible for the production of an antipernicious anaemia substance) must be decided by experiments specially devoted to this problem. All we know from the literature at the moment is, that this extrinsic factor is present in meat and in yeast autolysate (marmite), that it is very thermostable and soluble in water and alcohol [Castle and Rhoads, 1932; Wills, 1931; 1933; 1934]. According to Miller and Rhoads [1934] the extrinsic factor is also present in egg-white. Since egg-white is known to be rich in lactoflavin, it might appear that the extrinsic factor will be more closely related to lactoflavin than to the other known components of vitamin B_2. It is interesting to compare foodstuffs according to their lactoflavin contents on the one hand and their anti-anaemic powers on the other. The latter was studied by Whipple and Robscheit-Robbins [1927; 1928; 1929; 1930], working with nutritional anaemia, sustained and regulated by repeated bleedings in dogs, who found that fish flesh and fish liver were inactive, and our experiments have shown these to be the animal products which are poorest in lactoflavin [György, 1935, 1]. On the other hand, ox liver possesses the greatest anti-anaemic powers and the greatest lactoflavin content. Veal has a more potent anti-anaemic action than beef and is also richer in lactoflavin. Even allowing for the fact that the salts (Fe, Cu) and the haemoglobin contents of the nutritive products tested by Whipple and Robscheit-Robbins were also concerned in the therapeutic effects on anaemia investigated by them, the parallelism which is revealed between the anti-anaemic values and the lactoflavin contents is still a striking one. On the other hand, it must be pointed out that no sign of anaemia could be seen in our rats fed on a lactoflavin-free diet. True, this negative result might also be explained by the fact that rats are not suitable for the study of anaemia in this way, and further, the continued effect of repeated haemorrhages was also absent in the case of our rats in contradistinction to Whipple and Robscheit-Robbins's dogs. This question too will only be finally decided by direct clinical experiments.

In recent years the development of cataract in rats fed on a diet free from vitamin B_2 has been frequently described [Day *et al.*, 1931; Langston *et al.*, 1933]. In an extensive series of experiments in which over 500 rats were involved, we never observed this phenomenon either with complete or partial deficiency of the vitamin B_2 complex or with separate deficiencies of lactoflavin or vitamin B_6.

SUMMARY.

1. "Rat pellagra" can be produced, almost without exception, by the use of a crystalline or highly purified preparation of vitamin B_1 (3–4 pigeon day doses daily) added to a vitamin B-free basal diet.

2. The addition of lactoflavin, whether in the form of the pure substance (7–10 γ daily) or as egg-white (3–5 ml. daily), does not affect this result. Lactoflavin therefore can have no connection with "pellagra-like dermatitis". These observations extend over 211 animals.

3. The "pellagra-preventing" substance corresponds to the "supplementary substance" which is needed to demonstrate the growth-promoting action of lactoflavin. The combined administration of lactoflavin and the supplementary substance leads to a prolonged and marked increase in growth in rats in receipt of vitamin B_1 as the only member of the total vitamin B complex. Neither lactoflavin nor the "supplementary substance" by itself possesses any growth-promoting action.

4. Peters's "charcoal eluate" from yeast represents a suitable source of "supplementary substance" free from lactoflavin.

5. In view of its causal rôle in the development of "rat pellagra" the supplementary substance is termed the "rat pellagra-preventing factor" or, without making any further assumption, vitamin B_6.

6. The relations between the vitamin B_2 complex and its individual components and disease in man are discussed.

7. It is proposed that the designation vitamin B_2 be retained for the total complex. Lactoflavin might be known as such, and the pellagra-preventing substance as such, or provisionally as vitamin B_6.

It is with great pleasure that I express my deep gratitude to Prof. J. Barcroft whose hospitality has made possible the continuation of the experiments recorded in this and the accompanying papers.

My special thanks are due to Dr L. J. Harris who generously placed at my disposal the resources of the Nutritional Laboratory.

LXXXVII. INVESTIGATIONS ON THE VITAMIN B_2 COMPLEX.

II. THE DISTRIBUTION OF LACTOFLAVIN AND OF THE "PELLAGRA-PREVENTING FACTOR" (VITAMIN B_6) IN NATURAL PRODUCTS OF ANIMAL ORIGIN.

By PAUL GYÖRGY.

From the Physiological and Nutritional Laboratories, Cambridge.

(*Received January 31st, 1935.*)

THE isolation of lactoflavin as one of the components of the vitamin B_2 complex and the separation of the actual "pellagra-preventing factor"—provisionally termed vitamin B_6 [György, 1934; 1935]—made it possible to test natural products for their content of lactoflavin and vitamin B_6 by biological experiments. All the statements in the literature regarding the natural distribution of vitamin B_2 need re-examining, since the complex nature of vitamin B_2 was not formerly realised. This criticism applies to our own earlier communication [György *et al.*, 1934, 1] in which the quantitative data concerned only the total vitamin B_2 complex and not its individual components.

The example of egg-white illustrates the gross errors to which disregard of this complexity may lead. Egg-white is commonly regarded as a natural product rich in vitamin B_2 [Chick and Roscoe, 1929]. As we have pointed out in the preceding paper, this assertion holds good only for lactoflavin, and not for the "pellagra-preventing substance". As source of lactoflavin 3 ml. of fresh egg-white provide 1 rat day dose, whilst the vitamin B_6 content is too small to be demonstrable by biological methods.

Miss Chick has kindly pointed out to me that she always used egg-white in the cooked or dried state. Since the possibility had to be considered that the "pellagra-preventing substance" might be more easily absorbed from boiled than from unboiled egg-white, we repeated the experiments with boiled egg-white. However, we were unable to produce the slightest therapeutic effect in eight animals suffering from "pellagra", even with 3–10 g. of boiled egg-white; three animals died during treatment and the others could only be saved and eventually cured by the administration of active preparations.

Using the experimental technique described below, we determined the lactoflavin and vitamin B_6 contents of various natural products of animal origin. In the case of lactoflavin the titre was determined by means of the growth test, the skin symptoms being too irregular and frequently insufficiently obvious; the titre of vitamin B_6 was determined by its effect on the skin changes. In estimating the lactoflavin values, crystalline (or highly purified) vitamin B_1 (3–4 pigeon units), and B_6, in the form of Peters's eluate from bakers' yeast (equivalent to 10 g. of fresh bakers' yeast), were added to the diet. The additions to the diet for the elimination of vitamin B_6 were again vitamin B_1 and, in this instance, pure lactoflavin (10 γ daily) or egg-white (3–5 ml. daily).

Later on lactoflavin was generously placed at my disposal by my colleagues Kuhn and Wagner-Jauregg, while vitamin B_1 and Peters's eluate were supplied through the kindness of the I.G. Farbenindustrie Wuppertal-Elberfeld (Germany). The Peters's eluate used displayed a constant vitamin B_6 value, so that the experimental results obtained were strictly comparable. The Peters's eluate originally employed was prepared by myself.

A large part of this work was devoted to investigations of muscle tissue of various origins, since we had previously found [György *et al.*, 1934, 1] striking differences in the total contents of vitamin B_2 complex in red and white poultry muscle, and in heart-muscle, veal and beef. In the chicken, dark muscle was found to be richer in total vitamin B_2 than white muscle. On the other hand, these earlier experiments with the diet of Bourquin and Sherman, showed that ox heart muscle possessed the highest content of vitamin B_2 and skeletal muscle the lowest, the value for veal being intermediate between the two.

We repeated these latter experiments, using the new method in which the animals received, to begin with, only vitamin B_1 and the meat concerned in addition to the basal diet. After an initial increase, which, with the meat supplements, continued for 6–8 weeks, the weight became stationary. At this stage of the experiment a third supplement was added, one group receiving lactoflavin and the other vitamin B_6 in the form of Peters's eluate, whereupon a fresh increase in weight set in. We obtained the following mean weekly figures (in g.) for the two periods (*a*) with vitamin B_1 alone, (*b*) vitamin B_1 *plus* lactoflavin or vitamin B_6:

		Weekly increase in weight in g.	
Meat fed	Daily amount (g.)	(*a*) With vit. B_1	(*b*) After additional administration of lactoflavin
Heart muscle	0·75	6	3
Veal	2	8	7
Beef	2	3	4
		(*a*) With vit. B_1	(*b*) After the addition of vit. B_6
Heart muscle	0·75	8	11
Veal	2	10	8
Beef	3	6	12

Our earlier conclusions were thus fully supported by these preliminary experiments, which also yielded fresh information. In order to produce the standard rate of growth, heart muscle, at all events in the doses given, required the addition of vitamin B_6 rather than of lactoflavin. At first sight the same conclusion appeared to hold good for beef also, but the employment of different quantities of meat (2 and 3 g. respectively) in the two groups did not allow a definite comparison to be made.

Clearer results were obtained in experiments in which two groups of animals were given lactoflavin and Peters's eluate respectively, together with vitamin B_1 from the commencement, before supplementary feeding with meat was begun.

As determined by the growth test 0·75 g. heart muscle, 2 g. veal or 3 g. beef contain 1 rat day dose of lactoflavin. The results are thus of the same order as those obtained previously with the experimental methods which have since been superseded. There were no marked differences between the three kinds of meat in respect of their contents of vitamin B_6.

In their curative effects upon "pellagra-like" dermatitis 0·75 g. heart muscle, 0·6–0·75 g. of veal or 1 g. beef are of equal value.

The values for lactoflavin are much higher in veal, and even more so in beef, than the values for vitamin B_6. For these meats, therefore, lactoflavin represents the limiting factor. In this respect, striated skeletal muscle differs widely from egg-white, which as we have already seen, is practically free from vitamin B_6 and comparatively rich in lactoflavin.

		With vits. B_1+B_6 weekly increase in weight in g.	With vit. B_1 + lactoflavin	
Meat fed	Daily amount (g.)		Weekly increase in weight in g.	Healing of pellagra-like dermatitis
Heart muscle	1	12	9	Yes
	0·75	11	6	Yes
	0·5	6	3	No
Veal	3	12	12	Yes
	2	10	9	Yes
	1	—	7	Yes
	0·75	1	6	Yes
	0·5	—	5	Inconstant
Beef	3	12	9	Yes
	2	5	8	Yes
	1·5	5	7	Yes
	1	—	5	Yes
	0·75	—	5	No
	0·5	—	3	No

Fish muscle lies right at the other end of the series; salmon (fresh and frozen), herring and haddock were investigated.

		With vits. B_1+B_6 weekly increase in weight in g.	With vit. B_1 + lactoflavin	
Fish muscle fed	Daily amount (g.)		Weekly increase in weight in g.	Healing of pellagra-like dermatitis
Fresh salmon	3	0	—	—
	2	2	—	—
	1	1	8	Yes
	0·75	—	9	Yes
	0·5	—	8	Yes
Frozen salmon	1	—	8	Yes
	0·5	—	7	Yes
Herring	3	6	—	—
	2	4	10	Yes
	1	2	10	Yes
	0·5	—	6	Yes
Haddock	3	2	—	—
	2	1	9	Yes
	1	1	—	—
	0·75	—	9	Yes
	0·5	—	3	Yes

It will be seen that fish muscle is inadequate as a source of lactoflavin even in doses of 3 g. daily; only in the case of herring is there a slight increase of growth and even this, despite the high dosage, falls far short of the standard amount. In view of these results, the lactoflavin content of fish muscle must be extraordinarily small. In contrast to this however fish muscle is remarkable for its richness in vitamin B_6. The therapeutic dose of all the varieties of fish investigated was in the region of 0·5 g. daily, or even less. Fish muscle is the only natural product which we have so far investigated, which is practically free from lactoflavin, and is at the same time rich in vitamin B_6. In the absence of artificial preparations of lactoflavin and of vitamin B_6, egg-white and fish muscle may therefore be used as sources of lactoflavin and vitamin B_6 respectively in biological experiments. Frozen fish contains the same quantity of "pellagra-preventing substance" as fresh fish.

Not even the highest doses of fish muscle were able to exercise any favourable influence on the skin manifestations met with in cases of deficiency of lactoflavin [György, 1935]. The animals were refractory both as regards growth and the healing of the skin manifestations. The addition of lactoflavin to only 1 g. of fish muscle gave rise to a marked increase in weight which continued for weeks with undiminished intensity (Fig. 1). The impression was gained that the requirement of lactoflavin was lower in the presence of Peters's eluate + fish muscle than in experiments with Peters's eluate alone.

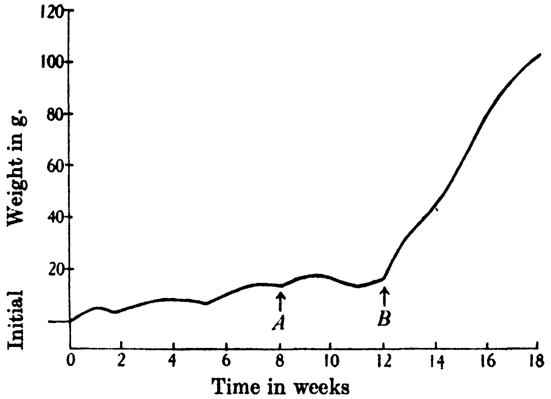

Fig. 1. Salmon in doses of 1 g. (beginning at *A*) is unable to supplement Peters's eluate + vitamin B_1. Lactoflavin (10γ daily) added at *B*.

By means of separate estimations of lactoflavin and vitamin B_6 we were able to confirm our previous conclusions [György *et al.*, 1934, 1], regarding the greater biological value of the red muscles of the leg of chickens as compared with the white muscles of the breast.

Meat fed	Daily amount (g.)	With vits. $B_1 + B_6$ weekly increase in weight in g.	With vit. B_1 + lactoflavin: Weekly increase in weight in g.	With vit. B_1 + lactoflavin: Healing of pellagra-like dermatitis
Leg of chicken	3	11	13	Yes
	2	6	—	—
	1	4	8	Yes
Breast of chicken	3	8	12	Yes
	2	3	—	—
	1	2	4	Yes

As in the case of striated mammalian muscle (beef and veal), poultry meat contains relatively more "pellagra-preventing" substance than lactoflavin. In the latter case however the difference does not amount to much, especially if the results of the growth tests are compared. Healing of pellagra-like dermatitis is obtained with red muscle of the leg as well as with white breast meat, smaller doses being required for this purpose than are necessary to produce the standard growth in animals fed with lactoflavin-free supplements, but in receipt of Peters's eluate. The red muscle is richer than the white, in lactoflavin especially, but also, according to the growth test, in vitamin B_6.

The contents of lactoflavin and of pellagra-preventing substance (vitamin B_6) of the smooth muscle of the chicken's gizzard are lower than those of striated muscle including the white muscle of poultry. The "rat day dose" of lactoflavin is equivalent to 3–4 g., and the antidermatitic, therapeutic, "rat day dose" of vitamin B_6 is equivalent to 2 g. of gizzard muscle. Daily doses less than 2 g. are unable to bring about healing of the pellagra-like dermatitis.

Among the viscera, mammalian liver (beef) was examined for its contents of lactoflavin and vitamin B_6. Liver is the organ which is richest in vitamin B_6 and lactoflavin. The "rat day dose" for lactoflavin was found to be present in 0·2–0·3 g., and for the "pellagra-preventing" factor in 0·3 g. daily. Thus the liver, like the heart and unlike striated and smooth muscle, appears to contain more lactoflavin than vitamin B_6.

Compared with mammalian liver, fish liver is very poor both in lactoflavin and in pellagra-preventing substance. The small lactoflavin content of fish liver had previously been established by means of a chemical, or fluoroscopic, method by Kuhn *et al.* [1934], and also by Euler and Adler [1934, 1, 2]. These authors agree that the lactoflavin content of cod liver is 0·5γ per g. fresh weight (in mammalian liver 15·9γ). According to the present biological investigations the lactoflavin "rat day dose" of cod-liver is over 3 g. per day. Such biological tests are preferable to chemical analysis, among other reasons because there is the possibility that mixtures of active and inactive flavins are present in all natural products, between which purely chemical analysis is, at present, unable to distinguish. The average weekly gain in weight with this dose of 3 g. amounted to 6 g. In contrast, bovine liver in doses 1/10 of these, *i.e.* 0·3 g. daily, caused an average increase in weight of 12 g. weekly. This comparison constitutes the most impressive proof of the poverty of fish liver in lactoflavin. The smallest therapeutic dose which will cure dermatitis is about 2 g. of cod liver daily, with which dose the effect on the weight curve is just noticeable.

Cow's milk contains about the same amount of lactoflavin as of vitamin B_6, the "rat day dose" for both components of the vitamin B_2 complex being equivalent to about 10 ml. These investigations were performed in the summer months.

Daily dose of milk (ml.)	With vits. B_1+B_6 weekly increase in weight in g.	With vit. B_1 + lactoflavin	
		Weekly increase in weight in g.	Healing of pellagra-like dermatitis
15	—	14	Yes
10	12	13	Yes
5	4	5	Mostly not

If, in unsuccessful treatments with 5 ml. cow's milk, Peters's eluate be substituted, a marked increase in weight sets in which exceeds the increase which usually occurs with this dose of Peters's eluate (Fig. 2). The preliminary feeding of milk therefore appears to reinforce the combined actions of lactoflavin and vitamin B_6 (Peters's eluate) on growth, much in the same way as was observed with fish muscle.

The investigations of Warburg and Christian [1932; 1933] have shown that in the oxidation of hexosemonophosphoric acid by the "yellow oxidation-ferment" (Warburg), a co-ferment from horse's red blood corpuscles plays an important rôle. After the identity of the coloured component of this flavoprotein [György *et al*, 1934, 2] with lactoflavin had been established, it became of importance to submit horse's red blood corpuscles to biological examination to test their possible activity in the second missing component, that is, the pellagra-preventing substance vitamin B_6. However, 2 ml. of an emulsion of erythrocytes obtained by centrifuging freshly drawn horse blood were shown to be free from the missing supplementary factor (vitamin B_6). In addition to this the content of lactoflavin was also very low. In the same way, we were unable to obtain either the slightest lactoflavin effect or pellagra-preventing effect with 2 ml. of horse serum. We were also unable to find any biologically active lactoflavin in the lens of the eye, even on administering as much as 8 g. of tissue daily.

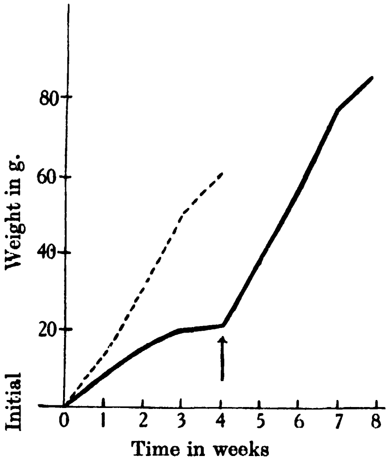

Fig. 2. 5 ml. milk do not contain sufficient pellagra-preventing substance to supplement vitamin B and lactoflavin (——). At ↑ Peters's eluate (equivalent to 10 g. fresh bakers' yeast) is substituted for the milk. The other weight curve (-----) shows the effect of 10 ml. milk in supplementing vitamin B_1 + lactoflavin.

The numerical results of these investigations on the contents of lactoflavin and vitamin B_6 of various natural animal products may be summarised in the two tables following:

	1 "rat day dose" of lactoflavin is contained in g.
Liver (beef)	0·2
Beef heart muscle	0·75
Veal	2
Beef muscle .	3
Leg of chicken	3
Breast of chicken	3–4
Chicken's gizzard	3–4
Egg-white	3
Milk	10 ml.
Horse serum	>2
Horse erythrocytes	>2
Fish liver (cod)	>3
Salmon muscle	>3
Herring ,,	>3
Haddock ,,	>3
Lens of eye	>8

	1 "rat day dose" of vit. B_6 is contained in g.
Liver (beef)	0·3
Salmon	0·5
Herring	0·5
Haddock	0·5
Veal	0·75
Heart muscle (beef)	0·75
Beef muscle	1·0
Leg of chicken	1·0
Breast of chicken	1·0
Chicken's gizzard	2·0
Fish liver (cod)	2·0
Milk	10·0 ml.
Horse serum	>2·0
Horse erythrocytes	>2·0
Egg-white	>10·0

While the lactoflavin values accepted in the above table are based on the results of the growth test, the titre values for the "pellagra-preventing substance" (vitamin B_6) are based on the antidermatitic therapeutic effects of the products examined for "rat pellagra". The values for lactoflavin and vitamin B_6 thus obtained are not therefore, strictly speaking, absolutely comparable and they hold good only for the method employed. However, these figures may be regarded as relatively correct.

SUMMARY.

Results are given of quantitative estimations of the vitamin B_6 and lactoflavin activities of foodstuffs of animal origin. It has been shown that various products differ in their absolute and relative contents of lactoflavin and vitamin B_6. Fish muscle (herring, salmon and haddock) is a rich source of the "antipellagra" factor but is practically devoid of lactoflavin. On the other hand, egg-white despite its high content of lactoflavin has no antipellagra activity.

Further, results are given for the lactoflavin and vitamin B_6 contents of the striated muscles of ox, calf and chicken, the heart muscle of ox, chicken gizzard, liver and milk.

LXXXVIII. INVESTIGATIONS ON THE VITAMIN B_2 COMPLEX.

III. THE INACTIVATION OF LACTOFLAVIN AND VITAMIN B_6 BY VISIBLE LIGHT.

BY PAUL GYÖRGY.

From the Physiological and Nutritional Laboratories, Cambridge.

(*Received January 31st, 1935.*)

THE inactivation of preparations containing vitamin B_2 by irradiation with visible light [György *et al.*, 1933, 1, 2] necessitated an extension of our experiments, for whilst the destruction of the activities of vitamins by ultra-violet light has been the subject of close study for some time, and has been successfully applied also to the study of vitamin B_2 [Hogan and Hunter, 1928], investigations by the present author in association with Kuhn and Wagner-Jauregg were the first to show that visible light can also exercise the same effect. The inactivation of lactoflavin by visible light is the logical consequence of what has later been shown to be its nature as a dyestuff.

Our first observations were concerned mainly with relatively unpurified concentrates of lactoflavin, which for the most part still contained considerable amounts of "vitamin B_6". In order to demonstrate the effect of light, we mostly employed an artificial source of light (500 K.W. bulb). The complete loss of the vitamin B_2 activity of liver concentrate, not only after direct irradiation but also after it had been exposed in a room to diffuse daylight for 18 months, has previously been reported [György *et al.*, 1934, 1]. It naturally seemed important to correlate this photosensitivity of lactoflavin with the conditions of occurrence of pellagra in man; but after it was seen that lactoflavin was not identical with the pellagra-preventing substance, and that in consequence deficiency of the former could play no part in the development of pellagra, any such correlation lost a great deal of its practical significance. Evidence was still lacking on the photosensitivity of the newly discovered factor, the actual "pellagra-preventing factor", vitamin B_6. This gap can be filled now that the production of pellagra-like dermatitis no longer presents any technical difficulties.

The first experiments of this nature served to confirm our earlier findings regarding the inactivation of lactoflavin by visible light. A concentrate from cow's liver prepared in the usual way [*cf.* György *et al.*, 1934, 2] was placed in a thick-walled, rectangular glass bottle at a distance of about 30 cm. from a 500 K.W. electric bulb, for 24 hours; cooling was carried out by a fan. Irradiation was performed not only at a neutral reaction, but in two further specimens at acid (p_H 2–3) and alkaline (p_H 9–10) reactions. At the termination of the irradiation the two latter solutions were neutralised, as was also another control solution which had not been irradiated but kept for 24 hours at the same alkaline reaction. This control was necessary because, as we have already shown [György *et al.*, 1934, 1] when confirming the finding of Chick and Roscoe [1929], the activity of a vitamin B_2 concentrate may diminish in intensity at alkaline reactions, even at room temperatures. Rats, which for the few weeks preceding had received the basal diet and supplements of vitamin B_1 (3 pigeon units daily), were treated with irradiated and non-irradiated specimens of the liver concentrate (L_2; 4 ml. daily, equivalent to 2 g. fresh liver). The animals were already stationary in growth but showed no signs as yet of pellagra-like skin changes owing to the short time the experiment had been in progress. After the administration of specimens of the liver concentrate, we obtained the following figures for growth (in g. weekly) in the first group:

Non-irradiated		Irradiated		
Neutral	Alkaline	Neutral	Acid	Alkaline
g.	g.	g.	g.	g.
9	9	1	3	2

A second group of animals reacted similarly. Growth, which failed to increase in the animals treated with the irradiated specimens of liver concentrate, could be restored once more by the addition of lactoflavin (10 γ daily). The exact data in Fig. 1 give an impressive proof of the inactivation of lactoflavin by visible light.

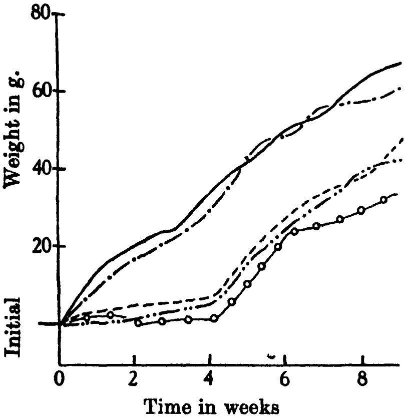

Fig. 1.

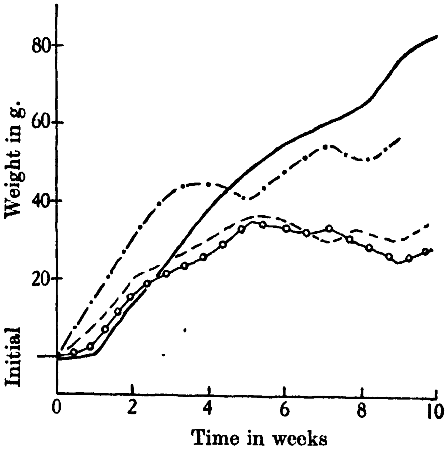

Fig. 2.

Fig. 1. The weight curves of five rats which were given vitamin B_1 + liver concentrate irradiated at neutral (o—o), at alkaline (—·—) and at acid (– – –) reactions: and non-irradiated liver concentrate at neutral (——) and at alkaline (—·—) reactions. Addition of lactoflavin at the end of the 4th week.

Fig. 2. Weight curves of rats which, apart from vitamin B_1 + lactoflavin, received Peters's eluate daily, the latter irradiated at neutral (—·—) or at alkaline (o—o) reactions, and non-irradiated at neutral (——) or at alkaline (– – –) reactions.

The inactivation of a concentrate of vitamin B_2 by irradiation with visible light is however not limited solely to the lactoflavin. Experiments carried out for a similar length of time with suitable doses of a second liver concentrate (L_3; 1·5 ml. = 1 g. of fresh liver) submitted to the same treatment, showed conclusively that vitamin B_6 was destroyed by visible light. In this experiment the specimens of liver concentrate were fed to animals in receipt of a basal diet supplemented by vitamin B_1 *plus* lactoflavin. In the following table are given the mean values of the weekly increases in weight over a period of 10 weeks and indications of the appearance or otherwise of symptoms of pellagra.

It will be seen from this table that, despite the addition of lactoflavin, the growth-promoting activity has been markedly diminished by irradiation with visible light. The differences in the weight curves do not appear so much in the first weeks of the experiment as later on, when a definite flattening of the curve makes its appearance in the case of the irradiated specimens. With the largest doses employed (3 ml. daily) this diminution in the growth-promoting property is manifested only by the specimen irradiated at alkaline reaction, and to some extent also by the non-irradiated specimen kept at alkaline reaction for 24 hours. Symptoms of pellagra did not develop. With doses of 2 and 1·5 ml. daily all the animals in receipt of the irradiated specimens developed definite symptoms of pellagra, whilst these were completely absent from the animals which were given corresponding non-irradiated control solutions. The slighter increases in weight of the animals treated with the non-irradiated alkaline liver concentrate as compared with those of the animals treated with the non-irradiated neutral liver concentrate are again very striking.

Liver concentrate daily ml.	Non-irradiated		Irradiated		
	Neutral g.	Alkaline g.	Neutral g.	Acid g.	Alkaline g.
3	12 No pellagra	9 No pellagra	13 No pellagra	10 No pellagra	7 No pellagra
2	12 No pellagra	7 No pellagra	7 Pellagra	9 Pellagra	8 Pellagra
1·5	8 No pellagra	6 No pellagra	3 Pellagra	6 Pellagra	3 Pellagra

Very similar results were obtained in further experiments with heart concentrate (1 ml. = 0·5 g. cow's heart). Observations extended over 10 weeks in this case also. The administration of heart concentrate to animals which again had been receiving vitamin B_1 *plus* lactoflavin from the commencement of the experiment, was begun quite early, before the appearance of pellagra-like symptoms. The latter then developed, if at all, during the period in which the heart concentrate was administered.

Heart concentrate daily ml.	Non-irradiated		Irradiated		
	Neutral g.	Alkaline g.	Neutral g.	Acid g.	Alkaline g.
5	9 No pellagra	7·5 No pellagra	4 Pellagra	6 Pellagra	6 Incipient pellagra

These and similar experiments, which, to avoid repetition, will not be given here, appear to prove that the pellagra-preventing substance is destroyed by visible light. The objection that the inactivation is an indirect effect of the sensitising action of the fluorescent lactoflavin, which is also present in concentrates of heart and liver, is disposed of, or if not completely disposed of at least rendered extremely improbable, by the fact that the fall in vitamin B_6 activity also occurs in the specimens irradiated at strongly acid or alkaline reactions. As is well known, lactoflavin no longer shows any fluorescence at these extreme reactions [Kuhn *et al.*, 1933]. Experiments which were performed with lactoflavin-free solutions of vitamin B_6, with Peters's eluate, and with concentrates or alcoholic extracts of salmon, also oppose the theory of the indirect nature of the photo-inactivation of vitamin B_6, at all events so far as lactoflavin as the photosensitive agent is concerned.

Fig. 2 gives the weight curves of four animals treated with Peters's eluate before and after irradiation (at neutral and alkaline reactions). Here again it will be seen that even irradiation at neutral reaction lowers the rate of growth in experiments extending over corresponding lengths of time. This effect is less marked with the specimen irradiated at alkaline reaction than with a non-irradiated control specimen which was kept at alkaline reaction. Both specimens gave rise to a much smaller increase in growth than did the original concentrate. There was however a marked difference in the development of rat-pellagra. Pellagra-like symptoms were only seen in animals which received the irradiated specimens of Peters's eluate, independently of whether irradiation were carried out at alkaline or neutral reaction.

Specimens of Peters's eluate (equivalent to 10 g. fresh baker's yeast) irradiated at alkaline reaction were compared with non-irradiated controls in two further experiments. The corresponding figures for growth (average per week) were

	Non-irradiated g.	Irradiated at alkaline reaction g.
1.	10	5
2.	12	2

Here again symptoms of pellagra appeared only in those animals which were given irradiated Peters's eluate. By doubling the dose in the second experiment we were able to bring about disappearance of the pellagra together with simultaneous increase in growth (9 g. weekly).

In all the experiments mentioned so far a powerful electric light (500 K.W.) was used for the destruction of the pellagra-preventing substance and lactoflavin by irradiation for 24 hours. If the results obtained by this technique were in all respects uniform, the photo-inactivation produced by exposure to diffuse daylight for correspondingly longer periods was still more impressive.

A liver concentrate (L_4), in a thick-walled transparent glass bottle, was kept in a room with diffuse daylight behind a window of opal glass. When this specimen was compared with a control specimen kept in the same room, but in a dark bottle wrapped in black paper, it showed a very marked fall in its activity in lactoflavin and vitamin B_6. Our earlier work, which, as has already been mentioned, was concerned with the total vitamin B_2 content of a liver concentrate which had been exposed to diffuse daylight for 18 months, is thus not only supported by these new findings but supplemented in another way. It was now shown that under the influence of diffuse daylight alone the vitamin B_6 as well as the lactoflavin titre of this liver concentrate had fallen to a very marked extent. In Fig. 3 are reproduced the weight curves of two animals, one of which received in addition to the basal diet 4 ml. daily of a liver concentrate kept in the dark and the other 4 ml. of the specimen exposed to light; apart from this both animals were given 10 γ lactoflavin *plus* vitamin B_1. The animal treated with the specimen exposed to light died in 5 weeks of pellagra, with weight completely stationary, whilst in the control animal the pellagra healed completely and the body weight increased by 97 g. Two animals which had also been submitted to the same treatment (basal diet *plus* vitamin B_1 *plus* lactoflavin), and were also already suffering from pellagra, were given 2 ml. of the specimen not exposed to light, and as a result showed an average weekly increase in weight of 17 and 16 g. respectively (68 and 65 g. respectively in 4 weeks), associated with rapid cure of the pellagra symptoms. The "exposed" specimen given in the same dose was again unable to supplement the lactoflavin. The body weights of two other animals, otherwise submitted to the same conditions, showed an average weekly fall of 2 and 1 g.

respectively, whilst the pellagra symptoms were aggravated. The irradiated liver concentrate also failed as a source of lactoflavin, *i.e.* as a supplement to Peters's eluate (vitamin B_6), not only in doses of 2 ml. but even 4 ml. daily. Fig. 4 shows the weight curve of one of these animals, which received 2 ml. of irradiated liver concentrate *plus* Peters's eluate (equivalent to 10 g. fresh baker's yeast) in addition to the basal diet. The sudden effect of the addition of lactoflavin supplement in this case affords the best proof of the assumption that lactoflavin was, in fact, absent from the "exposed" liver concentrate, at least in the doses given.

Experiments with the liver extract "campolon"[1] yielded results just as impressive as those already recorded. Specimens were exposed to diffuse daylight in thick-walled transparent bottles for 7½ weeks (Aug. 18th–Oct. 10th, 1934), (*a*) at a neutral reaction, (*b*) at a highly acid reaction with HCl (p_H 1–2), and (*c*) at a highly alkaline reaction with NaOH (p_H 11·0). Three corresponding controls were kept under similar conditions, except that they were protected from light of any kind. After 7½ weeks the specimens, neutralised and diluted 1:10, were tested biologically on animals which, apart from the basal diet, had received vitamin B_1 *plus* lactoflavin and already displayed symptoms of pellagra. The daily doses given were 5 ml. in one group, and 3 ml. in the second group, of each of the six different solutions of "campolon". In both series of experiments the non-irradiated specimens produced pronounced increase in weight with rapid healing of the pellagra. The non-irradiated specimens kept at alkaline reaction again gave rise to the slightest acceleration of growth only. Under the influence of diffuse daylight all the "campolon" solutions irrespective of their reactions

[1] Kindly supplied by the I.G. Farbendindustrie, Wuppertal-Elberfeld, Germany.

had completely lost their vitamin B_6 activity, at least in the doses in which they were given, 3–5 ml. daily. In spite of treatment, the symptoms of pellagra were aggravated without exception. A few animals died (Fig. 5). Substitution of the corresponding non-irradiated controls for the irradiated specimens resulted in the improvement anticipated, with increase in weight and resolution of the manifestations of pellagra (Fig. 6). As the animals were in receipt of vitamin B_1 *plus* lactoflavin, in addition to the "campolon" solutions, the difference in action between the "unexposed" and "exposed" solutions can only be explained by the differences in their contents of "pellagra-preventing substance" depending on its photo-inactivation.

(*c*) Campolon solution "exposed" at alkaline reaction △—△. Exchanged at *C* for corresponding "unexposed" specimen.
All the animals received vitamin B_1 and lactoflavin.

The prolonged action of diffuse daylight, and especially of its visible portion, upon solutions which are practically free from lactoflavin, such as Peters's eluate, or concentrates or alcoholic extracts of salmon, leads to the destruction of the pellagra-preventing substance. For example, we obtained the following average figures for growth on using Peters's eluate exposed for 4 weeks to diffuse daylight.

	Non-irradiated			Irradiated		
	2 ml.	1·5 ml.	1 ml.	2 ml.	1·5 ml.	1 ml.
Weekly gain (g.)	10	8	7	4	1	0

All the animals had received lactoflavin from the very beginning and had displayed pellagra-like manifestations. Treatment with the unexposed specimens led, with all doses, to rapid resolution of the symptoms of pellagra. The highest dose of exposed specimen (2 ml. daily) also produced a definite improvement, if not a complete cure of the pellagra; but the pellagra was unaffected by 1·5 and 1 ml. daily.

The results of experiments with an ordinary concentrate and with an alcoholic extract of salmon used in addition to vitamin B_1 and lactoflavin were equally unequivocal. The alcoholic extract was prepared by the same process as that described by Bourquin and Sherman [1931] for the preparation of alcoholic extract of wheat. Both salmon extracts were exposed to the visible portion of the spectrum of daylight for 6 weeks (Aug. 29th–Oct. 11th, 1934). Control solutions were kept in the dark. Biological experiments performed later showed that the irradiated specimen had been completely inactivated (Figs. 7 and 8). This was in solutions which were, again, practically free from lactoflavin.

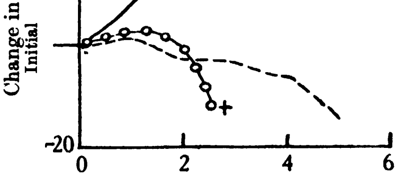

Fig. 7.

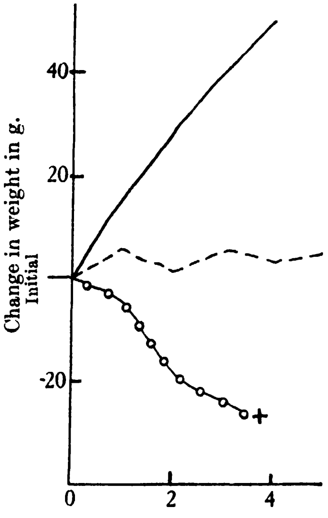

Fig. 8.

Fig. 7. Salmon concentrate, non-irradiated —— (3 ml.≡3·5 g. salmon), and "exposed" - - - (5 ml.), and likewise "exposed" o—o (3 ml.). All the animals received vitamin B_1 and lactoflavin.

Fig. 8. Alcoholic salmon extract, non-irradiated —— (3 ml.≡3 g. salmon), and "exposed" - - - (3 ml.), and likewise "exposed" o—o (5 ml.). All the animals received vitamin B_1 and lactoflavin.

All these identical results led to the indisputable conclusion that the pellagra-preventing substance (vitamin B_6) like lactoflavin is destroyed by visible light. This inactivation may also occur in the absence of lactoflavin. Under these circumstances it should be of importance to correlate this phenomenon, using the example of lactoflavin as an analogy, with the nature of the pellagra-preventing substance as a dyestuff, and not to regard it as a secondary photosensitisation. However the possibility must be considered that there may have been present, in all these solutions of vitamin B_6, yet another fluorescent substance, differing from lactoflavin, which might have exercised a photosensitising action.

Another point of interest in connection with the photo-inactivation of the pellagra-preventing substance is the fact that all the vitamin B_6 solutions examined so far have been coloured yellow, including the purified Peters's eluate, and that under the influence of diffuse daylight (from which the ultra-violet rays are excluded) they take on a darker, reddish brown colour. This change in colour is especially marked in concentrated solutions (3–5 rat day doses of vitamin B_6 in 1 ml.) of salmon extract, and also in Peters's eluate, *i.e.* again in the absence of lactoflavin. The curves in Fig. 9 give the quantitative data of the spectrophotometric examination of a salmon concentrate. (I am very much indebted to Prof. R. Kuhn for carrying out this investigation at his Institute.) The only fact which emerges from these measurements with certainty is the shift in the absorption of light of long wave-length in the irradiated extract, which was also obvious to the naked eye. The curves exhibited no characteristic maxima. Further chemical purification of the vitamin B_6 concentrates is now required; experiments in this direction have already been begun. The results of these experiments will decide whether this change of colour in solutions containing vitamin B_6 after exposure to the visible portions of diffuse daylight depends on the pellagra-preventing substance, or only on an associated substance which differs from it and is biologically inactive.

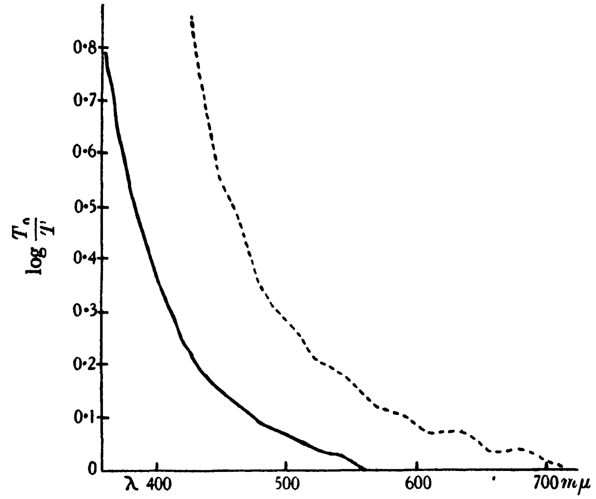

Fig. 9. Spectrogram of "unexposed" (——) and "exposed" (- - -) salmon concentrate (*cf.* Fig. 7) after concentration to 1:10.

According to Hogan and Richardson [1932, 1, 2; 1933] extracts of yeast or liver lose their activity as sources of pellagra-preventing substance on irradiation with ultra-violet light, and such loss of activity is much more rapid than is the case with vitamin B_1 activity. These authors have shown that this observation may be utilised in a process for the production of pellagra-like dermatitis in rats. This statement has been confirmed by the present writer in a large series of experiments involving over 80 rats. Daily doses of 0·1 g. of dry yeast which had been exposed in thin layers to ultra-violet radiation, led in fact almost constantly to the development of "rat pellagra", when given to rats fed on the vitamin B-free diet. However, this procedure possesses several disadvantages, which led us to discard its further use. In the first place numerous spontaneous healings were observed, and secondly there was a long "preparatory period" before the pellagra-like symptoms disappeared. Nevertheless, the use of this method on a large number of animals suffering from pellagra gave convincing evidence of the complete therapeutic inefficacy of lactoflavin, and of the curative effect of the "supplementary factor" (vitamin B_6).

The slight diminution in the growth-promoting action of solutions which have not been irradiated but which have been kept for some time at an alkaline reaction appears from the above experiment to be independent of any action of lactoflavin and probably of the pellagra-preventing substance also. This finding constitutes the sole support which we possess at present for the assumption that, in addition to the pellagra-preventing substance and vitamin B_1, Peters's eluate must contain yet another substance with the character of a vitamin. Further investigations are necessary to elucidate this last problem.

SUMMARY.

Both lactoflavin and the pellagra-preventing substance (vitamin B_6) may be destroyed by visible light. The inactivation of the pellagra-preventing substance also occurs in lactoflavin-free solutions, so that if it is dependent on an indirect photosensitisation it must be through some agency distinct from lactoflavin. The possibility is discussed and left open as to whether the pellagra-preventing substance is, like lactoflavin, a natural dyestuff.

LXXXIX. FLAVIN AND THE PELLAGRA-PREVENTING FACTOR AS SEPARATE CONSTITUENTS OF A COMPLEX VITAMIN B_2.

By LESLIE JULIUS HARRIS.

From the Nutritional Laboratory, Medical Research Council and University of Cambridge.

(*Received January 31st, 1935.*)

THE observations to be recorded in this paper arose in quite an indirect manner from enquiries in progress in this Laboratory on certain interrelations between vitamin function and redox systems on one side and cell activity on the other. (This work has since been continued in conjunction with Dr S. N. Ray and Dr P. György; and one aspect of it is dealt with in an accompanying paper [Ray *et al.*, 1935].) In the course of these investigations it was observed incidentally that rats fed on certain diets deficient in "vitamin B_2", modelled on the cataract-producing diet of Langston and Day [1933], developed symptoms of severe and characteristic pellagra in a large proportion of cases. As a necessary preliminary to the further prosecution of this work, and also in order to help to clarify the present position with regard to flavin and vitamin B_2, it was thought desirable to examine the nature of the several factors concerned in restoring growth and preventing pellagra on these dietary regimens. As will be shown, the results obtained have confirmed the conclusion of György [1934; 1935] that flavin is not the "rat antipellagra factor". It possesses vitamin B_2 activity in the sense that it is partly responsible for the growth-promotion observed when the usual natural sources of "heat-stable, growth-promoting vitamin B_2" are added to the rat's diet as the supplement to vitamin B_1.

Past work. The growth-promoting action of flavin was demonstrated by Kuhn *et al.* [1933]. They left it undecided whether or not flavin was identical with the antipellagra factor. György [1934] later reported that flavin possesses no antipellagra action for rats. Elvehjem and Koehn [1934] have recently reached the same conclusion using chickens. A number of earlier workers [Sure *et al.*, 1931; Thatcher *et al.*, 1931; Gurin *et al.*, 1931; Sherman and Sandels, 1929; 1931] had in fact suspected that vitamin B_2 (or G) as usually measured might be a complex; but Roscoe [1933] could find no convincing grounds for differentiating between the dermatitis-preventing principle and the factor responsible for growth in various sources of vitamin B_2.

In recent papers Kuhn and his coworkers have used the term vitamin B_2 as though synonymous with flavin; whereas Elvehjem and Koehn [1934] now propose to restrict it to the antipellagra factor. György [1934] on the other hand has proposed to name the antipellagra factor vitamin B_6 and retain vitamin B_2 for flavin.

EXPERIMENTAL.

In the first experiment to be mentioned, begun early in 1934, a group of 20 rats was put on the following diet, similar to that described by Langston and Day.

Extracted caseinogen (Glaxo)	18
Salt mixture	4
Cod-liver oil	2
Butter-fat	8
Maize starch	68

International vitamin B_1 standard, 2 "doses" per rat daily.

After three and a half months no signs of cataract were visible; but six animals had developed severe symptoms of "pellagra".[1] This took the form of a symmetrically disposed intense dermatitis accompanied by a striking scaliness, more especially noticeable on the paws, the nose and the ears. A sticky secretion accumulated in the eyes, the lids remaining half-closed. All animals had ceased to gain weight after the first 4 weeks (except two rats which became spontaneously refected, with characteristic faeces—nos. 7 and 10, Fig. 3—and grew normally and remained free from symptoms without any addition of flavin or antipellagra concentrate, or other source of vitamin B_2 to the diet).

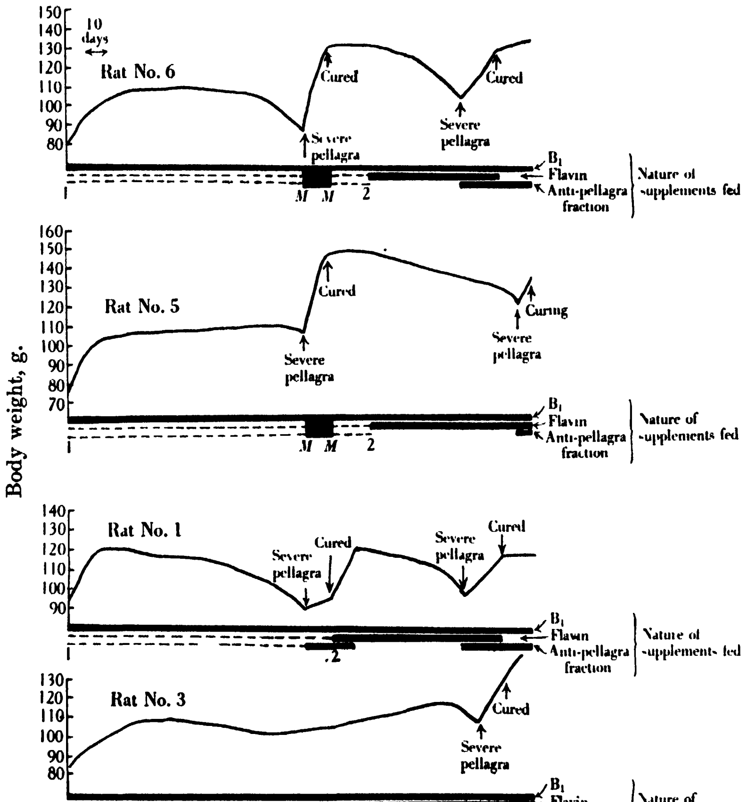

Fig. 1. Effect of different constituents of the vitamin B complex on cure or prevention of "rat pellagra", and corresponding weight curves. From 1 to 2 vitamin B_1 was given in the impure form of the International Standard, contaminated with traces of the other B-factors. After 2 it was given in a highly purified condition. At *MM* the entire complex was given in in the form of marmite.

To test the nature of the deficiencies in this diet and their individual responsibilities for the different symptoms observed, various supplements (concentrates or natural food materials) were fed. Thus, in the first place, two animals were given the complete vitamin B complex in the form of 1·0 ml. daily of a 50 % solution of marmite (laboratory quality). The result was that the pellagrous lesions disappeared in 8–10 days in one animal, and in 12–14 days in the other and growth was resumed (see rats nos. 5 and 6, Fig. 1). The corresponding untreated controls remained uncured.

---

[1] Throughout this paper the term "pellagra" is used to describe this condition in rats without prejudice to the question of its identity or otherwise with pellagra in man.

In all later work the activated acid clay (International Standard) was replaced by a purer preparation of vitamin B_1 prepared according to the method of Windaus.[1] This was found to permit the more regular production of symptoms. It may be concluded from this finding that the International Standard contains sufficient traces of the antipellagra factor to delay the regular appearance of symptoms. It may also possibly contain other "B"-factors as impurities.

Apart from purified vitamin B_1, the other active fractions employed were (1) a crystalline preparation of lactoflavin, and (2) the further "supplementary fraction" used by Kuhn *et al.* ("Peters's eluate"). The latter contains the antipellagra principle: it is free from flavin, but contains additional vitamin B_1, and possibly also other "B"-factors.

Results.

To save space, the principal results are summarised in the form of charts (Figs. 1–3) and in Table I.

Table I. *Results of prophylactic and curative tests.*

Nature of supplements given in prophylactic tests	Result	Further additions made in curative tests	Result
Impure vitamin B_1 (as Donath and Jansen's acid clay absorbate) Vitamin B_1	Loss in weight; pellagra in many cases	(1) Flavin	Some improvement in weight but no cure of pellagra
		(2) "Peters's eluate"	Pellagra cured but weight curves still subnormal
		(3) Flavin + "Peters's eluate"	Pellagra cured and weight curves normal
		(4) B complex as marmite	
Vitamin B_1 + flavin	Pellagra in all cases	"Peters's eluate"	
Vitamin B_1 + "Peters's eluate"	No pellagra, but weight curves subnormal	Flavin	
Vitamin B_1 + flavin + "Peters's eluate"	No pellagra; weight curves normal	—	—

DISCUSSION.

The above results confirm the finding of György that flavin does not prevent or cure pellagra in rats. The pellagra-preventing factor is present in the "Peters eluate". For normal nutrition, both flavin and the antipellagra factor must be present simultaneously. Uncomplicated deficiency of flavin (*i.e.* in the presence of vitamin B_1 *plus* the antipellagra supplement) was mainly manifested, in our experiments, by the loss of weight; and the rather unspecific skin lesions reported by György were not a prominent feature.

Vitamin B_2 nomenclature.

According to the definition given by the Committee on Accessory Food Factors [1927] vitamin B_2 is "the more heat-stable, water-soluble dietary factor,

---

[1] We are indebted to the I.G. Fabenindustrie of Germany for the supplies of purified vitamin B_1, crystalline flavin and "Peters's eluate".

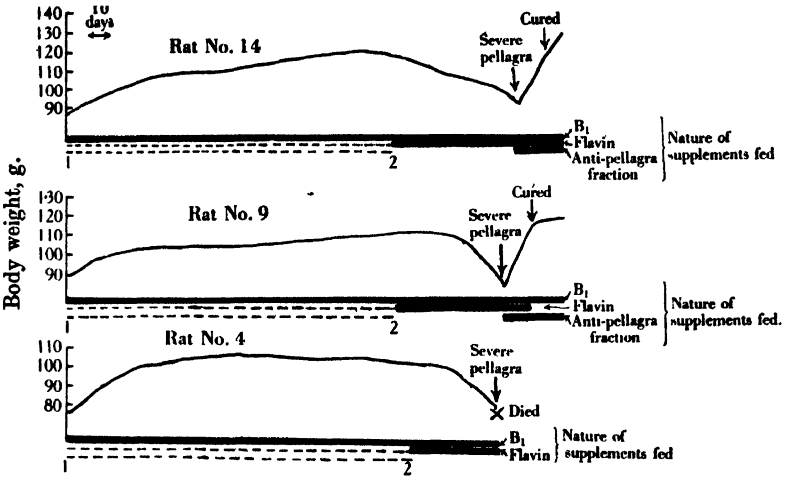

Fig. 2. The dietary supplements are indicated as in Fig. 1.

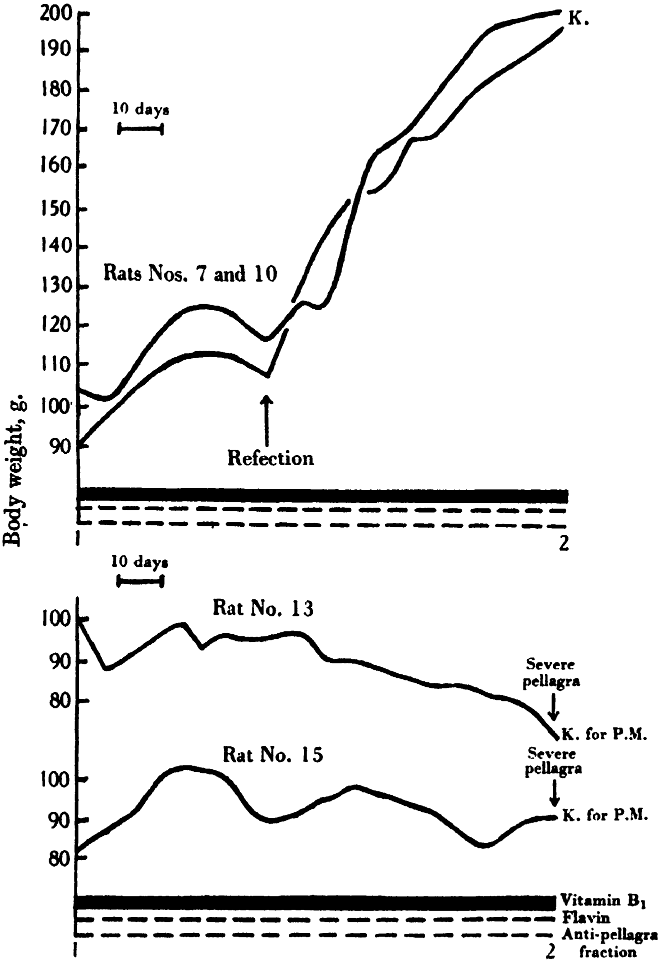

Fig. 3. Above, synthesis of vitamin B_2 complex by refection, with prevention of pellagra. Below, unrefected controls.

recently described and named P-P ('pellagra-preventive') factor by Goldberger, Wheeler, Lillie and Rogers (1926) and found necessary for maintenance of growth and health and prevention of characteristic skin lesions in rats, and considered by the latter workers to be concerned in the prevention of human pellagra". Now, in a large proportion of past experimental work the criterion of vitamin B_2 activity has not been antidermatitis action (since the symptoms of dermatitis were found difficult to produce in experimental animals), but has been rather the restoration of growth. More concretely, vitamin B_2 activity has been measured in actual practice either by the growth-promoting action or by the antidermatitis action of a material such as autoclaved yeast fed as a "heat-stable supplement" to vitamin B_1. In this sense therefore both flavin and the antipellagra factor are constituents of vitamin B_2. Normal growth is impossible in the absence of either flavin or the antipellagra factor.

It has been suggested that the term vitamin B_2 should now be restricted to the antipellagra factor [Elvehjem and Koehn, 1934]. A serious objection to this suggestion is that it would render the bulk of past work (in which growth tests have been the criterion) confusing, if not unintelligible, to future readers. On the other hand it has alternatively been recommended that the term vitamin B_2 should be applied to flavin, and indeed this has already become the current practice in many German papers. This also seems unfortunate, since vitamin B_2 has come to acquire so definite an association with the prevention of pellagra, or pellagra-like lesions. The only logical solution, which will avoid confusion, and render the past literature intelligible, is to retain the term vitamin B_2 for this complex, and to have separate names for the two (or possibly more) constituents. As flavin ("lactoflavin" of Kuhn) already has a chemical name it could be referred to simply as such; or for convenience the two constituents might perhaps be referred to as "vitamins B_2 (F)" and "B_2 (P)", or more shortly vitamins BF and BP; "F" recalling "flavin", and "P" "pellagra" (or rather the "pellagra-like lesions" in experimental animals). (The term "P-P" is already well known and may be kept for the pellagra-preventive factor in man, which further work will probably prove to be identical with the "BP"-factor which prevents the "pellagra-like lesions" in experimental animals.) Thus vitamin BF replaces the vitamin B_2 of Kuhn *et al.*; and vitamin BP replaces the vitamin B_2 of Elvehjem (=the vitamin "B_6" of György; probably identical also with "factor Y" of Chick).

$$\text{vitamin } B_2 \begin{cases} \text{vit. BF } (=\text{flavin} = \text{vit. } B_2 \text{ of Kuhn } et\ al.). \\ \text{vit. BP } (=\text{“pellagra factor”} = \text{vit. } B_2 \text{ of Elvehjem} = \text{vit. } B_6 = (?)\ Y = (?)\ \text{P-P}). \\ \text{—} \end{cases}$$

Final decisions on nomenclature should rest with an international body, such as the Committee on Vitamin Standardisation of the Health Department of the League of Nations. The exact letters chosen do not matter greatly. But in order to preserve continuity in the literature it should be recognised that past work on vitamin B_2 has in fact related to a complex and that new names should therefore be given to the several constituents.

SUMMARY AND CONCLUSIONS.

During the course of experiments on the interrelations between "vitamin B_2" and the redox systems in the eye, rats were fed on a vitamin B_2-deficient diet similar to that used by Langston and Day for the production of cataract, but with the vitamin B_1 provided in the form of the International Standard. It was observed incidentally that about 30 % of these rats developed symptoms of

severe and characteristic pellagra after 3 to 4 months. The opportunity was therefore taken to investigate the antipellagra properties and growth-promoting actions of the different fractions of the vitamin B complex. These were added separately and in different possible combinations, both in curative and in preventive tests, so that their individual functions might be analysed. (In later experiments purer preparations of vitamin B_1 were used and found to lead to the more regular production of symptoms—a result indicating that the International Standard is contaminated with the antipellagra vitamin and possibly with other "B"-factors.) The following conclusions were reached.

(1) *Flavin.* It is confirmed that flavin has no antipellagra action. It is however a constituent of the vitamin B_2 complex in the sense that it causes some improvement in the weight curve when given as a supplement to vitamin B_1. For adequate growth however it was necessary to supplement the vitamin B_1 *plus* flavin with a third fraction, which possesses antipellagra properties. Following Kuhn *et al.* [1933] this was given in the form of "Peters's eluate". With vitamin B_1 and flavin alone all rats without exception developed severe pellagra (eight cases).

(2) *Pellagra-preventing factor.* With vitamin B_1 *plus* the pellagra-preventing fraction only ("Peters's eluate") pellagra was always prevented or cured (thirteen cases). Without the further addition of flavin, however, body weights remained subnormal.

(3) The combined effect of vitamin B_1 *plus* flavin *plus* "Peters's eluate" (containing the antipellagra factor) was approximately equal, in its weight-promoting action and in the cure or prevention of symptoms, to that of the total complex given in the form of marmite.

These results confirm the finding of György that flavin does not possess antipellagra activity. Both flavin and the antipellagra factor should be regarded as separate constituents of the "heat-stable, growth-promoting vitamin B_2 complex".

XC. THE NITRATE CONTENT OF ANIMAL TISSUES, AND THE FATE OF INGESTED NITRATE.

By MARY WHELAN.

From the Department of Biochemistry and Pharmacology School of Medicine, University of Oklahoma.

(*Received January 10th, 1935.*)

Previous work with ammonium nitrate has shown that it is not completely excreted. In man approximately 80 % is excreted by the kidney during the period of intake. The total excretion may reach 90 % since nitrate continues to be excreted for several days after ingestion is discontinued. In dogs the percentage is not nearly so high. On an average, about 70 % is excreted by the kidney. The work of Keith *et al.* [1930] has shown that the amount of nitrate excreted by man in the faeces is negligible. That this is true in the case of dogs has not been proved. In future work on this problem we shall check that point. The fate of nitrate retained in the body is unknown. Nitrate taken by mouth appears quite soon in the blood stream, and analyses of oedema [Keith *et al.* 1930] and ascitic fluids show that it appears in these fluids in concentrations closely approaching that of the serum. Because of the ease with which it diffuses it comes in contact with all tissues. In an effort to determine what becomes of the nitrate retained this study was undertaken.

Method of study. Four dogs six weeks old and of the same litter were used. They were placed on a diet of 250 g. of prepared dog food per day. This was supplemented by a pint of milk and 500 ml. of water. Analysis showed that the nitrate content of food, milk and water was not appreciable. That this was an adequate diet is shown by the fact that the dogs gained weight steadily, on an average 1·7 kg. per dog during the 23 days of the experiment. The dogs receiving no nitrate gained 2 kg. each; the two receiving ammonium nitrate gained 1·4 kg. each. The exact significance of the difference is not apparent but it may be due to dehydration resulting from ingestion of such a large quantity of ammonium nitrate.

The dogs were kept on this diet for 7 days as a control period, and then dogs 1 and 2 were given 10 ml. of 10 % ammonium nitrate per day, by stomach tube, for 16 days. On the twenty-fourth day, 24 hours after the last dose of nitrate, the dogs were killed. This was done by inserting a cannula into the femoral artery, under local anaesthesia, and producing death by bleeding. This removed practically all the blood, as shown by the fact that little bleeding occurred when the tissues were removed. As soon as death had occurred the tissues and organs desired for analysis were removed and weighed. Each organ was then cut into small pieces and mixed, and representative samples were selected for determination of water and chloride contents. The remainder of the tissue was treated with sufficient sodium hydroxide to ensure an alkaline reaction throughout the drying process, and was then placed in a drying oven at 100° until thoroughly dry. It was then ground in a food chopper with a fine knife and was ready for analysis. The nitrate content was determined according to the technique outlined elsewhere [1935]. Chloride content was determined by the method of Wilson and Ball [1928]; the water content, by drying to constant weight. All determinations were made in duplicate and some of the nitrate determinations were made in triplicate. Nitrate in blood and urine was determined according to the method of Whelan [1930].

During the entire period of the experiment, the dogs were kept in metabolism cages and the urine collected under toluene. On each twenty-four hour specimen, volume, p_H and nitrate-nitrogen were determined (Table II). Blood was analysed at intervals for chloride and nitrate-nitrogen (Table I).

Discussion. As has been repeatedly observed, the ingestion of ammonium nitrate increased the average daily excretion of urine and decreased the p_H. The urine remained negative for nitrate during the control periods, and in the case of the dogs receiving no nitrate remained nitrate-free during the entire period of the experiment. The average daily excretion of nitrate-nitrogen during the period of ingestion in dogs 1 and 2 was 0·0305 and 0·0322 g. respectively. Although the concentrations were similar, less total nitrate was excreted by dog 2 than by dog 1. Dog 1 excreted 53·8 % of that ingested and dog 2, 45·4 %. At the time of death approximately half of the nitrate had not been excreted. The possibilities are: (1) that it was all retained and had been taken up by the various tissues, possibly replacing chloride; (2) that it had been destroyed, by being broken down into some form which does not produce a colour reaction with diphenylbenzidine; (3) that it entered into organic combination of some type, which is not altered by treatment with acid, and therefore cannot be extracted with ether; (4) that it is not completely absorbed from the gastro-intestinal tract. Possibilities (2) and (3), as will be shown later, are substantiated by data.

Analyses of tissues.

Chloride. Chloride determinations (Table III) were made on all tissues. The results were variable and seemed to bear no relation to nitrate ingestion. The table is included because the variability of results may have some bearing on the analysis of the problem.

Nitrate. Table IV gives the results of analyses of tissues for nitrate-nitrogen. In all cases, with the exception of the oesophagus, the nitrate contents of the tissues of dogs 1 and 2 were markedly higher than those of the corresponding tissues of dogs 3 and 4. Taking the average difference between the tissues of dogs which had received nitrate and of those which had received none shows that the greatest difference occurs in trachea, pancreas, liver, spleen, kidney and muscle. Of these, the largest differences occurred in trachea, pancreas and liver; the least differences occurred in the oesophagus; the urinary bladder and intestine also showed very small differences. In the other tissues, namely brain, spinal cord, lung, heart, stomach and skin, the difference in nitrate content between control and nitrate-fed dogs is marked and almost identical in all cases.

Dog	5800·0	—	—	—	5200·0	—	—	—	6000·0	—	—	—	6200·0	—	—	—

in Table IV, but the values shift somewhat because of differences in water content. In this table are included the estimated total contents of muscle, skin and blood. The calculations were made by using the figures given by Skelton [1927] for the proportion of the weight of the organs to the total body weight.

Table VI gives the total values for nitrate-nitrogen ingested, excreted and retained, as well as total amounts determined in the tissues. The nitrate content of tissues of the dogs which received nitrate was six to eight times higher than that of those which did not receive nitrate. Dog 2 excreted a smaller percentage of nitrate than dog 1, and the nitrate content of the total tissues was also smaller. But the differences are slight in comparison to the total amount of nitrate retained.

Table VI. *Relationship between nitrate-nitrogen ingested, excreted and retained.*

	Dog 1 mg.	Dog 2 mg.	Dog 3 mg.	Dog 4 mg.
Nitrate-N ingested	2700	2700	0	0
Nitrate-N excreted	1452	1225	0	0
Nitrate-N retained	1248	1475	0	0
Nitrate-N in tissues	47·59	33·21	6·15	10·18
Nitrate-N in tissues per kg. body weight	8·21	6·39	1·02	1·66

This shows, then, that nitrate retained in the body is either destroyed or enters into some organic combination which is not broken down by the treatment to which we have subjected these tissues. Upon this theory we are undertaking some further work on this problem. There is also the possibility that nitrate taken by mouth by dogs is not completely absorbed from the gastro-intestinal tract. From experimental work on human subjects, it would seem that this is quite unlikely. However, the possibility of this fact accounting for the loss of 50 % of the total amount seems to be very remote. As shown in Table VI, the amount of nitrate which can be accounted for in the tissues is less than 4 % of the difference between the amount ingested and that excreted in the urine. This leads us to the conclusion that nitrate is destroyed or altered by the tissues and therefore accounts for the fact that it is not recovered quantitatively in the urine.

Table VII shows that only 75 % of the nitrate-nitrogen added to the dry tissue *in vitro* can be recovered. But pure potassium nitrate added to the same amount of asbestos fibre as is used in all extractions can be completely recovered.

Table VII. *The recovery of nitrate added to tissues.*

Weight of sample g.	NO_3-N in sample mg.	NO_3-N added mg.	NO_3-N determined mg.	NO_3-N recovered mg.	% recovered
2	0·0275	0·05	0·055	0·0375	75
2	0·0169	0·05	0·057	0·0386	77·5

SUMMARY.

1. The nitrate-nitrogen content of animal (dog) tissues is given. Tissues analysed were taken from dogs which had received no additional nitrate, as well as from dogs which had received large amounts of ammonium nitrate. The latter showed an increase of six to ten times the content of normal tissues.

2. Approximately 50 % of the nitrate-nitrogen ingested was excreted by the kidney.

3. Although it has not been shown experimentally in dogs, it seems unlikely that lack of absorption from the gastro-intestinal tract explains the recovery of only 50 % in the urine.

4. Analyses showed that only a small part is taken up by the tissues and retained as inorganic nitrate.

5. The findings in this study suggest that nitrate is destroyed in the tissues and this explains why it cannot be recovered quantitatively in the urine.

XCI. A PRELIMINARY NOTE ON THE APPEARANCE OF PARESIS IN ADULT RATS SUFFERING FROM CHRONIC AVITAMINOSIS E.

By AXEL RINGSTED.

From the University Institute of Hygiene and the State Vitamin Laboratory, Copenhagen, Denmark.

(*Received January 24th, 1935.*)

This paper deals with the observation of some characteristic neuropathic disturbances which have developed in adult albino rats fed on various vitamin E-free food mixtures. Similar observations have not, to my knowledge, been previously dealt with, though Evans and Burr [1928] have observed the appearance of paresis in suckling rats bred from vitamin E-free mothers.

Evans and Burr [1928] found that the progeny of mothers fed on a diet very poor in vitamin E developed paresis in the hind quarters during the latter part of the lactation period. The paresis appeared as a rule on about the 20th day after birth and always before the 25th day. Otherwise the animals did not become paretic. An initial relaxed paretic stage appeared in some of the animals, whilst the majority showed signs of spasticity in the hind legs from the outset. A claw-like condition of the feet developed later. No disturbance of sensibility was evident. In the course of the following months, symmetrical baldness of the hind quarters and femur and atrophy of the skin occurred. Paresis spontaneously disappeared in scarcely 20 % of the diseased animals. Some individual animals suffering from a mild attack of paresis were cured by a liberal supply of substances containing vitamin E. The great majority appeared to be quite unaffected by treatment with various vitamins—even vitamin E.

Evans and Burr were able to show, by means of a wide range of experiments, that this paresis was due to lack of vitamin E in the diet, and that other organic and mineral ingredients of the food had, *per se*, no direct causal significance in the appearance of paresis. The experiments showed that it was possible completely to prevent the appearance of paresis by giving the mothers, prophylactically, substances rich in vitamin E, such as yellow corn, corn oil and wheat germ oil. It was evident that it was the vitamin E component of wheat germ that was the conclusive factor in experiments with many different fractions of wheat germ oil. These experiments showed a quantitatively exact agreement in the properties of the wheat germ in curing sterility and preventing paresis.

Evans and Burr's observation on this paresis was later confirmed by Mason [1933]. Mason succeeded in producing this paralysis in suckling rats but not in keeping the latter alive. He is of the opinion that that was due to the difficulty of finding just the right quantity of vitamin E which is sufficient to maintain life and insufficient for the vigorous development of the nervous system in the lactation period.

Evans and Burr and Mason give no information as to the morbid anatomical changes in the nerve system of these paretic rats.

Experimental methods.

The animals used for experiment comprised three groups of albino rats, A, B and C, 27 animals in all, 26 female and 1 male. The mothers of these animals had all had a uniform diet, Gudjonsson's diet 4 for breeding animals. The animals were used for the experiment at the age of 24–35 days (see Tables II, III, IV). The cage of each rat was provided with a wire mesh base so that the faeces fell through.

The rats were constantly supplied with fresh drinking water, were given fresh food three times a week and were weighed once a week, and during pregnancy every day.

From puberty, a vaginal smear was taken six times a week from all the females. The purpose of this was to ascertain the regularity of the period of oestrus; to decide the optimum time for copulation; to find out whether copulation had taken place (bouchon vaginale, sperm in the vaginal smear) and whether conception had occurred (placental sign). The vaginal smear provides, furthermore, information as to the period of the cessation of the resorption-pregnancy and as to the reserves of vitamin A in the organism (see below).

The rats were kept at a constant temperature of 22°. No sign of acute or chronic infection was ever observed among the animals that were killed. The composition of the food mixtures, the content and method of administering the vitamin preparations and also their preservation and manner of distribution are given in the two following sections.

As to the composition of the breeding diet and further data as to fertility and the suitability of the experimental animals for vitamin A experiments, the reader is referred to Gudjonsson [1930, 1, 2].

Table I. *Food mixtures.*

Group of animals ...	A	B	C
	Vitamin E-free I	Vitamin E-free III	Vitamin E-free II
Food mixture	%	%	%
Caseinogen	18	20	20
Rice starch	50	53	53
Oxidised lard	20	15	15
Dried autolysed top yeast	7	7	7
Salt mixture (185)	5	5	5
Daily additions of vitamin A	Cod-liver oil	Carotene	Cod-liver oil
Daily additions of vitamin D	Cod-liver oil	Vit. D-standard	Cod-liver oil

The vitamin E-free food mixtures may all be taken together under the same heading.

Caseinogen. To avoid any possibility of its containing vitamin E, ether-extracted caseinogen was used during the first 1½ months of the experiment. As contemporaneous experiments showed that caseinogen treated with acid did not contain any appreciable quantity of vitamin E, this was used for the rest of the experiment.

Rice starch was an ordinary commercial product, as also was the lard. The *lard* was oxidised by being kept at a temperature of 110° for 10 hours with simultaneous aeration. This prevented the possible presence of vitamins A and E.

McCollum's salt mixture (185) was used.

At first, a peanut oil solution of a biologically standardised cod-liver oil was used as a source of *vitamin A* for Group A, so as to give a daily dose of 8 I.U. of vitamin A. As some of the rats about 8–12 weeks old evinced a prolonged period of oestrus[1], up to 3–4 days' duration, the daily dose was increased to 40 I.U. of vitamin A of fresh standardised cod-liver oil, after which this phenomenon disappeared.

---

[1] Evans and Bishop [1922] showed that at the commencement of deprivation of vitamin A the period of oestrus—confirmed by the vaginal smear—became longer and dioestrus shorter. Later on the stage with cornification becomes continuous. This was subsequently confirmed by Hohlweg und Dohrn [1930] and Aberle [1934].

From the beginning of the experiment the animals in Group B were given 20γ of standard carotene dissolved in sesame oil daily.

The same cod-liver oil solution in the same dose as mentioned for Group A was used for Group C from the commencement of the experiment, *i.e.* 40 I.U. of vitamin A.

Dried autolysed top yeast mixed with the diet so as to form 7 % of it was used as a source of *vitamin B* for all three groups.

The yeast was autolysed at 38° for 24 hours, after which it was dried on flat trays at 30° and then powdered. As the increase in weight began to diminish, certain of the animals were given an addition of 0·5 g. dry yeast for a longer period.

We gave no *vitamin C*, as rats do not need this supplied in their food.

The animals in Group A received in their daily addition of cod-liver oil 0·4, and later 2, I.U. of vitamin D, those in Group C had 2 I.U. of vitamin D throughout the whole experiment. A sesame oil solution of standard vitamin D was used for Group B, mixed with food so that the mixture contained 0·8 I.U. of vitamin D per 10 g. of food.

The vitamin E content of the food mixture is certainly very low or nil. The phenomenon of initial fertility, which is due partly to the presence of reserves of vitamin E and partly to the food containing small quantities of vitamin E, never appeared in animals fed on these food mixtures. Even animals that became pregnant after having only been on the experimental diet for 20–30 days had so exhausted their vitamin E reserves that they resorbed the foetus. The reason for the low content of vitamin E in the diet lies certainly in the thorough oxidation of the lard by which the whole of the vitamins A and E are effectively destroyed [Fridericia, 1924; Mattill and Crawford, 1931; Cummings and Mattill, 1930].

We lay the greatest stress on the very low vitamin E content of the diet which is certainly of decisive significance for the appearance of paresis (see later).

A preparation of wheat germ oil "*Fertilan*"[1] was used as a source of vitamin E. The wheat germ oil was kept in hermetically sealed ampoules at 0°. The contents of the ampoule were warmed and shaken up before use and kept at 0° after use again. An ampoule lasted for 2–3 days. The oil was measured with the same standard pipette for all the experimental groups. One drop weighed on an average 25·4 mg.

Clinical observations.

The animals in the three groups, except No. 58, throve well for the first 8–12 weeks.

At about the 10th week of the experiment the rate of increase in weight appreciably diminished and in spite of a doubling, shortly followed by a quadrupling, of the daily dose of cod-liver oil, the animals put on weight very slowly. The average weight curve of the animals was, meanwhile, very near the average weight curve for rats of the same breeding fed on "diet 4 for breeding animals" [Gudjonsson, 1930, 2] (Fig. 1).

The females were mated with normal males between the 80th and the 100th experimental days. All pregnancies resulted in resorption. The females were, thereupon, available for use as test animals and were used for investigation as to the vitamin E content of various substances, by the curative method exclusively [Evans and Burr, 1927]. Ten females (see Tables II, III, IV) were given varying quantities of wheat germ oil at different periods after conception had been verified. They all gave birth to live progeny except No. 55 which was first given wheat germ oil on the 7th day of pregnancy[2] and No. 78 which had

---

[1] "Fertilan" wheat germ oil was very kindly supplied to us by the Danish Medicinal Company's Experimental Laboratory. For information as to its preparation reference may be made to Vogt-Møller's [1931] articles on this subject.

[2] This confirms Evans and Burr's observation that vitamin E should be given before the 5th or 6th day after conception has taken place so that the fertile ovum may develop fully.

had too small doses. None of these 10 animals later showed signs of neuropathic disturbances.

The 16 other females were used for investigation of the vitamin E content of various foodstuffs. All these and the only male later developed paresis.

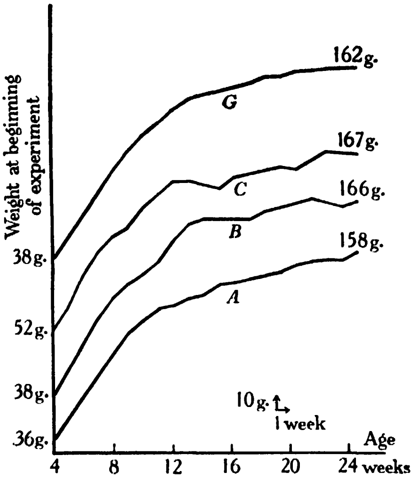

Fig. 1. Average weight curves for the first 20 experimental weeks for animals in groups *A*, *B* and *C* compared with Gudjonsson's average weight curve (*G*) for female rats on "diet 4 for breeding animals".

As the details concerning these tests have no relation to the pareses described later on they are left out of this preliminary communication.

It should however be pointed out that the vitamin E content of the substances was so low that all the pregnancies resulted in resorption. In about the 19th week of the experiment it was noticed that one animal (No. 58) was beginning to drag its hind legs a little. Simultaneously the legs began to straddle slightly. About 8 weeks later, when similar disturbances in gait were observed in three other rats (Nos. 51, 53 and 56), the conclusion was come to that this was no accidental phenomenon.

It was further confirmed by a closer examination of the gait of all the animals in Groups B and C during the following weeks. It appeared that several of these animals had already begun to show disturbances in their gait. We were hereby in a position to observe the very first stage in the development of the disease.

These observations have provided the basis of the following description in which, for practical reasons, the disease has been divided into three stages, or grades, as all the animals did not develop the disturbances to the highest degree, even though they continued on the diet for several weeks after the appearance of the first symptoms.

Stage I. The first clinical symptoms are a dragging of the legs and slight degree of inco-ordination in the gait. The gait is slower and a little cautious and the feet are placed slightly out to the side[1]. The strength of the hind legs is good, and the animal can jump with ease (7–8 cm.). In some cases the fur has begun to loosen on the hind quarters and the hind legs. The animal is lively and eats well. This condition changes with no definite break into stage II.

---

[1] The disturbance in the gait is most evident when the animal is allowed to walk over the wide-meshed wire netting of the roof of the cage.

Table II. *Group A. Vitamin E-free diet I.* (*Female rats.*)

Serial no.	Litter no.	Age at commencement of exp. days	Addition of W.G.O. during 1st test pregnancy	Time of appearance of paresis weeks	Stage of paresis	Treatment of paresis	Result of treatment

* Nos. 57 and 60 were killed during the first test pregnancy long before the paresis had appeared. No. 56 was operated on shortly after the commencement of paresis and died a few days after the operation with symptoms of ileus.

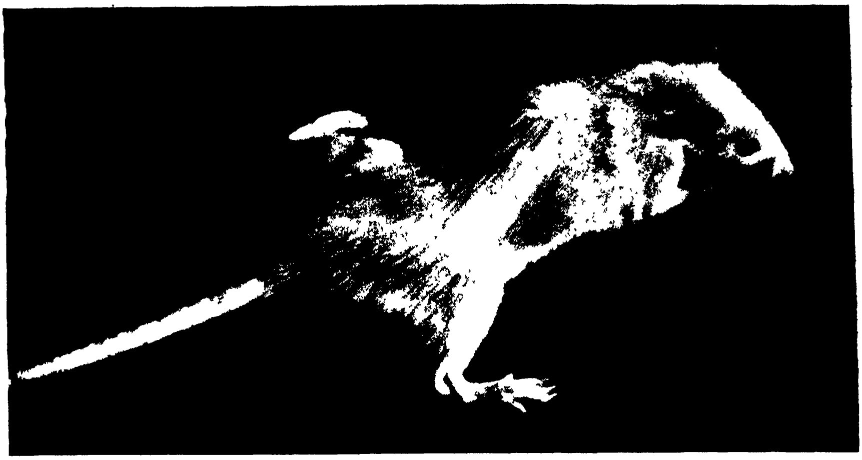

Fig. 2. BfR. 58. Noticeable straddling of the hind legs. Low position of the body. Stage II.

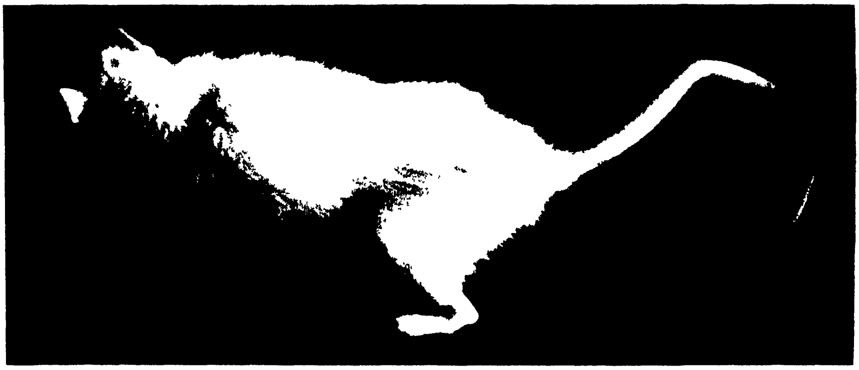

Fig. 3. BfR. 58. Noticeable straddling. Soles of the feet flexed. Toes flexed. The animal treading on the lateral edge of the foot.

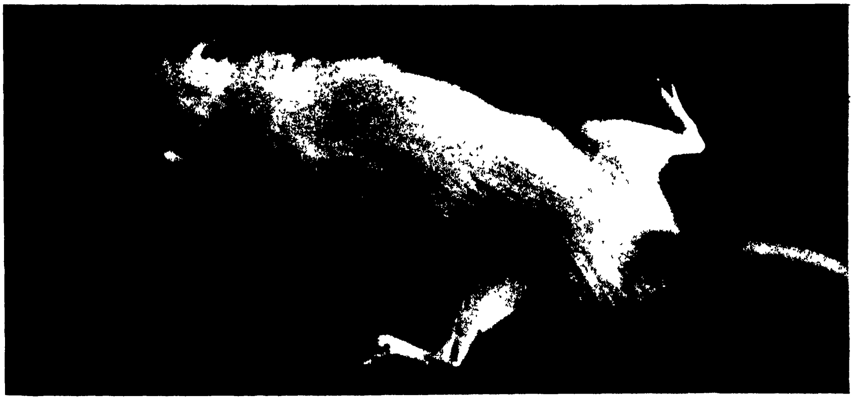

Fig. 4. BfR. 85. Hind quarters atrophied. Baldness most pronounced on the legs. Distinct straddling gait. Hind quarters dragging along the floor. Flexion of feet and toes. Stage III.

Stage II. This stage (Figs. 2 and 3, Plate I) is distinguished by a pronounced straddling of the hind legs when walking. A healthy rat keeps the foot under the femur so that it is covered by the latter when seen from above [Aberle,1934]. In this stage there is a considerable diminution in the functions of the adductors. There is flexion of the sole of the foot and extension of the knee joint. The inco-ordination is pronounced. The animals frequently walk upon the side of the foot (Fig. 3) and on the tail without noticing it. Paresis of the adductor is clearly apparent when the animals are taken out of the small opening in the cage. They must be taken out in a slanting position as, otherwise, the straddling leg is caught. When moving, the hind quarters are kept low. There is incipient atrophy of the muscles of the hind quarters and hind legs. The fur begins to fall out, especially from the extremities, but to a less degree in the centre. Susceptibility to touch seems also to be lessened. If the tail and hind legs be taken in a pair of forceps, there is an impression that there is hypoaesthesia in most of the animals in this stage and hypoalgesia in many of them.

The fore legs seem to be quite normal at this stage. The animals are lively, but move round the cage slowly.

Stage III. The gait is more characteristic in this stage (Fig. 4, Plate I). The hind legs are kept very highly abducted, and cannot be adducted. The hind quarters are dragged along the floor (Fig. 4). The animals in reality move forwards on their stomachs. The hind quarters and tail swing from side to side at every step. The sole of the foot is highly inflexed when walking, as are the small joints of the toes. If the animals are taken up by the nape of the neck, there is no dorsal flexion of the foot, as is the case with normal rats [Aberle, 1934]. Ataxia is still more pronounced and gives rise to the most grotesque attitudes and attempts to walk. These phenomena were most pronounced when the rat tries to jump up in the cage and in walking tests on the wide-meshed netting roof of the cage. There is anaesthesia or hypoaesthesia of the tail and hind legs and nearly always hypoalgesia of the tail. The fur is thinned out to a very great extent, mostly on the legs and nates, to a less degree on the other parts of the hind quarters. In most cases the baldness was found to be diffused symmetrically. The animals are less lively and constantly sit quietly in a corner and sleep. Their appetite is diminished and a slow falling off in weight of some few g. a week is noticed in a few of them.

Therapeutic experiment.

As part of the attempt to find the causes of the neuropathic disturbances, therapeutic experiments were carried out with large doses of vitamins A, B, D and E. Animals in different stages were selected, as well as those which had shown the symptoms for various lengths of time. The details of dosage and the results obtained are shown in Tables II, III and IV.

Since all the observations indicated that animals that had been given a potent preparation of vitamin E were protected against paresis, it seemed also desirable to investigate whether the paretic syndrome was affected by wheat germ oil. Treatment was begun in four animals (Nos. 53, 90, 104, 105) 2–4 weeks after the paresis was observed. Unfortunately there was no more of the same wheat germ oil as was used earlier on in the experiment. The new preparation, which was also called "Fertilan" was prepared in a different way—not otherwise further elucidated [Vogt-Møller, 1934]. It was supposed to be of the same strength as the wheat germ oil which had been given previously in the experiment. From later experiments, however, it has shown itself to be ineffective with regard to the preservation of pregnancy in doses of as much as 20 drops (500 mg.) daily.

As a result of these experiments we may conclude that large doses of vitamins A, B and D have no curative effect on the paresis, while nothing definite can be said as to the effect of vitamin E therapy.

DISCUSSION.

The clinical phenomena which have been described have a general similarity to the neuropathic disturbances in rats suffering from vitamin A deficiency described by Aberle [1934] and to the phenomenon in suckling rats from mothers on a diet low in vitamin E described by Evans and Burr [1928] but differ from them in essential points. The characteristic in the paralysis in the suckling young [Evans and Burr, 1928] is the initial stage with a sudden development of a spastic paralysis of the hind legs, feet and toes in a period of pronounced growth, from the 20th to the 25th days. The few that primarily showed a relaxed paresis also ended in a spastic condition.

All my paretic animals were almost adult when the paresis set in. The paresis was of the relaxed type. It developed slowly so that it was possible to differentiate the various stages. The paresis was accompanied by disturbances of the sensibility affecting especially the deep-seated and to a less degree the cutaneous sensibility of the legs and tail.

Since the vitamin E preparation given in our therapeutic experiment was shown to be quite inactive—in some control experiments—we are not able to compare the negative curative effect in our paretic animals with the beneficial effect obtained by Evans and Burr in some of their mildly affected animals.

The neuropathic disturbances described above bear a stronger resemblance to the neuropathic disturbances in rats fed on a diet low in vitamin A described by Aberle [1934].

In her animals the clinical phenomena appeared successively in the following order: spreading of the hind legs when in motion increasing to pronounced straddling, ataxia, later on spasticity and finally helpless trailing of the hind quarters and hind legs when walking. Aberle did not observe disturbances of sensibility or atrophy of the hind quarters or hind legs, or even atrophic disturbances of the skin or fur. On the other hand, Aberle observed incontinency of urine in several of her animals, a phenomenon which I have not observed in mine. On the contrary, I have got the impression that many of the paretic animals have had a greatly increased capacity of the bladder. Finally, the paresis in Aberle's animals was cured by large doses of vitamin A, a result which is quite different from my experience.

I wish to emphasise that the clinical phenomena in the skin and nervous system do not resemble those seen in rats with experimental beriberi [Hofmeister, 1922; Stern and Findlay, 1929] or rat pellagra [Goldberger and Lillie, 1926; Clemmensen, 1933]. The fact that the content of yeast in the food mixture corresponds with a daily intake of 0·7 g. dried yeast speaks strongly against the supposition of a lack of vitamin B_1 or B_2 as an aetiological factor.

Similarly lack of vitamins A and D may be left out of consideration since more than sufficient daily doses of these vitamins were given. The negative therapeutic result of greater doses of cod-liver oil points also in the same direction.

The following facts make it probable that lack of vitamin E is the cause of the paresis. Vitamin E is the only definitely known vitamin that was lacking in the food mixture. If the animals in the three groups be compared, it is a striking fact that all the non-paralytic animals had an addition of vitamin E (wheat germ oil) during one or more pregnancies. None of the paretic animals was given wheat germ oil. They were given substances free from vitamin E or containing very little of it, far less than sufficient to permit of a successful pregnancy. All the paretic animals have, then, suffered for a long period of time—4–7 months—from a pronounced lack of vitamin E. The non-paretic animals were given vitamin E preparations relatively early and thereby replenished their deposits. By reason of this effect of protection against paresis by early dosing with vitamin E, in conjunction with the above-mentioned conditions, I consider that the origin of the paresis is lack of vitamin E of long standing and very high degree.

XCII. THE USE OF SODIUM FLUORIDE AS A BLOOD ANTICOAGULANT IN BLOOD PHOSPHORUS DETERMINATIONS.

By JAN CORNELIS JOHAN BURKENS.

From the Laboratory of General Pathology, University of Amsterdam.

(*Received January 29th, 1935.*)

For estimating the acid-soluble phosphorus fractions of the blood—especially the inorganic blood phosphorus—we possess an excellent colorimetric technique of a simple character; in capable hands the experimental error should not be more than 3 %.

The real difficulty in blood phosphorus estimations is that the several acid-soluble fractions are extremely unstable. The organic acid-soluble compounds are rapidly hydrolysed in shed blood; when blood is allowed to stand without separating the red blood cells from the plasma a rapid and great increase of inorganic phosphorus results. But even if the red blood corpuscles are separated immediately after the withdrawal of the blood an increase in the plasma inorganic phosphorus is to be expected, as blood plasma contains an amount of ester-phosphorus corresponding to 0·2–0·5 mg. P per 100 ml. of blood; in some cases even 1·0–2·0 mg. P per 100 ml. of plasma can be found without any appreciable haemolysis. If blood becomes more alkaline ester synthesis is possible from inorganic phosphorus, resulting in a fall of the inorganic phosphorus content; this is liable to happen if blood is strongly shaken to defibrinate it: much CO_2 is lost and the blood becomes more alkaline.

The hydrolysis of ester-phosphorus takes place both in serum and in plasma of blood to which oxalate, citrate, hirudin or heparin is added as anticoagulant[1], as Table I shows.

Table I. *Inorganic blood phosphorus in mg. per 100 ml. of blood.*

	Oxalate		Citrate		Hirudin	
Immediate determination	3·26	2·86	3·29	3·20	4·10	3·13
After 1 hour	3·45	3·10	—	3·33	4·20	—
After 5 hours	—	3·28	3·73	3·60	—	3·42

Blood standing at room temperature.

It is obvious, and this fact is well known to all workers on phosphorus metabolism, that only determinations done in blood immediately after the blood has been collected have any value. In scientific work this is no great objection, but in clinical work this fact offers a great difficulty. Many physicians are unable to do an analysis immediately after the withdrawal of the blood, and in many cases it is impossible even to keep the blood at freezing temperature because it must be sent to a laboratory somewhere else. Many determinations which physicians out of town ask us to do give useless results for this reason.

---

[1] Heparin is unsuitable for blood in which phosphorus must be determined as it contains phosphorus.

The impression is often held that there is no longer any risk of an undue increase of inorganic blood phosphorus if blood or plasma has been precipitated with trichloroacetic acid, and that the filtrate obtained in this way can be kept for some time, as the strong acid should prevent all phosphatase action. This is not true: the same hydrolysis will occur in the acid protein-free filtrate. Table II illustrates this fact; the figures are taken from experiments of Byrom and of myself [Byrom, 1931].

Table II. *Inorganic phosphorus in protein-free filtrate after precipitation with 20 % trichloroacetic acid (mg. per 100 ml. of blood).*

	Room temperature	38°
Byrom:		
0 hours after precipitation	4·89	4·89
5 ,,	5·06	—
24 ,,	5·62	6·50
48 ,,	5·82	7·10
Burkens:		
0 hours after precipitation	2·80	2·80
5 ,,	3·58	3·71
24 ,,	3·85	4·70

In blood, serum, plasma or protein-free filtrates, estimations give quite unreliable results after a few hours. Yet this difficulty can be avoided quite easily by using sodium fluoride to prevent the clotting of the blood instead of the ordinary anticoagulants.

Sodium fluoride has a double action on the blood: it prevents clotting when added in the same concentration as that usually employed with oxalate; and it prevents all phosphatase action. The result is that blood, when treated with sodium fluoride, can be kept for days without any hydrolysis or synthesis of ester-phosphorus occurring. The amount of inorganic phosphorus of blood or plasma remains entirely unchanged, as do the relative amounts of the several acid-soluble fractions. This is even the case if the blood is laked.[1]

10 mg. of sodium fluoride as powder were added per 5 ml. of blood.

One must be sure that the adding of sodium fluoride does not have more influence on the development of the colour in the colorimetric analysis than has oxalate. Phosphorus estimations made simultaneously in serum and in plasma of blood after adding oxalate or fluoride give identical results (Table III).

Table III. *Inorganic phosphorus in serum and plasma of blood to which oxalate or fluoride had been added (mg. per 100 ml.).*

Serum	2·92	3·65	3·08
Oxalate-plasma	2·95	3·60	3·15
Fluoride-plasma	2·90	3·60	3·15

Table IV shows that keeping the plasma for hours at 38° causes no increase in the amount of inorganic phosphorus if sodium fluoride has been added. A protein-free acid filtrate of blood can also be kept. Of course evaporation must be prevented.

After addition of sodium fluoride as a blood anticoagulant, blood or plasma can be despatched without running any risk of obtaining faulty results. If it is advisable to perform the estimation on serum, sodium fluoride can be added after the separation of the serum. Blood, plasma or serum can be kept in this way till ultimately (after several days) the growth of bacteria in some cases will cause decrease of the amount of inorganic phosphorus.

---

[1] If laked blood is kept for hours at 38° ultimately ester hydrolysis occurred.

Table IV. *Inorganic blood phosphorus (mg. per 100 ml. of plasma).*

Fluoride-plasma:						
Immediate determination	3·52	3·20	2·78	2·68	4·89	3·20
After 5 hours at room temperature	3·54	3·21	—	—	—	—
After 48 hours at room temperature	—	—	—	2·73	4·97	—
After 16 hours at 38°	—	—	2·83	—	4·97	3·15
Protein-free filtrate of fluoride-plasma:						
Immediate determination	3·50	2·85	4·95	—	—	—
After 5 hours at room temperature	3·50	—	4·95	—	—	—
After 16 hours at 38°	—	2·80	4·95	—	—	—

Sodium fluoride is not very soluble in water and therefore it is impossible to prepare a concentrated (*e.g.* 20 %) solution. It is necessary to add the sodium fluoride as powder: 10 mg. per 5 ml. of blood. A little more or less makes no difference. Very large amounts of sodium fluoride prevent all development of colour in the colorimetric phosphorus analysis, exactly as is the case with high concentrations of oxalate or citrate. A 2 % solution of sodium fluoride in distilled water can also be used: 1 part to 9 parts of blood. In that case there arises some difficulty in calculating the dilution of the blood. If the analysis is performed in whole blood the dilution is 1:10 and the amount found must be multiplied by 10/9; if the estimation is made in plasma it is necessary to reckon with the fact that only the blood plasma is diluted. Actually it would be necessary in cases where a 2 % sodium fluoride solution is used instead of the powder to determine the relative volume of the plasma before and after the adding of the sodium fluoride. However, I found that if the blood had a normal or nearly normal ratio of the relative volumes of corpuscles and plasma the addition of one-tenth part of a 2 % solution of sodium fluoride results in a dilution of the plasma of 14–16 %. By multiplying the value found by 100/85 the real amount is estimated fairly accurately.

SUMMARY.

On standing an increase in inorganic blood phosphorus is found in serum or in plasma of blood to which oxalate, citrate or hirudin has been added to prevent clotting; in the acid protein-free filtrate of blood, plasma or serum the same increase occurs. Adding sodium fluoride prevents clotting of the blood and also all phosphatase action. Ester-phosphorus hydrolysis and synthesis do not occur and correct values for inorganic phosphorus are ensured, even when the blood or plasma is kept for hours or days at room temperature or at 38°. When the correct amount of sodium fluoride (10 mg. per 5 ml. of blood) is used no influence is found on the colour development in the analysis.

XCIII. THE BIURET METHOD OF ESTIMATING ALBUMIN AND GLOBULIN IN SERUM AND URINE.

By JOSEPH FINE.

From the Laboratory of Chemical Pathology, St Bartholomew's Hospital.

(*Received January 30th, 1935.*)

QUANTITATIVE determinations of serum and urinary proteins are of considerable clinical importance; that such estimations are made relatively infrequently is probably due to the lack of a simple yet trustworthy technique.

The methods of Esbach and Aufrecht are notoriously crude, while the gravimetric and the Kjeldahl methods are too laborious for ordinary clinical purposes. Of the colorimetric procedures the biuret method and that of Wu [1922] are both reliable, the error usually not exceeding 5 % in experienced hands. The latter however has the disadvantage that the calculations are somewhat involved, and it is moreover more lengthy than the biuret method modified as described below.

THE BIURET METHOD AS HITHERTO CARRIED OUT.

Protein is separated by salting out or by coagulation, and the precipitate is treated with NaOH and $CuSO_4$. The resulting violet colour is compared with that of a standard solution (usually of protein) similarly treated.

The method was first introduced by Riegler [1914] who applied it to urine and used as a standard pure dry serum. Autenrieth [1915] used a standard serum solution diluted with normal urine, and also extended the method successfully to the estimation of proteins in ascitic fluid and serum [1917]. Hiller [1927] proposed as standard a solution of 0·266 % pure biuret.

DISCUSSION OF THE BIURET METHOD.

1. *Choice of a standard.* In the writer's work biuret has been unsatisfactory for two reasons. Firstly, it is difficult to obtain pure biuret; a sample from a well-known firm contained about 55 % biuret, the remainder being urea and NH_4Cl. Until this was ascertained the protein results were consistently about double the correct values.

Secondly, the tint of the treated biuret solutions differs materially from that of protein solutions, leading to an increased personal error. The use of serum as standard obviates this difficulty.

When preserved with chloroform the serum-protein keeps for long periods; no change has been observed in 6 months.

As a standard the serum is diluted to contain 0·24 % protein. On keeping, a small deposit separates, but this is immaterial for the same result is obtained whether or not the deposit is resuspended.

2. *Biuret colour values of albumin and globulin.* Autenrieth [1917] states that on treatment equal quantities of albumin and globulin yield violet solutions of practically the same intensity. This was confirmed as follows. Solutions of albumin and globulin were obtained from a sample of serum by half saturating

with ammonium sulphate and filtering. The globulin deposit was dissolved in NaOH; the albumin in the filtrate was precipitated with $CCl_3.COOH$, the mixture centrifuged and the albumin redissolved in NaOH. The protein contents of the albumin and globulin solutions were determined by the Kjeldahl method.

Varying amounts of the two solutions were then taken and the total protein content in each estimated in duplicate by the biuret method (see technique below) using as standard first the albumin solution and then the globulin solution. The results are shown in Table I.

Table I.

Volume of solution estimated ml.	Protein content (Kjeldahl) mg.	Protein content, biuret method: Albumin standard mg.	% error		Globulin standard mg.	% error	
Albumin 2	10·4	10·4	0	Mean error -2·5 %	9·9	-5	Mean error -5·6 %
2·5	13·0	13·0	0		12·6	-3	
3	15·6	15·2	-3		14·7	-6	
3·5	18·2	17·3	-5		16·9	-7	
4	20·8	20·2	-3		19·4	-7	
4·5	23·4	22·5	-4		21·9	-6	
Globulin 2	7·4	8·06	+9	Mean error +4 %	7·4	+1	Mean error -1·4 %
3	11·1	10·9	-2		10·4	-6	
4	14·8	15·2	+3		14·8	0	
5	18·5	19·1	+3		18·5	0	
6	22·2	22·75	+2·5		22·2	0	

Table I shows that out of 22 estimations by the biuret method the error is between 0 and 5 % in 16 cases and between 5 and 10 % in 6 cases, and that accuracy is greatest when an albumin standard is used to estimate albumin, and a globulin standard used to estimate globulin.

When a globulin standard is used to estimate albumin the results tend to be low, and when albumin is used to estimate globulin the results tend to be high. These results suggest that globulin has a biuret colour value slightly higher than that of albumin.

The difference, however, is small and is within the range of experimental error, particularly as there was a slight difference in tint between the colorimetric solutions obtained from the albumin and globulin standards (a difference infrequently obtained in other estimations).

3. *Discrepancies between albumin results obtained by different salting-out methods.* Howe [1923] states that all the proteins of plasma except albumin are precipitated by

(1) $1{\cdot}5M$ Na_2SO_4 (21·3 %),
or (2) $2M$ $(NH_4)_2SO_4$ (26·4 % or "half saturated"),
or (3) $2{\cdot}375M$ $MgSO_4$ ("saturated").

Race [1932] points out that in Howe's own work these three methods do not give the same albumin figures and my own results confirm this.

Table II gives the percentages of albumin in various sera after salting out with Na_2SO_4 and $(NH_4)_2SO_4$ respectively and applying the biuret method.

Out of a total of 9 estimations only once has salting out with ammonium sulphate led to a lower result than with sodium sulphate; in all other cases the results with ammonium sulphate have been higher as illustrated in Table II.

Table II. *Albumin percentages of serum.*

Serum	Using 21·3 % Na_2SO_4 %	Using 26·4 % $(NH_4)_2SO_4$ %	% difference
Ox	3·80	4·40	+16
Human H.	4·40	4·75	+ 8
„ B.	4·55	5·00	+10
„ T.	4·44	5·06	+14
„ W.	4·73	5·20	+10
Mixed human	4·80	5·70	+19

Fig. 1 illustrates the amount of protein precipitated in three sera by increasing concentrations of ammonium sulphate and shows that to obtain protein precipitates equal to those brought down by 21·3 % sodium sulphate the respective concentrations of 4*M* ammonium sulphate required were 48, 59 and 65 %.

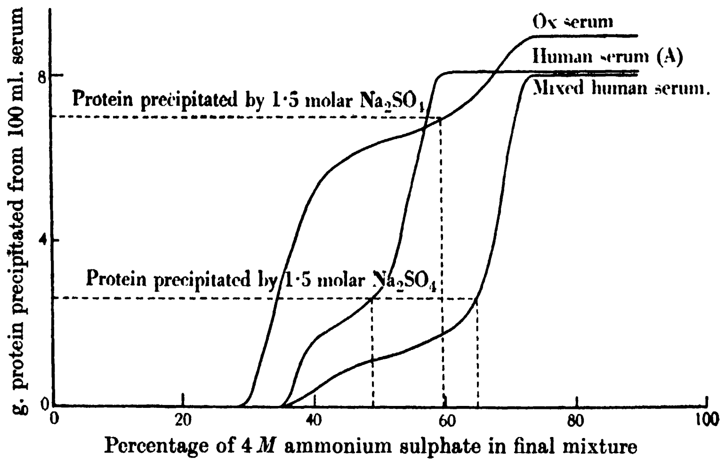

Fig. 1.

It is clear that 2*M* ammonium sulphate is not invariably equivalent to 1·5*M* sodium sulphate in fractionating proteins from serum.

If globulin is defined as that portion of the serum proteins which is precipitated by 2*M* ammonium sulphate, salting out by 1·5*M* sodium sulphate may give different results for "globulin", and further such differences are irregular.

Similarly if globulin is defined as that portion of the serum proteins which is precipitated by 1·5*M* sodium sulphate, salting out by 2*M* ammonium sulphate will often give different results.

It is important that this discrepancy should be generally realised, and that some convention should be adopted in defining "globulin". In the meanwhile in the writer's work ammonium sulphate has been employed, because it avoids the need for working at 37° which is essential for salting out by sodium sulphate in Howe's technique.

4. *Time required for the method.* Any accurate method of protein estimation involves many hours, and even the colorimetric methods are greatly delayed in estimating albumin owing to the customary procedure of allowing the Na_2SO_4-protein mixture to stand for 3 hours before filtering. I have found that this filtration can be completed in 15 minutes without affecting the result if

the salt + protein is filtered immediately after mixing and refiltered as soon as the filtrate comes through clear.

Performed in this way the estimation of albumin and globulin can be completed in less than 45 minutes.

TECHNIQUE OF MODIFIED METHOD FOR SERUM PROTEINS.

1. *Total proteins.* With a blood pipette calibrated "to contain", measure 0·2 ml. serum into 2 or 3 ml. distilled water in a 15 ml. graduated centrifuge-tube: add more distilled water up to 5 ml. and 10 % $CCl_3.COOH$ up to 10 ml.: mix, centrifuge for 3 minutes at about 3000 revolutions per minute.

Decant the clear supernatant fluid: add 1 ml. 30 % NaOH and about 3 ml. distilled water and shake: when the protein has dissolved add more water up to 9 ml. then 5 % $CuSO_4$ up to 10 ml. Shake for 10 seconds.[1] Centrifuge as before. Decant the supernatant fluid for comparison in the colorimeter with the standard.

2. *Albumin.* With an Ostwald pipette calibrated to "blow out", measure 0·5 ml. serum into a test-tube and add 9·5 ml. of 27·79 % ammonium sulphate (the resulting mixture is 2 *M*). Mix, filter through No. 44 Whatman filter-paper, and when the filtrate comes through clear refilter through the same paper. Measure 5 ml. of the filtrate into a centrifuge-tube and add 5 ml. 10 % trichloroacetic acid. Continue as for total protein.

3. *Preparation of the standard.* Measure 5 ml. of the standard 0·24 % solution of protein into a centrifuge-tube, add 5 ml. 10 % $CCl_3.COOH$ and continue as for total protein.

Calculation. If the unknown is set at 20 mm. and the readings of the standard for total protein and albumin are X and Y mm. respectively, then

$$\begin{aligned}\text{Total protein} &= 0{\cdot}3X\ \%.\\ \text{Albumin} &= 0{\cdot}24Y\ \%.\\ \text{Globulin} &= (0{\cdot}3X - 0{\cdot}24Y)\ \%.\end{aligned}$$

Application of method to urine.

The following modifications are involved when the method is applied to urine:

1. The urine must be made faintly alkaline to litmus (about p_H 7·4).

2. The amount of urine for the determinations must vary with the total protein content as approximately determined (*e.g.* by Aufrecht's method).

When the protein content is in the region of 1 % (a figure not often exceeded in pathological urines), 1 ml. should be used for total protein, 3 ml. for albumin. When the protein content is low (about 0·25 %), the quantities used are 4 ml. and 12 ml. respectively.

At intermediate values corresponding quantities of urine are used.

3. Saturated ammonium sulphate (52·8 %) should be used for the albumin estimation, the volume added being equal to that of the urine. Half the filtrate may then be used as in the case of the serum method.

---

[1] Autenrieth states that shaking for 3 minutes is necessary for the maximum development of colour, but I have found no significant difference between shaking 5, 10, 30 and 180 seconds.

SUMMARY.

1. A modification is described of the biuret method of estimating serum proteins.

2. It is confirmed that the violet colour developed by equal amounts of albumin and globulin is practically the same, and that therefore serum may be used as the standard solution for estimating both total protein and albumin.

3. The standard advocated is serum diluted to contain 0·24 % protein. It keeps for several months at least in the presence of chloroform.

4. Ammonium sulphate ($2M$ finally) is used for the separation of globulin. The results of the albumin estimation do not correspond with those obtained when sodium sulphate ($1{\cdot}5M$) is employed and are usually higher. This is important as it has been claimed that fractionation of the protein is the same with both.

5. The modifications required for urine are described.

I am indebted to Dr G. A. Harrison for his interest in this work and for the facilities provided in his laboratory.

XCIV. ON THE CHANGES OF WHEAT PROTEINS UNDER THE ACTION OF FLOUR AND YEAST ENZYMES.

By ANDREY VASSILIEVICH BLAGOVESCHENSKI
AND MARIA PETROVNA YURGENSON.

Scientific Research Institute of Bread Making, Moscow, U.S.S.R.

(*Received December 31st, 1934.*)

THE observation of Blagoveschenski and Sossiedov [1933] of the occurrence in wheat flour of an enzyme with the specific power of disaggregating gluten made it desirable to study in greater detail the changes undergone by wheat proteins in the process of bread making.

In a preliminary orientating experiment an examination was made of the distribution of nitrogen in the flour itself and in the mixture at various stages up to baking; the wheat proteins were separated into fractions by successive extractions with (1) water, 50 parts, (2) 72 % alcohol, 30 parts, (3) 10 % NaCl, 30 parts and (4) 2 % NaOH, 50 parts; these fractions contained respectively (1) leucosin and non-protein nitrogen, (2) gliadin, (3) globulin, (4) glutenin. In the water-soluble fraction additional determinations were made of the nitrogen precipitable with lead acetate and of the free amino-nitrogen by the method of Linderström-Lang [1928].

The results obtained in this manner from two samples of flour are shown in Table I from which it appears that during fermentation of the dough there is a marked decrease in the water-soluble nitrogen and an increase in the gliadin-nitrogen. The glutenin remains constant as does also the total nitrogen if allowance be made for the slight increase of the latter due to addition of flour during making. The completeness of precipitation of the water-soluble nitrogen by lead acetate indicates the absence of any appreciable degree of proteolysis except in the sponge before making, and any increase which occurs in this fraction is therefore to be ascribed to increased solubility of the proteins.

Action of flour enzymes on wheat proteins.

Preparations of flour enzymes were made by extracting 10 g. of flour with 100 ml. of $M/6$ citrate-phosphate buffer at varying p_H and 37° for 24 hours; the filtered extracts were mixed with equal volumes of glycerol. For the experiments 1 g. of freshly prepared wheat proteins was mixed with 20 ml. of buffer solution, 5 ml. of enzyme extract and 1 ml. of toluene; fractional analyses of the products were made after digestion for 48 hours at 37°. The results of these analyses are shown in Table II, Experiment (A).

The possibility of adsorption of proteinases by the wheat protein preparation has to be considered. An attempt to eliminate this factor in the usual way by heating the preparation failed, since, as is shown by the figures in the second, third and fourth lines of Table II, heating rendered the proteins resistant to the action of the flour enzymes. Determinations were therefore made of the changes occurring in the protein and enzyme preparations separately on digestion under the above conditions (a and b in Table II); the differences between the figures obtained in the original experiment (A) and the sum of those obtained in experiments (a) and (b) were taken to represent the true action of the flour enzymes. It is evident that there is an increase in the water-soluble nitrogen and a decrease in the various protein fractions, this decrease being most marked with gliadin and least with glutenin.

Effect of p_H. The effect of p_H on the action of the flour enzymes on the wheat proteins is shown in Table III. The experimental mixtures consisted of 1 g. wheat proteins, 20 ml. buffer and 5 ml. enzyme extract; in the controls 5 ml. of buffer were substituted for the enzyme. It is seen that the maximum increase in water-soluble nitrogen occurs at p_H 8·5 and the minimum at p_H 7·5; furthermore these reactions correspond with the maxima and minima of the decreases in the various protein fractions.

It is noteworthy that glutenin remains unaffected during the first 24 hours, suggesting that it may be protected by the other proteins so long as these remain intact.

Changes in the amino-nitrogen. Table IV gives the results of amino-nitrogen determinations in the various fractions during digestion of wheat proteins with flour enzymes. Increases occur in both experimental and control solutions but the differences between the experiments and their corresponding controls are significant only in the case of the water-soluble fraction, and here only at the

more acid reactions; at p_H 8·5 where the maximum solution of proteins occurs the changes in amino-nitrogen are negligible. It is clear therefore that, except at the acid reactions (where some hydrolysis of the dissolved proteins must be assumed), the increased solubility of the proteins which has been shown to occur under the influence of the flour enzymes is not accompanied by true proteolysis.

Action of yeast enzymes on wheat proteins.

During the process of bread making the wheat proteins are exposed to the action of yeast enzymes as well as to that of the flour enzymes already considered. Table V gives the results of the action on wheat proteins under conditions similar to those employed in the experiments described above, of preparations made by extracting 10 g. of fresh pressed yeast with 100 ml. of buffer in presence of toluene at 37° for 24 hours, the filtered extract being mixed with an equal volume of glycerol. It will be observed that in contrast with the flour enzymes the yeast enzymes have no action at p_H 8·5; moreover the figures for amino-nitrogen in Table VI indicate that at the point of maximum activity (p_H 4·8–6·5) the action of the yeast enzymes consists of a true proteolysis.

The effects of temperature on the activities of the flour and yeast enzymes are shown in Table VII from which it will be seen that whilst the flour enzymes exhibit an optimum at 37–40° the yeast enzymes are equally active over the range 20–37° and only show a falling off when a temperature of 45° is reached.

SUMMARY.

1. Enzymes are present in flour which exercise a definite solvent effect on wheat proteins; this effect is to be regarded as disaggregation rather than proteolysis since it is not accompanied by increase in amino-nitrogen.

2. The effect of the flour enzymes is most marked at p_H 8·5. At this p_H yeast enzymes have no action on wheat proteins. At p_H 4·8–6·5 yeast enzymes also exercise a solvent effect on wheat proteins, but this is due to a true proteolysis.

We have to thank Mrs E. D. Dombinski for analytical assistance and Mr V. A. Nicolaieff for his interest in the work.

XCV. RÔLE OF GLUTATHIONE IN ANAEROBIC TISSUE GLYCOLYSIS.

By ALEXANDER GEIGER.

From the Hebrew University, Jerusalem.

(*Received January 15th, 1935.*)

The relative amounts of lactic acid produced anaerobically by animal tissues from glycogen and from glucose depend on the tissue. Skeletal muscles, while able to form a large quantity of lactic acid from glycogen, produce only a relatively small amount of lactic acid from glucose. On the other hand involuntary muscles, brain tissue, heart muscle and lungs produce far more lactic acid from glucose than from glycogen. Other tissues, such as kidney, spleen *etc.*, are able to glycolyse glycogen and glucose in about equal amount (for literature see Haarmann [1932]).

Recent evidence seems to suggest that the course of breakdown of glucose is different from that of glycogen. Thus while the presence of inorganic phosphate is essential in muscle glycolysis where glycogen is the main substrate, according to Ashford and Holmes [1929] no inorganic phosphate is necessary for lactic acid production from glucose by brain tissue. It has been later shown by Ashford [1933] that the amount of lactic acid formed by brain tissue from glycogen and from glucose when both are present is equal to the sum of the amounts formed from each substrate separately. Bumm and Fehrenbach [1930; 1931], examining the effect of different activators on the glycolytic action of different organs, suggest two ways for the breakdown of glucose one of which does not pass through the phosphoric ester stage.

There are different opinions as to the precursor of lactic acid. Neuberg and his school advocate methylglyoxal as an intermediary product. On the other side Embden and his co-workers [1933] and Meyerhof and Kiessling [1933] found that in muscle pyruvic acid is to be considered as the precursor of lactic acid. Case and Cook [1931] succeeded in isolating pyruvic acid as well as methylglyoxal from incubated muscle tissue. The quantity of pyruvic acid was always much larger than that of methylglyoxal.

In the present experiments on the rôle of glutathione in glycolysis evidence is offered in favour of the theory that the mode of anaerobic breakdown of glucose is different from that of glycogen, and that methylglyoxal can be considered as an intermediary product of glucose breakdown but not of glycogen breakdown.

METHODS.

The animals used for these experiments were albino rats from a uniformly bred strain. The animals were fed for generations on a standard diet consisting of

Caseinogen ("Physiological" Glaxo)	21 % of the total Calories
Starch	57 %
Sucrose	8 %
Olive oil	14 %
Osborne and Mendel salt mixture...	40 g. to each kg. food

In addition each rat received daily 0·5 g. dried yeast; 0·1 ml. cod-liver oil and a few drops of lemon juice. Litter-mates were used for comparative experiments.

The rats were killed by stunning or decapitation. The required organs were immediately removed, weighed and quickly ground over ice in a mortar. From the finely ground organs a fairly uniform emulsion was obtained by adding slowly during grinding an ice-cooled buffer solution or a saline solution of known volume and composition. Measured quantities of these emulsions were distributed in small Erlenmeyer flasks. From finely cut skeletal muscles weighed quantities were distributed in the Erlenmeyer flasks. For the anaerobic experiments the bottles were evacuated repeatedly and filled up with nitrogen. The incubating vessels were ordinary 50 ml. Erlenmeyer flasks each provided with a rubber stopper in which a stopcock was inserted. During the experiments these bottles were slowly rocked in a water-thermostat regulated to 37° (±1°).

The determination of lactic acid was carried out chemically by the method of Friedemann *et al.* [1927]. The original method with permanganate oxidation was used in those experiments in which methylglyoxal was the substrate. The error due to methylglyoxal was very low when permanganate was used as oxidising agent. When no methylglyoxal was present the more recent modification of this method was used with MnO_2. In the presence of methylglyoxal the trichloroacetic acid filtrates were used directly for lactic acid estimation. In the absence of methylglyoxal a copper-calcium precipitation of the neutralised trichloroacetic filtrates was carried out. Both methods gave uniform and reliable results.

The estimation of glutathione was carried out by Kuehnau's method [1931]. Qualitative nitroprusside tests were carried out according to Hopkins.

The methylglyoxal was estimated in the trichloroacetic acid filtrates by the method of Barrenscheen and Dreguss [1931]. This method was slightly modified in so far as Schott's sintered glass filters were used instead of centrifuging tubes. A weighed amount of repeatedly recrystallised methylglyoxalbis-2:4-dinitrophenylhydrazone, prepared by precipitating a methylglyoxal solution with 2:4-dinitrophenylhydrazine and dissolving a weighed amount of the recrystallised precipitate in nitrobenzene, served as standard for the colorimetric estimation of methylglyoxal. (The author is indebted to Dr M. Weizmann for the preparation of the 2:4-dinitrophenylhydrazine.) The volume of the nitrobenzene was adjusted so that 2 ml. of the solution corresponded to 0·1 mg. of methylglyoxal. 2 ml. of this solution made up with alcoholic potash solution to 100 ml. served as a standard. The nitrobenzene solution keeps very well and saves labour in preparing fresh standard solution for each experiment.

The methylglyoxal was prepared according to Neuberg and Hoffmann [1930]. Another solution of methylglyoxal was obtained by distilling dihydroxyacetone with sulphuric acid according to Neuberg. In the experiments both preparations gave the same result although both contained small quantities of impurities.

Adenosinetriphosphoric acid was prepared from rabbit muscle according to Barrenscheen and Filz [1932]. Two such preparations were used for the experiments.

Three glutathione preparations were used, one of which was a B.D.H. preparation, the other two were prepared from baker's yeast according to Pirie's method [1930]. All three preparations gave identical results. Oxidised glutathione was prepared by dissolving a weighed amount of glutathione in a known volume of 0·5 % $NaHCO_3$ solution and shaking this solution in the presence of oxygen until the disappearance of the nitroprusside reaction.

The general procedure (if not stated otherwise) was as follows. For each experiment at least four bottles were prepared, containing the buffer solution, the substrate and the other subtances. Equal volumes of the tissue emulsion were measured into each bottle, after which the bottles were quickly evacuated repeatedly, filled up with nitrogen and put in the rocking arm of the thermostat. The time was noted when the tissue emulsion was placed in the bottles. The first two bottles contained no substrate besides that contained in the tissue suspension. After adding the tissue suspension the whole contents of one bottle were immediately precipitated by trichloroacetic acid. The contents of the second bottle were precipitated at the end of the experiment. To the third and fourth bottles a known amount of the substrate was added. The contents of one of these were immediately precipitated and the contents of the second at the end of the experiment. When the influence of an activator was tested more bottles were added to the set. The final volume, the p_H and the osmotic pressure were the same in all bottles. By this arrangement the influence of interfering substances contained in the substrates and in the tissue emulsions could be excluded from the results. By subtracting the amount of lactic acid found in the first bottle from that in the second, the lactic acid production without substrate was obtained (A); by subtracting the value of the third from that of the fourth bottle the lactic acid production in the presence of the substrate was obtained (B); the amount of lactic acid produced from the added substrate alone could be calculated by subtracting from the value (B) the value (A).

COENZYMIC FUNCTION OF REDUCED GLUTATHIONE IN THE PROCESS OF LACTIC ACID FORMATION FROM GLUCOSE.

Lohmann demonstrated [1932] that muscle extracts freed completely from reduced glutathione by dialysis retained their ability to form lactic acid from glycogen but were unable to transform methylglyoxal into lactic acid. The addition of reduced glutathione restored the ability of these extracts to form lactic acid from methylglyoxal. From his experiments Lohmann concluded that reduced glutathione was the coenzyme of the methylglyoxalase. In order to explain the fact that glutathione was not required for the process of lactic acid formation from glycogen this author assumed the mechanism of conversion of synthetic methylglyoxal into lactic acid to be different from that of the methylglyoxal, formed according to the theory of Neuberg as an intermediary product of carbohydrate breakdown.

The experiments of Lohmann may, however, also suggest that methylglyoxal does not occur at all as an intermediary product in the process of glycogen breakdown in muscle. From the work of Embden *et al.* [1933] and of Meyerhof and Kiessling [1933] the intermediary formation of methylglyoxal from glycogen in muscle is very doubtful.

On the other hand methylglyoxal may be an intermediary product in the process of lactic acid formation from glucose. In this case reduced glutathione, being a coenzyme of methylglyoxalase, would have a coenzymic function in the process of glucose breakdown.

In order to test this hypothesis we first applied Lohmann's experiments to glucose by using such types of tissues as readily metabolise glucose, *i.e.* brain tissue and involuntary muscles.

(*a*) *Experiments with tissue extracts.*

The tissue extracts used in these experiments were prepared according to Lohmann, finely cut tissue being macerated in 0·5 % KCl solution. The centrifuged extracts were dialysed against 0·5 % KCl solutions through collodion membranes for 8–12 hours in ice-cooled vessels. At the end of the dialysis glutathione could still be detected in all the extracts. The extracts were therefore made slightly alkaline with $NaHCO_3$ (p_H 7·8) and were agitated for one hour with oxygen at room temperature. At the end of this period no more glutathione could be detected. For each substrate 5–7 bottles were set up provided with stopcocks as stated above. Each bottle contained 14 ml. of fluid, containing equal volumes of tissue extract. $MgCl_2$ was added in a final concentration of 8 mg./100 ml. The initial concentration of glucose or of glycogen or of methylglyoxal was 0·3 %. Phosphate buffer of p_H 7 was used in a final concentration of *M*/15. The concentration of reduced glutathione was 30 mg./100 ml. Adenosinetriphosphoric acid was added in a final concentration corresponding to 5 mg. P_2O_5 per 100 ml. The incubation lasted usually for 2 hours at 37°.

The tissue extracts had different concentrations according to the tissue. The proportions of tissue to 0·5 % KCl were as follows: 1 part muscle to 2 parts of KCl solution; 1 part brain to 5 parts of KCl solution; 1 part heart to 6 parts of KCl solution; 1 part uterus to 7 parts of KCl solution; 3 ml. of muscle extract or 4 ml. of the other extracts were used for each experiment. The results are summarised in Table I.

Table I.

,,	,,	-0·8	- 1·0	+ 20·0
Uterus, rabbit	,,	+0·35	+ 3·5	+ 12·9

The experiments reported in Table I demonstrate uniformly the inability of all the tissue extracts to form lactic acid from glucose or from methylglyoxal if no reduced glutathione is present, and the ability of the same tissue extracts to produce lactic acid from glycogen even in the absence of reduced glutathione. The addition of reduced glutathione to these extracts enables them to form lactic acid from glucose and from methylglyoxal, but it does not increase the amount of lactic acid formation from glycogen. Reduced glutathione seems, according to these experiments, to be a coenzyme common to the glycolytic enzyme system and to the methylglyoxalase, but it is not concerned in the process of lactic acid formation from glycogen.

According to these experiments methylglyoxal may be an intermediary product in the formation of lactic acid from glucose, reduced glutathione being essential in both processes. It is, however, impossible to consider this methylglyoxal as an intermediary product in the breakdown of glycogen as this last process takes place even in the absence of reduced glutathione.

It is evident that in this experiment the lactic acid production is very slight. The inhibiting factor of the lactic acid production in these extracts is probably the oxidised glutathione. Since it was not possible to eliminate completely the glutathione from the tissue extract by dialysis we oxidised it. Thus all the extracts contained small quantities of oxidised glutathione. As will be shown later small quantities of oxidised glutathione are able to exert a strong inhibiting action on glycolysis.

(*b*) *Experiments with chopped tissues.*

The following experiments were made on fresh chopped tissue suspended in phosphate buffer solution. It was intended to investigate the activating effect of reduced glutathione on lactic acid production from glucose and from glycogen. As the tissue suspensions already contain preformed glutathione only the activating effect of added reduced glutathione could be investigated.

The technical details of these experiments have been described previously. Three to four rats were used for each experiment with brain tissue.

The bottles were set up as follows:

Phosphate buffer p_H 7·0	5·0 ml.
3 % solution of glucose or glycogen	1·0 ml.
Tissue emulsion, containing 0·4 g. of tissue	3·0 ml.
Adenosinetriphosphoric acid (or water)	0·5 ml. containing 0·5 mg. P_2O_5
Glutathione solution (or water) ...	0·5 ml. containing 4·0 mg. of glutathione

Adenosinetriphosphoric acid or glutathione or both were added only where it is stated in the Table. The experiments are reported in Table II.

All the experiments reported in Table II demonstrate that reduced glutathione strongly accelerates the rate of lactic acid formation from glucose but depresses to a small extent the rate of lactic acid formation from glycogen. The low glycolytic values observed in the experiments in which no coenzymes were added are probably due to the high dilution of the coenzymes. As Jowett and Quastel [1933] have observed, lysis and high dilution of the erythrocytes may cause a complete inhibition of the activity of their methylglyoxalase which may be restored by the addition of reduced glutathione.

In the main these experiments corroborate the previous series made with tissue extracts; reduced glutathione added to the macerated tissues brought about a strong activation of lactic acid production from glucose. The activating effect of added reduced glutathione was of about the same magnitude as that of added adenosinetriphosphoric acid. The largest activation was observed when both reduced glutathione and adenosinetriphosphoric acid were added to the tissue suspensions. The activating effect of reduced glutathione on the lactic acid production from glucose was clearly evident in all the tissues examined. In the experiments made with liver tissue the effect of adenosinetriphosphoric acid was not examined. Reduced glutathione had no activating effect at all on lactic acid production from glycogen. On the contrary a small inhibiting effect is seen in the experiments made with skeletal muscle.

Table II.

			mg. lactic acid formed by 100 g. tissue per hour

A somewhat unexpected result of these experiments is the activating effect of adenosinetriphosphoric acid on the lactic acid production from glucose by brain tissue. Cozymase and adenosinetriphosphoric acid are generally considered to belong to the esterifying enzyme system. But according to Ashford and Holmes [1929] glucolysis (from glucose) by brain tissue is independent of the presence of inorganic phosphate. According to Bumm and Fehrenbach [1931] cozymase does not accelerate brain glycolysis.

An attempt to explain these seemingly contradictory results will be made below.

Activating effect of reduced glutathione in relation to its concentration.

The quantitative relationships of the activating effect of glutathione on lactic acid formation from methylglyoxal have been investigated by Lohmann [1932]. He found, that the maximum activation is reached when the concentration of reduced glutathione is about 40 mg. per 100 ml., but even with 20 mg./100 ml. the maximum activation is approached. In the present experiments made on brain tissue about the same quantitative relation has been found for lactic acid formation from glucose. In Table III two such experiments out of five similar ones are reported. These experiments were made exactly in the same way as those described in Table II. To all the bottles adenosinetriphosphoric acid was added in the usual concentration.

Table III.

	Concentration of reduced glutathione mg./100 ml.	mg. lactic acid formed by 100 g. tissue per hour

With added reduced glutathione	25·0	1075
With added reduced glutathione	45·0	971

These experiments show that the concentration of reduced glutathione necessary for full activation of the glucolysis by chopped brain tissue lies between 20 and 25 mg./100 ml.

The last experiment made on chopped skeletal muscle shows again a small but distinct inhibitory effect of reduced glutathione on lactic acid formation from glycogen.

The inhibitory effect of oxidised glutathione on glycolysis.

The indispensability of reduced glutathione for the glycolysis of glucose observed in the previous experiments offered a probable explanation of the so-called Pasteur-Meyerhof reaction.

In a recent paper Giršavicius [1933] reported that moderate access of oxygen caused rapid inactivation of glyoxalase. Bumm and Appel observed [1932] that the aerobic glycolysis of tumour tissue can be raised almost to the anaerobic level by addition of reduced glutathione. In view of the fact that reduced glutathione becomes slowly oxidised if agitated with oxygen in slightly alkaline solution it was supposed that the loss of reduced glutathione by oxidation might be responsible for the inhibitory effect of oxygen on glycolysis. In two experiments the effect of an excess of reduced glutathione in the presence of oxygen was examined. Quantities of reduced glutathione were added such that at the end of the incubation period each bottle still contained sufficient reduced glutathione to cause a full activation of glycolysis. The technique of these experiments was similar to that of the previous ones.

The flasks containing the tissue suspension, buffer solution together with glucose and the usual concentration of adenosinetriphosphoric acid, were divided into four groups. One of them to which no reduced glutathione was added was incubated anaerobically, the second one similarly prepared was incubated in oxygen. The third group to which an excess of reduced glutathione had been added was incubated anaerobically and the fourth group, similar to the third, was incubated in the presence of oxygen. At the end of the incubation period quantitative estimations of reduced glutathione were made in addition to the lactic acid estimations. Of the three experiments all giving similar results one is reported here (Table IV).

Table IV.

	mg. lactic acid produced by 100 g. tissue per hour	Final conc. of reduced glutathione in mg./100 ml.
Brain tissue without added glutathione in N_2	202	7
,, without added glutathione in O_2	82	Hopkins's reaction positive
,, with added glutathione in N_2	390	67
,, with added glutathione in O_2	76	24
,, without added glutathione in H_2O_2*	82	0
,, with added glutathione in H_2O_2*	72	11

* 0·2 ml. of 1 % solution of H_2O_2 was added to each 2 ml. of brain suspension (containing 0·4 g. of tissue) before it was introduced into the flasks. These flasks were filled with N_2.

The experiments described in Table IV show that molecular oxygen inhibits glycolysis even when an excess of reduced glutathione is present. The addition of small amounts of H_2O_2 causes the same inhibiting effect as molecular oxygen. It is thus evident that the inhibiting effect of molecular oxygen on glycolysis cannot be ascribed to the absence of reduced glutathione.

The next experiments show clearly that the inhibiting factor in the Pasteur-Meyerhof reaction is oxidised glutathione. The technical arrangements of these experiments were like those of the previous ones. To some of the bottles various quantities of oxidised glutathione were added at the beginning of the experiments. All bottles but one were incubated anaerobically. At the end of the experiments the nitroprusside reaction showed that during the incubation period a part of the oxidised glutathione had been reduced by the brain tissue. One of three uniform experiments is reported in Table V. Glucose was the substrate.

Table V.

	mg. lactic acid produced by 100 g. tissue per hour	Nitroprusside test at the end of the experiment
Brain tissue without added glutathione in N_2	282	+
,, with 10 mg./100 ml. oxidised glutathione in N_2	171	+ + +
,, with 20 mg./100 ml. oxidised glutathione in N_2	168	+ + +
,, with 40 mg./100 ml. oxidised glutathione in N_2	146	+ + +
,, without added glutathione in O_2	162	±

In these experiments 10 mg./100 ml. of oxidised glutathione cause about the same inhibition of glycolysis as the presence of oxygen. The inhibiting effect of oxidised glutathione on glycolysis is still more marked in the experiment with muscle tissue and with glycogen as substrate.

The next experiment on finely cut muscle tissue and with glycogen was made exactly like the previous ones. One of the three experiments which all gave the same result is given in Table VI.

Table VI.

	mg. lactic acid produced from glycogen by 100 g. tissue per hour	Nitroprusside test at the end of the experiment
Muscle tissue without added glutathione in N_2	1824	+
,, with 10 mg./100 ml. oxidised glutathione in N_2	810	+ + +
,, with 20 mg./100 ml. oxidised glutathione in N_2	132	+ + +
,, with 40 mg./100 ml. oxidised glutathione in N_2	74	+ + +
,, without added glutathione in O_2	1762	+

These experiments on muscle tissue show a powerful inhibitory effect of oxidised glutathione. In the presence of 40 mg. of oxidised glutathione inhibition of glycolysis is nearly complete. It is significant that in these experiments the inhibition of glycolysis caused by oxygen is very small in comparison with that caused by oxidised glutathione. It is to be observed too that in all the bottles at the end of the incubation a strong nitroprusside reaction was observed which indicated that a part of the added oxidised glutathione was reduced during the incubation period. The smallness of the inhibitory effect of oxygen in these experiments may thus be due to the reducing power of the tissue which is probably able to reduce quickly the oxidised glutathione slowly formed by the action of molecular oxygen.

With brain tissue and with glucose as substrate equal inhibition is caused by oxygen and by oxidised glutathione.

According to these experiments the inhibiting effect of molecular oxygen on glycolysis can be explained by the formation of oxidised glutathione which is directly capable of inhibiting glycolysis.

The rôle of the inorganic phosphorus in glycolysis of glucose.

According to Ashford and Holmes [1929] brain glycolysis from glucose proceeds in the absence of inorganic phosphates. It was therefore disconcerting to find that adenosinetriphosphoric acid activates the glucose breakdown by brain tissue. It was therefore decided to repeat the experiments of Ashford and Holmes and to investigate the effect of adenosinetriphosphoric acid and of reduced glutathione on tissue emulsions freed from inorganic phosphates.

At first the effect of the borate buffer alone on glycolysis was investigated. A borate buffer of p_H 8·1 was prepared according to Sørensen.

The bottles were set up as follows:

Phosphate or borate buffer p_H 8·1	5·0 ml.
2 % glucose solution	1·5 ml.
Brain emulsion in 0·9 % NaCl solution ...	2·0 ml. containing 0·3 g. of brain tissue
1·2 % $CaCl_2$ solution (or water)	1·0 ml.
Adenosinetriphosphoric acid solution (or water)	0·5 ml.

One of the two parallel experiments is reported in Table VII.

Table VII.

	mg. lactic acid produced by 100 g. tissue in 1 hour
Phosphate buffer	320
Phosphate buffer + adenosinetriphosphoric acid	540
Borate buffer	18
Borate buffer + adenosinetriphosphoric acid	29
Borate buffer + adenosinetriphosphoric acid + $CaCl_2$	130

These experiments show that borate itself strongly inhibits glycolysis. Adenosinetriphosphoric acid does not counteract this inhibition but strangely enough $CaCl_2$ does. To investigate this effect of $CaCl_2$ more experiments were set up with different amounts of $CaCl_2$.

The bottles were set up as follows:

Borate buffer p_H 8·2	5 ml.
3 % glucose solution	1 ml.
1·2 % $CaCl_2$ solution (or water)	3 ml.
Adenosinetriphosphoric acid (or water)	0·5 ml.
Reduced glutathione solution (or water)	0·5 ml.

The experiments were made anaerobically in every respect like the previous experiments. One of the two similar experiments is reported in Table VIII.

Table VIII.

	mg. lactic acid produced by 100 g. tissue per hour
Borate buffer without $CaCl_2$	28
„ with 0·5 ml. $CaCl_2$	51
„ with 1·0 ml. $CaCl_2$	111
„ with 2·0 ml. $CaCl_2$	174
„ with 3·0 ml. $CaCl_2$	175
„ with 2·0 ml. adenosinetriphosphoric acid	196
„ with 2·0 ml. adenosinetriphosphoric acid + glutathione	297

These experiments show that $CaCl_2$ counteracts the inhibiting effect of borate and that in the presence of borate and of $CaCl_2$ and thus in the absence of inorganic phosphate the activating effect of reduced glutathione is still very evident. These experiments also show that under the experimental conditions described so many factors introduce complications that it is difficult to estimate the rôle of the inorganic phosphorus in brain glycolysis. It seems, however, in agreement with Ashford and Holmes [1929] that the presence of inorganic phosphorus is not essential in this process.

A further fact of interest is that while the activating effect of adenosinetriphosphoric acid disappears under these conditions, the activating effect of glutathione is not altered. This phenomenon may suggest two mechanisms of glucose breakdown in the brain, one of which does not need the presence of inorganic phosphate and is activated by reduced glutathione and a second one which only proceeds in the presence of inorganic phosphate and of adenosinetriphosphoric acid. This may explain also why adenosinetriphosphoric acid activates brain glycolysis independently of glutathione.

A comparison of the glyoxalase activities of brain and muscle tissue.

In the previous pages it was suggested as possible that methylglyoxal may be an intermediary product of the breakdown of glucose but not of glycogen. It is to be expected accordingly that those tissues which produce lactic acid from glucose must be able to transform a correspondingly large quantity of methylglyoxal into lactic acid. On the other hand if methylglyoxal is not an intermediary product in lactic acid formation from glycogen those tissues in which lactic acid formation from glycogen is predominant should be unable to form a correspondingly large quantity of lactic acid from methylglyoxal.

The rats selected for these experiments were kept under strictly identical conditions at least for three generations. The technique of these experiments was described in the general part. The contents of the bottles were as follows:

Phosphate buffer solution p_H 6·95	5 ml.
Methylglyoxal 0·7 %	3 ml.
Tissue suspension containing 0·4 g. tissue	2 ml.

In the experiment with muscle tissue 0·4 g. of finely cut muscle was weighed into every bottle and 1·6 ml. of water were added. The methylglyoxal solution was accurately neutralised before addition. Four bottles were set up for each experiment as described above. Table IX shows the result.

Table IX shows that muscle tissue which is able to form on the average 1176 mg. lactic acid per 100 g. tissue per hour from glycogen and 101 mg. from

Table IX.

	mg. lactic acid produced by 100 g. tissue in 1 hour

glucose, forms only 251 mg. lactic acid from methylglyoxal. As a general rule it is to be expected that the conversion of an intermediary product should proceed at least with the same velocity as that of the initial product. Actually the transformation of glycogen into lactic acid in the muscle proceeds 4–5 times as rapidly as that of methylglyoxal. Thus methylglyoxal cannot possibly be an intermediary product in the breakdown of glycogen.

Brain tissue, on the other hand, which produces lactic acid mainly from glucose, is able to convert a large quantity of methylglyoxal. For 318 mg. of lactic acid formed from glucose, the brain tissue is able to form 1287 mg. of lactic acid from methylglyoxal.

Discussion.

The experiments contained in the first part of this paper demonstrate that the enzyme system which produces lactic acid from glycogen is unable to form lactic acid from glucose. While reduced glutathione is essential in the process of lactic acid production from glucose, glycogen can be split into lactic acid in its absence. Reduced glutathione added to tissue suspensions greatly accelerated the lactic acid formation from glucose but inhibited it to a small extent when glycogen was the substrate.

By the fact that reduced glutathione is a common coenzyme of the methylglyoxalase and of the glycolytic enzyme system, the probability of methylglyoxal being an intermediary product in the formation of lactic acid from glucose is strengthened. The concentrations of reduced glutathione necessary for the full activation of the glycolysis (of glucose) and of methylglyoxalase are similar.

On the other hand it is hardly possible to consider methylglyoxal as an intermediary in the process of lactic acid formation from glycogen, as this process proceeds also in the absence of glutathione. The experiments of Embden *et al.* [1933] of Meyerhof and Kiessling [1933] and of Meyerhof and McEachern [1933] excluded the intermediary formation of methylglyoxal from the lactic acid production from glycogen and hexosediphosphate by muscle. It is also known that muscle tissue splits mainly glycogen, glucose only to a small extent.

On the basis of these facts the hypothesis is ventured that glucose breakdown in the cells proceeds with the intermediary formation of methylglyoxal, in accordance with the theory of Neuberg, while the breakdown of glycogen proceeds as postulated by Embden *et al.* and Meyerhof *et al.* through pyruvic acid. A recent paper of Barrenscheen and Bereschkovsky [1933], according to which tissues other than muscle are unable to produce pyruvic acid from phosphoglyceric acid, also points in this direction.

The inhibiting action of oxidised glutathione is of peculiar interest as offering an explanation of the Pasteur-Meyerhof reaction. It was found formerly by Lipmann [1933] that oxidising agents such as iodine and quinone inhibited the glycolysis of muscle extracts. The glycolysis of these extracts was also reversibly inhibited by O_2 in the presence of a redox indicator, 2:6-dichlorophenolindophenol. Lipmann therefore concluded, that the Pasteur reaction is an oxidative inhibition of the glycolysis, as the glycolytic ferment of the cells becomes inactivated by oxygen transmitted by the autoxidisable respiratory enzyme.

According to the present experiments oxidised glutathione may be considered as the transmitter of oxygen to the glycolytic enzyme. Reduced glutathione can be easily oxidised by molecular oxygen in a weakly alkaline medium. In its turn, oxidised glutathione proved to be a powerful inhibitor of glycolysis.

Since in muscle glycolysis from glycogen no reduced glutathione is necessary and since the inhibitory effect of oxidised glutathione persists also in the presence of reduced glutathione it is evident that reduced glutathione in this case may act only as an intermediary by transmitting oxygen to the glycolytic enzyme.

On the other hand in the glycolysis of glucose the oxidation of glutathione has a double significance. First, by oxidation of reduced glutathione the glycolytic enzyme system is deprived of one of its coenzymes, and secondly, the presence of oxidised glutathione inactivates the glycolytic enzyme. It is to be noted that in the present experiments the quantitative aspect of the inhibition of these two types of glycolysis by oxidised glutathione has not yet been sufficiently considered. It seems, however, that a more complete inhibition can be obtained by oxidised glutathione in the breakdown of glycogen than in that of glucose.

No explanation can be offered for the observed actions of borate and of calcium on glycolysis.

The experiments on the glyoxalase activity of muscle and brain tissue provide further evidence in favour of the theory that methylglyoxal cannot be considered as intermediary in glycogen breakdown but is a possible intermediary in glucose breakdown.

SUMMARY.

1. Tissue extract from which reduced glutathione is removed cannot convert glucose into lactic acid. The addition of reduced glutathione restores this ability to the extracts.

2. Reduced glutathione added to tissue suspensions accelerates the rate of lactic acid formation from glucose but inhibits to a small extent that from glycogen.

3. Oxidised glutathione even in low concentration inhibits lactic acid formation from glucose as well as from glycogen.

4. Borate inhibits brain glycolysis, $CaCl_2$ restores it to a small extent.

5. It is concluded that reduced glutathione is a coenzyme of the glycolytic enzyme system and that lactic acid production from glucose may proceed through methylglyoxal as an intermediary, while this possibility is excluded in the case of glycogen.

6. An explanation is offered for the Pasteur-Meyerhof reaction.

XCVI. RAPID TITRIMETRIC ESTIMATION OF ARSENIC IN BIOLOGICAL MATERIAL.

BY RUTH ALLCROFT AND HENRY HAMILTON GREEN.

From the Veterinary Laboratory, Ministry of Agriculture, Weybridge.

(Received February 14th, 1935.)

IN the course of work upon the fate of arsenic in avian metabolism the need arose for a rapid method of estimating quantities of arsenic from 1 mg. down to 0·005 mg. As_2O_3 per 10 g. sample of biological material, with a probable error not exceeding ± 5 % for quantities around 0·005 mg. In a balance experiment on a laboratory animal in which it is desired to account quantitatively for administered arsenic as eliminated in faeces and urine or retained in various tissues, such a degree of accuracy meets most demands for physiological information; but wider errors are objectionable and in our opinion most of the older statements regarding prolonged retention of considerable quantities of arsenic in the body arose from faulty recovery of excreted arsenic and the unjustifiable assumption that the unrecovered arsenic was still in the tissues.

The range of accuracy arrived at is also satisfactory for public health administration concerning arsenic in foods where 1·4 parts per million is the permissible figure suggested by the Royal Commission of 1903.

A survey of existing procedures revealed laborious methods sufficiently accurate and rapid methods open to higher error, but despite the voluminous literature on arsenic determination it seemed probable that a more serviceable routine could be devised. The present communication claims to supply one which is effective with a few γ of material but has an "average working time" of only 20 mins. per determination in a routine series of half a dozen analyses. Since it involves a wet combustion, a separation as arsine and a final microtitration, a single determination cannot very well be completed in less than 90 mins., but since a rack of six blood analyses can be finished in 2 hours the procedure becomes as simple as the Kjeldahl process for total nitrogen. The economy of time is effected by combining a very rapid perchloric-nitric acid wet combustion with a rapid subsequent separation of arsine in a fast stream of hydrogen, absorption in dilute silver nitrate and direct micro-titration of the liberated arsenious acid with iodine in presence of sufficient potassium iodide to retain excess silver in clear solution and so render possible a delicate starch end-point. The iodine is arranged to express results directly on the burette and obviate arithmetic (1 ml. $N/495 = 0{\cdot}1$ mg. As_2O_3 or 1 ml. $N/375 = 0{\cdot}1$ mg. As).

Discussion of existing methods.

Since arsenic determination for biological purposes usually involves destruction of large amounts of organic matter and subsequent estimation of real quantities below 0·1 mg. ordinary gravimetric and volumetric methods are excluded and colorimetric or nephelometric methods and micro-titration or mirror-matching technique come into consideration. For literature on such methods the reader is referred to Heller [1934] who, in collecting references on micro-methods since 1928, cites 54 publications dealing with arsenic; to Kleinmann and Pangritz [1927] who give numerous references to previous technique; to

Minot [1926] who does the same and to Cox [1925] who concerns himself chiefly with English public analyst requirements and with checking the methods of Bang and Ramberg.

The precise technique of combustion is important since small losses are liable to occur both in wet and dry methods, and it is usual to effect a preliminary separation of arsenic from the combustion residue either as arsine or as arsenic trichloride before proceeding to actual estimation. Where the quantity of arsenic can be arranged to be relatively large (say 5 mg.) as in estimations on organic arsenicals the very simple method of Ewins [1916] is serviceable. Here the organic matter is destroyed with sulphuric acid as in an ordinary Kjeldahl combustion, with concomitant reduction of arsenic to arsenious acid, the excess sulphuric acid neutralised with soda lye and finally with sodium bicarbonate and the arsenic titrated directly with iodine. But where the amount of arsenic is small loss of traces of it by volatilisation and the possible presence in the combustion residue of substances which liberate iodine invalidate the procedure. Nitric-sulphuric acid combustion, in which the bulk of the organic matter is destroyed at lower temperature, is the generally recognised procedure and the technique of Ramberg [see Cox, 1925] is preferable to that described in the Report of the Conjoint Committee on the detection and approximate estimation of minute quantities of arsenic [1902]. The American Association of Official Agricultural Chemists [1930] also adopts combustion with nitric and sulphuric acids. Scott [1925] gives the unsatisfactory hydrochloric acid and potassium chlorate method. Hitherto no one seems to have recorded trials of perchloric acid with nitric or sulphuric acid. Amongst the little used dry methods, combustion with magnesium nitrate, as described below, would seem to be satisfactory.

In most cases where the nitric-sulphuric acid wet combustion is used it is now customary to remove residual traces of nitric acid by dilution, addition of oxalate and recombustion—a procedure which adds to the working time but is necessary when ensuing separation of arsenic is to be as trichloride.

Minot [1926] then proceeds to final determination without separation of the arsenic, reducing to trivalent form by saturating the diluted combustion residue with SO_2, expelling this by evaporation and finally titrating direct with *N*/500 iodine. Blanks, however, amount to 0·01 mg. As_2O_3 and vary ± 20 % (0·08 ml.–0·12 ml.), and the time saved in separating as AsH_3 or $AsCl_3$ is lost by reduction with SO_2 and final evaporation.

Cox [1925], the English Sub-committee on the determination of arsenic in food colouring materials [1930], von Fellenberg [1930] and most recent workers agree that arsenic must be separated from the combustion residue before final determination. Cox considers that separation by distillation of the trichloride [Bang, 1925] followed by micro-titration with standard potassium bromate as used by Ramberg is satisfactory if the amount of arsenic to be determined is not less than 0·01 mg.; below this he recommends the Marsh-Berzelius method following the Ramberg technique for destruction of organic matter. Nevertheless the personal trials of Cox with the bromate titration, using pure carbohydrate with known quantities of arsenic, gave recoveries of 0·06 mg. in place of 0·05 mg. (20 % too high), 0·03 mg. in place of 0·02 mg. (50 % too high) and 0·02 mg. in place of 0·01 mg. (100 % too high). The results from 0·05 mg. downwards are thus much too high and this is a more serious fault than being too low; in the latter case empirical correction can be justified if duplicates are good and small losses consistent.

Kleinmann and Pangritz [1927] regard colorimetric methods of the Gutzeit type as inherently unreliable and consider that amongst the titrimetric methods the technique of Billiter [1923], who dissolves the Marsh mirror in iodine and back-titrates with thiosulphate, is the most accurate. They themselves describe a nephelometric method sensitive to 0·5γ H_3AsO_4 in pure solutions and accurate to 5 % even with quantities below 0·01 mg. The principle of the method is precipitation with cocaine molybdate and nephelometric determination of turbidity; previous combustion being carried out by the nitric-sulphuric method of Ramberg and essential separation of arsenic being effected by the trichloride distillation of Bang [1925]. Unfortunately their recovery figures refer mainly to direct nephelometric determination on pure solutions and insufficient data are supplied on the operation of the whole process with tissues to which known amounts of arsenic have been added in order to test the summation of errors involved in combustion, distillation, precipitation and nephelometric matching.

Amongst newer colorimetric methods may be mentioned those of Maechling and Flinn [1930] and of Youngburg and Farber [1932]. The former use nitric-sulphuric combustion followed by distillation of arsenic trichloride, convert into quinquivalent form by evaporating with nitric acid and bromine, heat with reduced molybdate and compare in a colorimeter with an arsenate standard. The latter precipitate as arsenic sulphide, oxidise this and determine colorimetrically with molybdate and stannous chloride. But no recovery tables for arsenic added to tissues are given in either of these papers.

Von Fellenberg [1930] also precipitates as sulphide (with H_2S after distilling as $AsCl_3$ from the combustion residue) but titrates the isolated sulphide with permanganate in alkaline solution. Good results are shown even with a few γ but unfortunately in recovering added arsenic (limited data) the smallest magnitudes are returned too high and the higher magnitudes too low so that there is the suggestion of arbitrary compensatory errors just at the point (0·01 mg.) where recoveries by other methods begin to be unduly low.

On the question of separation of arsenic as AsH_3 by zinc and sulphuric acid most authors agree that recovery is good with pure solutions of arsenic provided that a properly activated pure zinc is used, but some consider that it may be rendered imperfect by substances in the combustion residue and therefore recommend a preliminary separation as trichloride even when subsequent arsine separation follows incidentally on the use of Gutzeit papers. This double separation occurs in the method described in the First Report of the Sub-committee on determination of arsenic in food colouring materials [1930], although Cox [1925] recommends the Marsh-Berzelius procedure direct on the Ramberg combustion residue.

Despite the variety of terminal procedures at disposal the most popular finishing estimation is still the colorimetric comparison of Gutzeit papers. But Neller [1929] in his study of the accuracy of the Gutzeit procedure considers the inherent error too high and the English Sub-committee, while regarding the stain produced by 0·005 mg. As_2O_3 as "a very suitable intensity to evaluate", concedes that "a stain actually due to 0·0045 mg. may be estimated at 0·004 or 0·005 according to individual judgment," and that this 20 % difference may appear equally in stating results of 1 part or 20 parts per million, irrespective of the real magnitude of the quantity in the analysed aliquot. Although the procedure is sound enough for most ordinary needs it might well be considered that the tedious combustion, dilution and reconcentration, distillation as trichloride and second separation as arsine, are labour lost if they end with an inherent error of ± 10 % irrespective of whether 0·20 mg. or 0·01 mg. As_2O_3 per 10 g. sample is dealt with. The significance of double separation of arsenic is worthy of further investigation but the usefulness of abbreviating combustion needs no defence, and the obviation of individual judgment is still more desirable. Since a starch-iodine end-point is as delicate as an arsenic-mercury stain we believe that microtechnique is capable of carrying titration as far as Gutzeit papers. If recovery of arsenic is then incomplete but duplicates agree well, and an empirical upward correction is indicated, varying with the real magnitude of the arsenic at disposal, the correction is at least deliberately made and not unconsciously incorporated.

The proposed method.

The combustion procedure is essentially that described by Bolliger [1932] for general use in destroying organic matter by means of perchloric and nitric acids. The use of sulphuric acid in place of nitric (1 ml. perchloric acid, 1 ml. sulphuric acid per 0·2 g. of dry matter) associated with higher combustion temperature, as used by McCance (personal communication) for subsequent colorimetric determination of total phosphorus in foods, is equally serviceable and even speedier when the quantity of organic matter is sufficiently small for the analyst to view possible conflagration in the combustion vessel with equanimity, but the lower boiling-point of the perchloric-nitric mixture is an advantage when large combustion volumes have to be considered in relation to traces of arsenic liable to loss by volatilisation. The need for secondary dilution, addition of oxalate and recombustion to get rid of residual nitric acid, disappears since separation as $AsCl_3$ does not follow. The technique of the arsenic titration is a refinement of that used by Green [1918] in which the familiar reaction

$$2AsH_3 + 12AgNO_3 + 3H_2O = 12Ag + 12HNO_3 + As_2O_3$$

is used; precipitation of silver iodide is held up by addition of excess potassium iodide and the arsenic is directly titrated with iodine. It is sufficient to add the observations (*a*) that perchloric acid does not interfere with the liberation of arsine by zinc and sulphuric acid, (*b*) that absorption of traces of arsine from large volumes of hydrogen by silver nitrate as dilute as $N/100$ is complete even when the gas is blown through a few cm. depth of liquid at the rate of several litres per minute, and (*c*) that the starch end-point is still sensitive to less than 1γ when soluble iodides are present in large excess so that micro-titration can take the place of the conventional Gutzeit papers and obviate the personal equation altogether. In general 10 g. of wet tissue form a suitable aliquot and since 1 ml. $N/495$ iodine $= 0·1$ mg. As_2O_3 the microburette reading gives mg. per 100 g. without further calculation.

Reagents. A.R. quality and As-free materials should be used throughout.

Perchloric acid 60 %.
Nitric acid, conc.
Stannous chloride solution. Dissolve 40 g. $SnCl_2, 2H_2O$ in HCl and make up to 100 ml. with the same strength acid [Assoc. Off. Agric. Chem. 1930].
Copper sulphate 5 %.
Lead acetate 1 %.
Silver nitrate, approximately $N/50$.
Starch solution 1 % (fresh).
$N/495$ iodine, freshly diluted from stock $N/10$ (2 ml. $N/10$ made up to 99 ml.).
Sodium bicarbonate.
Potassium iodide.
Zinc shot (tested for interfering impurities).
Sulphuric acid.
Standard arsenic solution. 1 ml. $= 0·1$ mg. As_2O_3 for intermittent checking of process.

Moir and Jamison [1925] have described an electrolytic generator for use with the titration method of Green [1918] but zinc and acid generators are more usual and more conveniently prepared in large numbers.

Perchloric acid frequently contains traces of arsenic (up to 0·75 mg. per litre) and although it is possible to obtain it As-free (B.D.H. supply usually is so) a sample should be procured before purchasing in bulk and a test made to ensure that it will not introduce too high a blank. As-free zinc shot is easy to obtain but should be tested in the actual process to ensure that it permits good recovery of arsenic from the standard solution. Samples have been encountered which contain no arsenic but which give low results, apparently by retaining traces of arsenic in the generator. In making this test a suitable strength of sulphuric acid to use in the generator is 1: 5, with catalysts as usual. It should be needless to point out that glassware often contains arsenic and that for combustion flasks exposed to high temperature and strong acid mere preliminary "pickling" is not enough. We have found monax glass quite suitable.

First stage. 10 g. of finely divided wet tissue or 2–5 g. dry matter are introduced into a 300 ml. Kjeldahl flask and covered with 20 ml. of perchloric acid. The quantity of perchloric acid (which should be noted if not quite As-free) naturally depends upon the material but to avoid the risk of explosion it is essential to err on the side of liberal excess. In the case of dilute liquids such as urine preliminary concentration by boiling precedes the addition of perchloric acid. If dry matter is used care should be taken to ensure thorough wetting with the acid before heating, and for adhesive powders such as flour it is best to wet to a paste with water first. Speculative adjustment of sample aliquots on the basis of anticipated real arsenic values naturally facilitates any final corrections which may have to be made. In the case of material rich in arsenic 1 ml. or 1 g., or less, may be taken and the scale of operation reduced to a test-tube 1 × 7 in. which, if desired, can also serve as subsequent Marsh generator for a reduced scale absorption apparatus.

Two glass beads are added to facilitate even boiling and the mixture is brought to ebullition and appearance of perchloric fumes over a bare flame. The flask is then transferred to a cork ring in the combustion cupboard and concentrated nitric acid added from a dropping pipette. Vigorous reaction sets in almost at once but is easily controlled by adjusting the rate of addition of nitric acid. When no further reaction occurs the yellow-brown mixture is heated on a Kjeldahl or other digestion rack until white fumes of perchloric acid appear. Continuous observation is necessary to control recrudescence of reaction. When the volume is reduced to about half oily drops appear on the sides of the flask and a vigorous reaction usually occurs. If so it is necessary to turn out the flame. After the reaction subsides the digest either turns practically colourless or else dark brown. If the latter then more nitric acid must be added, in which case it is advisable to remove the flask to its cork ring and allow to cool somewhat before adding the requisite further nitric acid and restoring to the digestion stand for completion of combustion. Usually 2 or 3 ml. are sufficient as indicated by the dark brown colour changing to a yellow-brown. Complete combustion is indicated by a clear, pale, yellowish green residue associated with white perchloric fumes. The residue is usually colourless on cooling, but if not can generally be rendered so by final addition of a few drops of perhydrol. Tissues such as muscle, blood and urine give a colourless cold digest; a faeces digest may be slightly yellow.

Although the digestion process requires constant attention it is not at all laborious. The time taken for the whole combustion varies from about 10 mins. for 10 ml. of blood or urine, to about 30 mins. for 10 g. of muscle or liver tissue and over an hour for 2 g. of dried faeces, but since 6 to 12 combustions can be supervised simultaneously the actual duration of a single digestion is unimportant.

Second stage. The digest is diluted and washed into a generating flask to a total volume of about 100 ml.; 10 drops of stannous chloride solution and 2 drops of copper sulphate are added to speed up evolution of hydrogen. About 15 ml. of concentrated sulphuric acid are added and the contents heated over a flame for a few seconds if the mixture is not warm enough to ensure immediate subsequent vigorous evolution of hydrogen; about 25 g. zinc shot are then quickly added and the flask immediately connected up to the previously prepared absorption tubes (A, B, C and D). Of these, the first tube A contains 1 % lead acetate to remove any traces of H_2S formed by reduction of the hot dilute sulphuric acid. The remaining three tubes B, C, D contain $N/50$ or $N/100$ $AgNO_3$, not stronger. Two are sufficient (*i.e.* B and C) in ordinary practice so that the last tube D becomes a guard tube in case unsuspectedly large amounts of arsenic are found (over 1 mg.). For quantities of 0·2 mg. over two-thirds is caught in the first tube; for 0·1 mg. or less the last tube D is unnecessary and C serves as guard. Three or four ml. of $N/50$ $AgNO_3$ in the first two tubes cover any range up to 1 mg. As_2O_3. For quantities below 0·01 mg. $N/100$ $AgNO_3$ (approximately) is preferable.

Evolution of hydrogen from the hot acid is very rapid and the arsenic is swept over completely in 20 mins.—the faster the better so long as the liquid is not blown out of the tubes. Too slow evolution of hydrogen seems to lead to bad recoveries of arsenic.

Tubes B and C are then detached and the contents of the latter added to the former if any trace of silver deposition is noted in it. It is rarely necessary to add the contents of the guard tube. About 0·1 g. of sodium bicarbonate and about 2 g. of potassium iodide crystals, or sufficient to redissolve the silver iodide first precipitated, are added. After final addition of about 0·5 ml. of fresh 1 % starch solution $N/495$ iodine is run in to violet end-point. On a titration volume of about 5 ml. one drop from an ordinary 1 ml. micro-burette with waxed tip, corresponding to 0·01 ml. = 0·001 mg. or 1γ As_2O_3, gives a sharp end-point but this is not the limit of sensitiveness since change of violet tint can be detected with less. By reducing the titration volume to 1 ml. and using an appropriate adaptation of the Rehberg type of burette an end-point of $0{\cdot}1\gamma$ could be reached. This would come into consideration if it were desired to reduce the whole scale of technique, combust small aliquots in test-tubes and absorb the AsH_3 in, say, 1 ml. $N/100$ $AgNO_3$; but such refinement is rarely required for physiological work.

With the 1 ml. burette used in this work for quantities up to 0·1 mg. As_2O_3 each division corresponded to 1/100 ml. = 1γ As_2O_3 in the sample, and the starch end-point was taken to one division. For larger quantities a 5 ml. or 10 ml. burette was used.

Illustrative results. The method has been used extensively in physiological work over the past year with sufficiently good results but the following data may be taken to illustrate the results in routine practice, working at a speed which allowed 24 determinations to be completed in an uninterrupted 8-hour day.

Table I shows the recoveries of arsenic added to the generator flask as standard solution, *i.e.* omitting the combustion process and considering only the perfection of separation as arsine, absorption in silver nitrate and subsequent titration with iodine.

Table I.

As_2O_3 added (mg.) ...		1·0	0·5	0·2	0·1	0·05	0·02	0·01	0·005
ml. *N*/495 iodine solution required	(1)	9·67	4·87	2·03	0·985	0·505	0·205	0·110	0·055
	(2)	9·82	4·87	1·92	1·015	0·495	0·195	0·100	0·060
	(3)	9·80	4·80	1·92	0·985	0·500	0·205	0·105	0·055
Blank, ml. iodine		0·02	0·02	0·02	0·015	0·015	0·015	0·015	0·015
Average, *minus* blank		9·74	4·83	1·94	0·980	0·485	0·187	0·090	0·042

% of theoretical value		97	97	97	98	97	94	90	84

A few determinations were also carried out in which the two drops of copper sulphate were omitted and only the stannous chloride activator used, to ascertain whether the trace of copper helped or hindered recovery. No noteworthy difference was recorded so that the function of the copper is apparently confined to speeding up the generation of hydrogen. Another series was executed to ascertain the best concentration of silver nitrate to use. Approximately *N*/50 was found to be optimum for quantities between 0·01 mg. and 1 mg. and *N*/100 for quantities below 0·01 mg. *N*/10 was definitely too strong in the sense that recoveries were about 10 % lower than with *N*/50 but the reason for this was not specially investigated.

From Table I it will be noticed that the recoveries are very good down to 0·05 mg., much better than could be counted upon in Gutzeit colour matching, and that triplicates are satisfactory.

There is, however, a definite small loss which diminishes as the real quantity of arsenic diminishes but which is exaggerated when results are expressed on a percentage basis. Triplicates, however, agree within the limitations of the endpoint of the burette and the titration volume, and the blank is open to the same titration error, so that nothing better could be expected. This point is brought out again in Table II which represents a series of recoveries on the whole process adding known quantities of arsenic to 10 g. of liver tissue in the combustion flask, and comparing with recoveries on pure solutions.

Table II.

	Recovered			
	From pure solutions		After digestion + 10 g. liver	
As_2O_3 added in mg.	mg.	%	mg.	%
1	0·965	97	—	—
	0·980			
	0·978			
0·5	0·485	97	0·480	97
	0·485		0·485	
	0·478		0·490	
0·1	0·097	98	0·095	93
	0·100		0·091	
	0·097		0·093	
0·05	0·049	97	0·048	94
	0·048		0·045	
	0·0485		0·048	
0·01	0·0095	90	0·008	82
	0·0085		0·0085	
	0·0090		0·008	
0·005	0·0040	84	0·003	64
	0·0045		0·0035	
	0·0040		0·003	

It will be noted that down to 0·05 mg. As_2O_3 the perchloric-nitric combustion process has not involved any significant loss. At 0·05 mg. the difference between 97 % and 94 % recovery is negligible in view of the fact that 0·048 mg. recoveries appear in both sets of triplicates. There is a real loss varying between 1γ and 2γ As_2O_3; this variation in recovery is of less consequence for quantities over 0·05 mg. but is more serious when results are expressed on a percentage basis with quantities so low as 0·005 mg. The average of 0·0042 mg. recovered from the pure solution and of 0·0032 mg. recovered from the liver tissue means a loss of 16 % in one case and 36 % in the other, but one would hesitate to attribute the difference wholly to the combustion. The agreement between triplicates, however, is within the limits of titration of the volume concerned so that in a balance experiment in which it was necessary to account on the basis of 100 % recovery, an upward correction of 0·002 mg. to the uniformly low results and admission of a variation of ± 0·0005 mg. (± 10 %) in drawing conclusions, would seem to be justifiable.

A further series of trials is offered in Table III, this time on different substances to which "1·4 parts per million", the critical limit for the public health analyst, were added.

Table III. *Recoveries in parts per million and as percentage of arsenic added to various materials. 0·014 mg.* As_2O_3 *per 10 g. or 10 ml.*

Urine		Beer		Blood		Milk		Flour	
Parts per million	%	Parts per million	%	Parts per million	%	Parts per million	%	Parts per million	%
1·30	93	1·20	86	1·10	79	1·30	93	1·20	86
1·25	89	1·15	82	1·20	86	1·30	93	1·15	82
1·15	82	1·15	82	1·15	82	1·25	89	1·25	89
1·20	86	1·20	86	1·15	82	1·30	93	1·25	89

It will be observed that recoveries vary from 1·15 to 1·30 parts per million, or 82 to 93 % of the added arsenic. Most analysts would agree that this is good and report the figures direct, but since all data are low a higher degree of accuracy could be obtained by correcting upwards by 12 % and stating results within a probable error of ± 7 %.

Comparison of combustion methods. Since the method of digestion utilised here does not seem to have been discussed for arsenic before, it is considered advisable to add comparative data on different methods of combustion. Table IV gives the recoveries of known quantities of arsenic added to 10 g. minced liver tissue in each case. The methods were:

(1) Ordinary Kjeldahl combustion with 3 g. potassium sulphate and a fragment of copper as catalyst.

(2) Combustion with nitric and sulphuric acids as described in Assoc. Off. Agric. Chem. [1930, p. 307].

(3) Hydrochloric acid and potassium chlorate method as given by Scott, [1925, p. 51].

(4) Perchloric-nitric combustion as described above.

(5) Dry ashing with magnesium nitrate, a method sometimes used by Green in dealing with large quantities of rumenal contents or grass. This consists in thoroughly mixing the material with 20 % magnesium nitrate solution (about 40 ml. for 10 g. liver tissue), taking to dryness on the water-bath and ashing at moderate temperature in an electric muffle. The light white ash is then moistened with water, dissolved by warming with 1 : 5 sulphuric acid and transferred to the generator flask for completion of the determination as usual.

Table IV. *Method of digestion.*

As_2O_3 added mg.	Sulphuric acid	Nitric acid + sulphuric acid	Hydrochloric acid + potassium chlorate	Perchloric acid + nitric acid	Ashing with magnesium nitrate
0·5	77	81	49	97	90
	59	84	41	96	88
	52	77	50	98	95
Average recovery	63	81	47	97	91
0·1	61	71	53	95	95
	72	70	—	91	83
	67	85	—	93	94
Average recovery	67	75	—	93	91
0·05	70	72	48	96	92
	72	72	36	90	84
	66	74	—	96	88
Average recovery	69	73	42	94	88
0·01	90	70	40	80	85
	50	70	50	85	70
	60	80	—	80	80
Average recovery	67	73	45	82	78
0·005	Nil	50	Nil	60	50
	40	70	Nil	70	40
	20	50	Lost	60	50
Average recovery	20	57	Nil	63	47

The combustion with hydrochloric acid and potassium chlorate was so troublesome and unsatisfactory that it was not considered worth completing the series. The high temperature sulphuric acid combustion obviously leads to material percentage losses even with quantities as high as 0·5 mg. Dry combustion with magnesium nitrate appears to be as satisfactory as nitric-sulphuric digestion and may occasionally be of service with certain classes of material. In using it abundant excess of magnesium nitrate should be used and care taken to ensure thorough permeation of the sample. The nitric-sulphuric combustion might have given higher recoveries, especially on the 0·5 mg. and 0·1 mg. quantities, if the precautions emphasised by Cox in discussing Ramberg's procedure had been studiously observed, but the Assoc. Off. Agric. Chem. [1930] method was purposely carried out as it would be in ordinary laboratory practice. The run of results with the perchloric-nitric combustion is obviously best of all so that it appears to have in its favour superiority of recovery as well as greater speed of destruction of organic matter. This is attributed to the lower boiling-point of perchloric acid as compared with sulphuric at the last stage of combustion, as well as to the shorter period at high temperature.

SUMMARY.

A rapid quantitative method for determination of arsenic in biological material is described which enables six determinations to be completed in about 2 hours. A mixture of perchloric and nitric acids is used for destruction of organic matter. Arsenic is liberated as arsine in a fast stream of hydrogen, absorbed in a few ml. of $N/50$ silver nitrate and directly titrated with $N/495$ iodine (1 ml. = 0·1 mg. As_2O_3) to starch end-point in presence of sufficient excess of potassium iodide to keep silver in solution. Micro-titration is regarded as superior to matching Gutzeit papers, the inherent error of which may operate indifferently over large and small real quantities of arsenic.

Recoveries of added arsenic in quantities of 0·50 mg. to 0·005 mg. As_2O_3 compare favourably with recoveries by other methods. Duplicates are good and probably validity of results can be improved by an upward correction for consistent small losses.

XCVII. THE CAROTENOIDS OF BUTTER.

By ALBERT EDWARD GILLAM and ISIDOR MORRIS HEILBRON.

From the Chemistry Department, Manchester University.

(*Received February 22nd, 1935.*)

In a series of papers [Gillam *et al.*, 1933; Watson *et al.*, 1933; 1934; Gillam, 1934] data have been collected on the carotene and vitamin A contents of the butter of several breeds of cattle fed under various conditions. In view of the fact, however, that carotene exists in more than one isomeric form [Kuhn and Lederer, 1931; Kuhn and Brockmann, 1933] and that, of these, the α- and γ-forms are physiologically only half as active as the β-isomeride [Kuhn, Brockmann *et al.*, 1933] it is obviously important to ascertain precisely in which form the pigment is present in butter. The present paper describes the results of a chromatographic examination of the carotene fractions of a number of ordinary and colostral butter samples with a view to elucidating this problem. The colostral butters, which became available during a larger experiment at present in progress, were especially useful in this investigation on account of their exceedingly high carotene content [*cf.* Dann, 1933; Semb *et al.*, 1934].

The butters (100–500 g.) were saponified as previously described [Gillam *et al.*, 1933] and the unsaponifiable material, after removal of the major part of the sterols by crystallisation from methyl alcohol, separated into carotene and xanthophyll fractions by partition between light petroleum and 90 % methyl alcohol. The methyl alcoholic solution, containing the major part of the vitamin A and all the xanthophyll, was discarded. The light petroleum solution (30–40 ml.) was washed with water to free it from methyl alcohol, dried over sodium sulphate and subjected to the Tswett chromatographic process using a 3 × 20 cm. column of alumina (Brockmann's activated Al_2O_3 (Merck) diluted 1 : 2 with inactive Al_2O_3). The chromatogram was developed by washing successively with light petroleum of B.P. 40–60° and 60–80°. The separated zones were eluted individually with light petroleum containing methyl alcohol, filtered from adsorbent and examined spectroscopically in either light petroleum or carbon disulphide.

The principal pigments.

The majority of the samples exhibited two main coloured zones which washed down the columns separately, the lower one being yellow or buff in colour whilst the upper one was brown or pink. A similar separation was observed when calcium hydroxide was employed in place of alumina [Karrer and Walker, 1933]. The spectroscopic values are shown in the accompanying table, together with the absorption maxima recorded for α- and β-carotene in the literature. As Haüsser (quoted by Kuhn, 1931) has shown that different spectroscopic techniques give slightly different values for the absorption maxima of carotene solutions, we have also made chromatographic and spectroscopic examinations of carotene samples definitely known to contain the α- and β-isomerides, under conditions exactly comparable with those used in the case of the butter pigment, employing for this purpose:

(*a*) the unsaponifiable matter of palm oil [Kuhn and Brockmann, 1931], and

(*b*) a sample of crystalline carrot carotene, M.P. 178° [Kuhn and Lederer, 1931; Mackinney, 1935].

Table I.

		Lower zone (α-carotene)			Upper zone (β-carotene)			
			Absorption maxima			Absorption maxima		
Sample	Adsorbent	Colour of zone on adsorbent	Petrol 70–80° $m\mu$	CS_2 $m\mu$	Colour of zone on adsorbent	Petrol 70–80° $m\mu$	CS_2 $m\mu$	Ratio of $\alpha:\beta$ carotene present

	MgO	—	—	507 476	—	—	511 485	Strain [1931]

A comparison of the data (see Table I) with the corresponding butter values definitely proves that butter contains both α- and β-carotene and that the relative amounts of these isomerides vary considerably in different samples. The ratio of the two substances present in each butter was determined as follows. The separately eluted pigments were made up to equal volumes in light petroleum B.P. 70–80°, and the intensity of absorption of light of each solution was determined at the wave length of maximum absorption (447 $m\mu$ for α-carotene, 452 $m\mu$ for β-carotene). When equal thicknesses of solution are examined the relative amounts of pigment present are directly proportional to the respective intensities of absorption recorded.

Pigments present in only small amount.

In addition to α- and β-carotene, several of the more highly pigmented butters were found to contain minor amounts of other petrol-phasic lipoid pigments, whose presence was indicated by the appearance of one or more coloured bands (usually a yellow-brown ring with a reddish violet ring just over it) situated above the β-carotene on the developed chromatogram. The yellow pigment was definitely characterised as kryptoxanthin by the following properties: (*a*) the yellow-brown colour of the ring and the fact that it is adsorbed just above the β-carotene; (*b*) absorption maxima in light petroleum at 481 and 451·5 $m\mu$. Kuhn and Grundmann [1933], using a grating spectroscope instead of our prism spectroscope, record maxima for kryptoxanthin at 485·5 and 452 $m\mu$; (*c*) the pigment, although epiphasic in light petroleum to 90 % methyl alcohol, is partially extracted by 95 % methyl alcohol; (*d*) the pigment is adsorbed only with difficulty on calcium carbonate.

In the case of one Ayrshire colostral butter the amount of this pigment was estimated to constitute approximately 3 % (*i.e.* 0·15 mg. per 100 g. fat) of the total carotene fraction.

The reddish violet band was usually present in too small quantity for definite characterisation, but in the case of the casual Danish butter sample, which was much richer than usual in both these subsidiary pigments, it was found possible to separate it almost completely from the kryptoxanthin by repeated adsorption on alumina. The pigment is characterised by absorption bands at 503, 470 and 442 $m\mu$, which agree with the maxima of lycopene recorded by Kuhn and Brockmann [1932] who give 506, 474 and 446 $m\mu$. The slight discrepancy in the wave lengths is probably due to incomplete separation of all the kryptoxanthin, and in this connection Kuhn and Grundmann have reported that these two carotenoids are not sharply separable on alumina. In this particular sample of butter, the kryptoxanthin and lycopene were present in approximately equal amounts, and together constituted nearly half of the total petrol-phasic colouring matter.

In the light of these results it was argued that as the carotenoids of milk fat must come from the food ingested by the cow *via* the blood, then the blood serum carotenoids might be expected to be similar to those of butter. A preliminary examination of the lipoid pigments of the blood serum of cows indicates a striking similarity to those of butter. We are at present examining the matter in more detail.

SUMMARY.

The petrol-phasic carotenoid fractions of the unsaponifiable matter of a number of ordinary and colostral butters have been examined by combined chromatographic and spectroscopic methods. It has been found that the carotene present is a mixture of α- and β-forms, the relative amounts of which vary considerably in different samples. Kryptoxanthin and lycopene have also been detected in small amount in several of the more pigmented samples of butter.

We wish to thank Messrs Imperial Chemical Industries Ltd. Research Council for financial assistance and to acknowledge the invaluable co-operation of Messrs Page, Watson and Ferguson of Jealotts Hill Agricultural Research Station in the collection and preparation of the butter samples.

XCVIII. STABILITY OF THE INTERNATIONAL STANDARD OF THE OESTRUS-PRODUCING HORMONE IN ALCOHOLIC SOLUTION.

By IDWAL WYN ROWLANDS and ROBERT KENNETH CALLOW.

From the National Institute for Medical Research, London, N.W. 3.

(*Received February 6th, 1935.*)

THE International Standard of the oestrus-producing hormone consists of the hydroxyketonic compound known in this country as ketohydroxyoestrin or oestrone. Since it is desirable, for some purposes, to prepare and store alcoholic solutions of the standard substance, it has been considered advisable to investigate its stability when kept in this form for various periods and at different temperatures. Butenandt [1930] reported that the stability of oestrone in alcoholic solution was small, a decrease of activity of at least one-third taking place in 2 months.

Technique.

Preparation of alcoholic solution. For biological assay a sample of the International Standard was dissolved in the proportion of 2 mg. in 100 ml. of absolute alcohol (*i.e.* 0·002 %); for spectrographic examination the concentration was 0·0125 %. Solution in the cold was slow, and was completed by heating to 50° for 10 minutes on a water-bath. The solution was cooled, transferred to dry sterile ampoules of non-alkaline resistance glass and immediately sealed.

Storage. Each set of ampoules was divided into batches. Those for biological assay were stored at $-2°$, at room temperature in the dark and at 37°, respectively. Those for spectrographic examination were divided into four batches stored (*a*) at $-2°$, (*b*) at room temperature in the dark, (*c*) at room temperature, in diffused daylight, (*d*) at 37°. Batches (*a*) and (*d*) were occasionally exposed to artificial light but otherwise kept in the dark. The absorption spectra were measured on the instrument described by Philpot and Schuster [1933].

Biological assay. The method of assay consisted in the determination, by means of a dose-response curve, of the dose necessary to cause oestrus in 50 % of a group of ovariectomised mice. It followed closely that employed by Deanesly and Parkes in some work on the suitability of the International Standard, a report of which has been submitted to the Permanent Commission on Biological Standardisation of the League of Nations Health Organisation, but not yet published.

Test animals. 111 immature albino mice about 4 weeks old were ovariectomised. After a period of about one month, control vaginal smears were taken. The mice were divided into four groups, the number in each being shown in Table I. The same group was injected with the same batch of hormone at each test, except in the last test, where four animals from group 1 were removed to group 4. A fortnight before each test all the mice were "primed" with 1γ of hormone contained in 0·5 ml. 10 % alcohol. The smears were stained in methylene blue. A mixture of nucleated and cornified epithelial cells, or cornified cells alone in the absence of leucocytes, was considered as a positive reaction.

Table I.

Number of mice per group for each test.

Group	Solution injected kept at	For standard curve	Number of animals After 3 months	 After 6 months	 After 12 months
1	37°	30	27	27	17
2	−2°	28	28	26	20
3	Room temp.	25	23	23	18
4	Control	28	24	18	18

Biological assay.

Preliminary experiment. An experiment on the freshly made alcoholic solution containing 1 mg. of crystalline hormone in 50 ml. absolute alcohol was made to verify the curve obtained previously by Deanesly and Parkes. Four aqueous solutions were made from the alcoholic solution containing known amounts of hormone as shown in Table II.

Table II.

Solution	Volume of alcoholic solution in 50 ml. H_2O ml.	Crystalline substance in 0·4 ml. of the aqueous solution γ	Percentage positive reactions
A	1·0	0·16	100
B	0·6	0·096	90
C	0·35	0·056	60
D	0·20	0·032	29

0·4 ml. of each of the solutions A–D was injected subcutaneously over 36 hours into the groups 1–4 shown in Table I. The times of injection were as follows: 1st day, 9.30 a.m., 9.30 p.m.; 2nd day, 9.30 a.m., 9.30 p.m.; and smears were taken: 3rd day, 4 p.m., 11.30 p.m.; 4th day, 9.30 a.m., 4 p.m., 11.30 p.m.; 5th day, 9.30 a.m. The percentage number of positive reactions is shown in Table II and plotted in Fig. 1.

The curve conforms in shape very closely to that obtained by Deanesly and Parkes, but it is displaced somewhat to the left so that the weight giving a 50 % response is 0·047γ (see Table III) as compared with 0·061γ for the previous curve.

Stability tests. After 3 months one ampoule from each of the batches kept at different temperatures was opened and from each 0·45 ml. of the alcoholic solution was taken and made up to 50 ml. with distilled water. 0·4 ml., of the aqueous solutions was injected over 36 hours into each mouse, which thus received 0·072γ. As shown in Table I these aqueous solutions made from the alcoholic solutions kept at 37°, −2° and room temperature were injected into groups 1, 2 and 3 respectively.

From Fig. 1 a 70–80 % response was to be expected from a fresh solution and, allowing for a slight loss in activity during the 3 months, approximately a 50 % response was aimed at. From the 100 % positive result obtained it is not possible to calculate the unit in any of the groups. This high response can only be explained by variation in the sensitivity of the mice, a fact which emphasises the need for a control group in the tests.

After 6 and 12 months the test was repeated. In both instances 0·35 ml. of the original alcoholic solution was made up to 50 ml. with water. A similar amount of the aqueous solution (0·4 ml.) was injected into the same groups of mice. The amount of hormone injected into each mouse in both of these tests was reduced to 0·056γ. After 6 months the units for the three batches and the control shown in Table III are uniformly higher than expected. The difference between the units is insignificant. The group receiving the hormone kept at 37° gave the highest response, which further shows that no loss in activity had occurred. On account of this a period of another 6 months was allowed to elapse before making a further test. After 12 months the units for the three solutions are almost identical and show very little difference from the control unit of 0·044γ. No loss in activity has occurred.

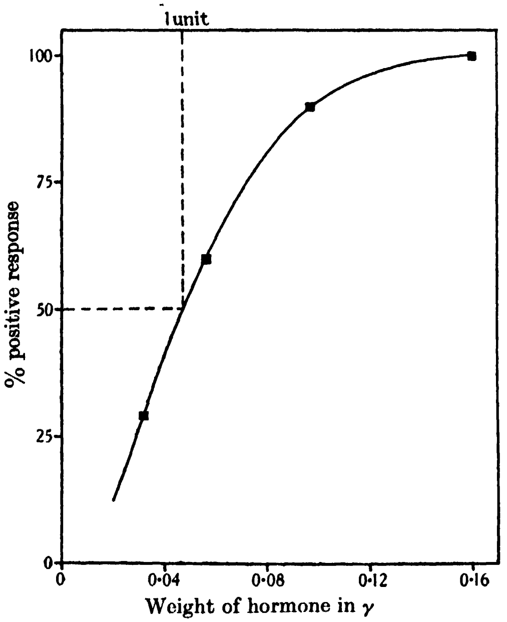

Fig. 1. International Standard of the oestrus-producing hormone; curve showing percentage positive response of vaginal smears to various doses of the hormone. The weight giving 50 % response is 0·047γ (0·47 International Unit) and is considered as one mouse unit.

Table III.

Weight of hormone in γ required to cause 50 % response.

Time from start of exp. at which the solutions were tested	Kept in alcoholic solution at			Control solution
	−2°	Room temp.	37°	
—	—	—	—	0·047
3 months	—	—	—	—
6 months	0·067	0·080	0·066	0·077
12 months	0·047	0·046	0·048	0·044

Simultaneously with each test a similar volume of a freshly made alcoholic solution (1 mg. in 50 ml. of absolute alcohol) of the International Standard was injected into group 4 so that each animal received the same amount of hormone. The results, which are shown in Table III, are expressed in terms of the amount of hormone required to induce a 50 % response (1 M.U.), the amounts being calculated from the curve in Fig. 1.

Spectrographic examination.

Fresh solutions of hormone. The absorption spectrum measured in 0·0125 % alcoholic solution was in fair agreement with that recorded by Dingemanse *et al.* [1931] showing a maximum value of $E^{1\%}_{1\,\text{cm.}}=81$ (as compared with 82·5) at 281·5$m\mu$, but the small subsidiary hump which they record at 291$m\mu$ was, in our measurements, visible only as an inflection in the curve. The curve is plotted in Fig. 2, in terms of

$$\epsilon=\frac{1}{d}\cdot\log_{10}\frac{I_0}{I}-\epsilon_0.$$

Stability measurements. Measurements were taken of the contents of one ampoule from each batch at intervals of 3, 9 and 12 months after the original sealing.

In batches (*a*), (*b*) and (*c*) no change in the absorption outside the range of the experimental error was detected. In batch (*d*) (kept at 37°) as shown in Fig. 2, there was a slight increase of doubtful significance in the absorption at the peak at 281·5$m\mu$, but at the minimum at 250$m\mu$ there was a progressive increase of absorption, amounting in all to a change in the value of ϵ from 0·06 to 0·31. This change is not sufficiently large or characteristic for definite conclusions to be drawn as to its exact cause. It may be due to decomposition of oestrone, but the retention of the shape of the absorption curve as a whole makes it extremely unlikely that, if such decomposition actually occurs, it does so to any considerable extent.

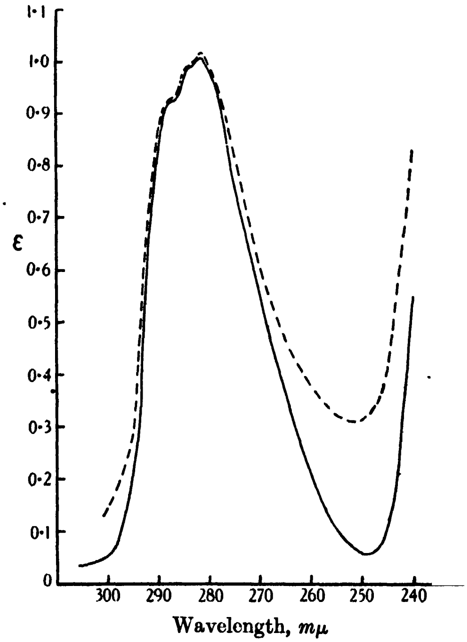

Fig. 2. Absorption spectra of solutions of the International Standard of the oestrus-producing hormone in 0·0125 % alcoholic solution.

——— Fresh solution. - - - - - Solution kept 12 months at 37°.

SUMMARY.

Alcoholic solutions of the International Standard of the oestrus-producing hormone stored in sterile sealed ampoules at −2°, room temperature or 37°, for 12 months show neither decline in activity as measured by the vaginal cornification test, nor any change in ultra-violet absorption, with the exception of a small increase in general absorption when stored at 37°.

XCIX. RESEARCHES ON THE PHOSPHATASES.

II. INACTIVATION AND REACTIVATION OF THE PHOSPHATASES OF ANIMAL ORGANS.

By SERAFINO BELFANTI, ANGELO CONTARDI
and ALBERTO ERCOLI.

From the Istituto Sieroterapico Milanese and R. Istituto Superiore Agrario, Milan.

(*Received February 8th, 1935.*)

Recently Robison and Rosenheim [1934] made the interesting observation that sodium fluoride, even in extremely small quantities, impedes *in vitro* the deposition of calcium in hypertrophic cartilage; however, even in much higher degrees of concentration, it does not alter the extent of hydrolysis brought about by a purified preparation of bone phosphatase on sodium β-glycerophosphate.

In a recent paper Belfanti *et al.* [1935], after having examined the inhibitory action of sodium fluoride on the "acid" phosphatases of extracts of animal tissues, mentioned, in connection with the probable importance of the fluorides in the phenomena of calcification and decalcification of bone, the fact that in certain circumstances sodium fluoride may also inhibit the activity of the "alkaline" phosphatases.

In the present work, we have attempted to find under what conditions that phenomenon may occur.

It seemed moreover that it would be of interest to find out if the inactivation effected by sodium fluoride was permanent in character or was reversible.

Inouye [1929], when experimenting with the glycerophosphatase of *Aspergillus oryzae*, found that on eliminating the fluorine ions by the addition of an excess of calcium chloride, the phosphatase activity was not restored, whereas the inhibitory effects of oxalate ions and sulphate ions could be eliminated by the addition of $CaCl_2$.

Experimental.

As regards the preparation of the enzymic extracts and the method used to estimate the phosphatase activity, we refer the reader to our previous work and when necessary discuss any modifications that have been introduced.

Reactivation of phosphatases inactivated with sodium oxalate.

(1) *Reactivation by the addition of $CaCl_2$.* Experiments made with an extract of rabbit liver agree in the results with those made by Inouye [1929] on the phosphatase of *A. oryzae*: we obtained, in other words, the restoration of the phosphatase activity of the extract. In order to ascertain if the time of contact between the oxalate and the enzyme before treating with calcium chloride had a

sensible influence on the inactivation, a series of five numbered test-tubes each containing 7 ml. of the undermentioned solution was prepared.

Acetate-veronal solution ...	15 ml.
8·5 % solution of NaCl ...	15 „
Distilled water	12 „
Rabbit liver extract	30 „
HCl $N/5$	36 „

$M/5$ sodium oxalate solution (1 ml.) was added to test-tubes 1, 2, 3 and 4. In test-tube No. 1, this addition was made immediately, whereas in test-tube No. 2 it was made after 30 mins., in test-tube No. 3 after 85 mins. and in test-tube No. 4 after 90 mins. 1 ml. of distilled water was added to test-tube No. 5. 1 ml. of $N/2$ $CaCl_2$ solution was then added to test-tubes Nos. 1, 2, 3 and 5 whilst 1 ml. of distilled water was added to test-tube No. 4. Finally, 1 ml. of 5 % (anhydrous salt) solution of sodium glycerophosphate was added to all five test-tubes, together with two drops of toluene. The five test-tubes were then placed at the same time in a thermostat at 37° and 16 hours later the inorganic phosphorus contents were estimated. Table I shows that, even when the sodium oxalate is allowed to act for one hour and a half and at p_H less than 5 on an enzymic solution obtained from rabbit liver, there is no notable alteration in the activity of its acid phosphatase.

Table I. *Influence on the acid phosphatase of rabbit liver of the time of contact between enzymic solution and sodium oxalate before reactivation with $CaCl_2$.*

Test-tube No.	Time of contact before the addition of $CaCl_2$	p_H of the solutions under examination	P hydrolysed mg.
1	90 mins.	4·87	0·0407
2	30 „	4·91	0·0414
3	5 „	4·88	0·0402
4	Control without oxalate	4·92	0·0398
5	Control without $CaCl_2$	5·02	0·0125

(2) *Reactivation by means of dialysis.* 25 ml. of $M/10$ sodium oxalate solution (portion A) were added to 25 ml. of a rabbit liver extract, whilst another 25 ml. of the same extract were diluted with 25 ml. of distilled water (portion B). The two portions were subjected to dialysis through cellophane against distilled water for 24 hours. When the dialysis was terminated, both liquids were brought to a volume of 60 ml. with distilled water. Three 25 ml. flasks were then prepared, each of which contained: solution of sodium glycerophosphate (5 % anhydrous salt), 1 ml.; acetate-veronal solution, 2 ml.; NaCl solution, 2 ml.; N HCl, 1·5 ml. 10 ml. of the enzymic extract (A) were added to flask No. 1, 10 ml. of extract (B) were added to flask No. 2 and 10 ml. of extract (B) *plus* 5 ml. of $M/5$ sodium oxalate were added to flask No. 3. All three flasks were then filled up to the mark with distilled water. Their p_H was about 3·2. After the addition of toluene and digestion in the thermostat for 16 hours, the following results were obtained:

Flask No.		P hydrolysed per ml. mg.
1	Dialysed after the addition of sodium oxalate	0·0289
2	Dialysed without the addition of sodium oxalate	0·0277
3	Control in the presence of $M/25$ oxalate added after dialysis	0·0074

The enzymic solution inhibited with sodium oxalate had reacquired its activity during dialysis.

Reactivation of phosphatases inactivated with sodium fluoride.

(1) *Reactivation by means of addition of $CaCl_2$.* Experiments carried out both with rabbit liver extract and with rabbit kidney extract demonstrate the possibility of reactivating, at least partially, by means of addition of $CaCl_2$, an enzyme which has been previously rendered inactive with NaF. The extent of this reactivation was, however, unlike that which was found in the case of sodium oxalate, in inverse relation to the time during which the fluorine ions had acted on the enzyme of the solution before being precipitated in the form of calcium salts. The experiment was carried out in exactly the same way as those done with sodium oxalate (see Table I). Table II shows the results obtained in two experiments with rabbit liver extract and rabbit kidney extract respectively.

Table II. *Influence on the acid phosphatase of rabbit liver and of rabbit kidney of the time of contact between enzymic solution and sodium fluoride before the addition of $CaCl_2$.*

Test-tube No.	Time of contact before the addition of $CaCl_2$	p_H of the solutions under examination	P hydrolysed mg.	Reacquired activity as % of the original activity
		Rabbit liver extract		
1	90 mins.	4·94	0·0136	15·4
2	30 „	4·86	0·0286	29·1
3	5 „	4·93	0·0296	59·3
4	Control without NaF	4·86	0·0364	—
5	Control without $CaCl_2$	4·89	0·0080	—
		Rabbit kidney extract		
1	90 mins.	4·9	0·0142	37·7
2	30 „	4·9	0·0207	65·8
3	5 „	4·8	0·0226	74·0
4	Control without NaF	4·92	0·0231	—
5	Control without $CaCl_2$	5·07	0·0055	—

As may be seen from Table II, under similar conditions, the activity of the acid phosphatase of kidney extract is reacquired in a greater measure than that of the acid phosphatase of liver extract.

(2) *Reactivation by means of dialysis.* 40 ml. of rabbit liver extract were added to 8 ml. of a solution of NaF, acidified with acetic acid to p_H 4·4. The whole was allowed to stand at room temperature for three hours. Afterwards, the solution was divided into two equal parts: the first was dialysed for three days against distilled water (extract A) whilst the second was kept in the ice-chest (extract B). Simultaneously with A, 20 ml. of liver extract with the addition of 4 ml. of distilled water (extract C) were dialysed. The phosphatase activities of the three extracts as regards sodium glycerophosphate and in the presence of veronal buffer were then estimated in the usual way.

An experiment was also carried out, by the same method, on an extract of hog kidney prepared according to Asakawa [1929].

The following results were obtained:

Extract		Rabbit kidney		Hog kidney	
		p_H of the solution	P hydrolysed per ml. mg.	p_H of the solutions	P hydrolysed per ml. mg.
A	Dialysed after adding NaF	5·4	0·0243	4·77	0·0818
B	Not dialysed after adding NaF	5·2	0·0040	4·60	0·0225
C	Dialysed without adding NaF	5·4	0·0389	4·72	0·0803

These experiments show that dialysis leads to the partial reactivation of the acid phosphatases of extracts of rabbit and hog kidney previously inactivated with sodium fluoride. We wish to point out, however, that the contact between fluoride and enzyme, although protracted over a very long period of time, took place at room temperature instead of at 37° as was the case in the experiments on reactivation with calcium chloride.

Inactivation with sodium fluoride of the "alkaline" phosphatase of the liver and kidney. Lability of bone phosphatase in an acid medium.

In each of four 25 ml. flasks, numbered from 1 to 4, were placed:

	No. 1 ml.	No. 2 ml.	No. 3 ml.	No. 4 ml.
Liver extract	5	5	5	5
Acetate-veronal solution	4·5	4·5	4·5	4·5
N/5 HCl	6	6	—	—
2 % NaF	1	—	1	—
H_2O	—	1	6	7

The four flasks were left in the water-bath at 37° for 2 hours and then to each of them were added:

N/5 NaOH	5·5	5·5	—	—
5 % glycerophosphate	1	1	1	1

and the whole brought up to the mark with distilled water. After determination of the p_H, addition of toluene and digestion in the thermostat for 16 hours, we proceeded to estimate the P hydrolysed. The following is the result of the four tests:

No. 1	p_H 8·65	P hydrolysed per ml. mg. 0·0235
No. 2	p_H 8·80	,, ,, 0·0484
No. 3	p_H 8·62	,, ,, 0·0605
No. 4	p_H 8·90	,, ,, 0·0610

A second experiment, carried out with another extract of liver of the rabbit, much more active than the previous one, gave the following results:

No. 1	p_H 9·27	P hydrolysed per ml. mg. 0·1000
No. 2	p_H 9·32	,, ,, 0·1935
No. 3	p_H 8·70	,, ,, 0·1818

The data given above show that exposure to 37° for two hours at p_H about 4·5 partially inactivates the "alkaline" phosphatase of rabbit liver extract. In presence of sodium fluoride, the resultant inactivation is much higher.

The alkaline phosphatase of the kidney behaves in an analogous manner, as is shown by the results of an experiment made with an extract of hog kidney prepared according to Asakawa's method [1929], in which exposure to 18° in an acid medium at p_H 4·5 was protracted for 17 hours.

No. 1	p_H 8·71	P hydrolysed per ml. mg. 0·0182
No. 2	p_H 8·75	,, ,, 0·1066
No. 3	p_H 8·85	,, ,, 0·2286

Similar experiments were carried out with an extract of bone (metaphysis and epiphysis) from the adult rabbit and the results obtained were as follows:

No. 1	p_H 8·65	P hydrolysed per ml. mg. Traces
No. 2	p_H 8·70	,, ,, Traces
No. 3	p_H 8·95	,, ,, 0·0631
No. 4	p_H 8·90	,, ,, 0·0727

As exposure for two hours to 37° in an acid medium had of itself completely inactivated the alkaline phosphatase, the experiment was repeated for shorter periods of time. In a second test at p_{H} 4·5 the mixture was heated for only 20 mins.:

No. 1	p_{H} 8·66	P hydrolysed per ml. mg.	Traces
No. 2	p_{H} 8·67	,, ,,	Traces
No. 3	p_{H} 9·06	,, ,,	0·0789
No. 4	p_{H} 9·05	,, ,,	0·0789

In a third experiment the mixture was heated for 5 mins. at p_{H} 4·5 and at 37°:

No. 1	p_{H} 8·83	P hydrolysed per ml. mg.	0·0125
No. 2	p_{H} 8·80	,, ,,	0·0130
No. 3	p_{H} 8·84	,, ,,	0·0670
No. 4	p_{H} 8·84	,, ,,	0·0720

These experiments show that the "alkaline" phosphatases may be inactivated by sodium fluoride when the latter acts for a certain period of time in an acid medium. The results also show that the alkaline phosphatase of bone is much more sensitive to the inactivating action of the acid medium than the alkaline phosphatases of the liver and of the kidney.

SUMMARY.

1. The "acid" phosphatases of extracts of liver and of kidney are reversibly inactivated by sodium oxalate and can be reactivated without loss by precipitating the oxalate ions by means of calcium salts or removing them by dialysis.

2. Inactivation of the "acid" phosphatases of the liver and of the kidney by sodium fluoride is of a different nature from that produced by oxalate. In the latter case, there is probably a formation of an inactive enzyme-oxalate complex which can easily be split up, restoring the unaltered enzyme. The formation of the inactive enzyme-fluoride complex on the other hand is accompanied by a profound alteration of the enzyme, which occurs in a relatively long period of time and may lead to the permanent disappearance of the phosphatase activity. Eliminating the fluorine ions from the system more or less rapidly restores the enzymic activity in a greater or less degree. Permanent inactivation of the "acid" phosphatase by sodium fluoride occurs more rapidly at 37° than at room temperature.

3. If the "alkaline" phosphatases of the extracts of kidney and of liver at 37° are kept at p_{H} about 4·5 and then brought back to an alkaline p_{H}, there occurs an inactivation of greater or less degree according to the duration of the treatment in an acid medium.

4. Sodium fluoride also inactivates the "alkaline" phosphatases of extracts of liver and of kidney when it is allowed to act for some time on these extracts brought to p_{H} about 4·5. This is probably due to the fact that the formation of the inactive fluoride-alkaline phosphatase complex occurs only in an acid medium. By this process the inactivation of the alkaline phosphatase occurs in a much more rapid and complete manner than occurs with a simple acid treatment.

5. The "alkaline" phosphatase of bone is extremely sensitive to the acid reaction of the medium and in this is different from the "alkaline" phosphatase of the liver and of the kidney as the latter is much less sensitive. This provides evidence that the "alkaline" phosphatase of the liver and of the kidney is not identical with that of bone, a subject which will be further discussed in our next paper.

C. FAT METABOLISM IN FISHES.

VI. THE FATS OF SOME PLANKTON CRUSTACEA.

By JOHN ARNOLD LOVERN.

From the Torry Research Station, Aberdeen, of the Department of Scientific and Industrial Research.

(*Received February 18th, 1935.*)

In previous papers [Lovern, 1932; 1934, 2] it has been shown that the fats from freshwater fish, taken as a whole, form a class distinct from those of marine species. It was suggested that differences of food might account for this, but at that time no data were available concerning the type of fat ingested in each case. The larger carnivorous fish (including all the marine species examined and all but one of those from fresh water) consume smaller creatures, mainly other fish in most cases, and here presumably the fat is of a type similar to that of the larger fish. The very small fish live largely on copepods and similar small crustacea, which are, indeed, the main link between vegetable and animal life in both salt and fresh water. The planktonic crustacea are almost exclusively vegetable feeders. It is of interest to know whether the same class distinction holds between freshwater and marine zooplankton as obtains for the fishes. If it does the idea of food differences being the cause of the observed distinctions in the case of the larger fish is considerably strengthened. This theory will receive further support if the composition of the zooplankton fats is closely similar to that of the fish fats, suggesting that ingested fat is largely deposited unchanged.

Very little is known regarding the composition of these crustacean fats. Collin *et al.* [1934] examined the fat from *Calanus finmarchicus* and also mixed copepod fat. Their results, whilst not giving details of composition, indicated a resemblance of type between the fatty acids of these fats and those of fish fats. They further found appreciable quantities of wax alcohols present. No freshwater crustacea seem to have been examined.

In this paper the results obtained with the fats from one marine species and three freshwater species are given.

EXPERIMENTAL.

The fats were obtained by desiccating with anhydrous sodium sulphate and extracting with ether. The marine species used was *Calanus finmarchicus*. This is a relatively large organism and easily obtained pure by the use of tow nets of a suitable mesh. It was collected in large quantities in Loch Sunart, Argyllshire, during May 1933, and sufficient fat was available for a full-scale quantitative analysis (200 g.).

As for freshwater organisms, it is often the case that a particular pond or lake is dominated by one organism, and by the use of a suitable net fairly pure samples may be collected. From a small sheet of water near Aberdeen, a considerable quantity of *Cyclops strenuus* was obtained almost pure, the contaminants being mainly other species of *Cyclops*. From Loch Lochy, Inverness-shire, a pure sample of *Daphnia galeata* was obtained and from Loch Ness a somewhat mixed sample, almost all of the genus *Diaptomus* with *D. gracilis* greatly predominating. There will be no serious error in considering this as all *D. gracilis*. From these freshwater organisms only sufficient fat was available in each case for analysis by semi-micro-methods [Lovern, 1934, 1]. All the fats were deep red in colour and all contained a considerable quantity of acid pigment matter. The characteristics of the fats are given in Table I, and the compositions of the mixed fatty acids in Table II, as weight and molar percentages.

Table I. *Characteristics of fats.*

DISCUSSION.

It will be observed that all the fats contain large amounts of unsaponifiable matter. Whilst this was not examined in detail, its appearance strongly suggested the presence of wax alcohols, in agreement with the finding of Collin *et al.* [1934].

It will be seen from Table II that all the fats contain the typical "fish oil" fatty acids (palmitoleic, C_{20} acids *etc.*). Moreover, the class distinction between fats of marine and freshwater origin is markedly in evidence. This difference has been previously defined [Lovern, 1932] as increased proportions of C_{16} and C_{18} unsaturated acids and decreased C_{20} and especially C_{22} acids in the freshwater fats, as contrasted with those from marine sources. *D. gracilis* fat is the least typically freshwater fat, but even here the entire lack of C_{22} acids and the high content of C_{18} unsaturated acids would put this fat into the freshwater class.

A point of interest is the extremely high average unsaturation of the C_{18} and C_{20} unsaturated acids, as well as the presence of polyethylenic C_{16} acids in all cases.

It would seem that the fats of the vegetable-feeding zooplankton, from both salt and fresh water, correspond so closely to those of the marine and freshwater fish respectively that a simple deposition of ingested fat, largely unchanged in composition, would account for the observed characteristics of marine and freshwater fish fats. It may well be that the whole character of fish fats is due to the type of fat occurring in their essential food supply—the plankton crustacea.

It would be of interest to know whether the compositions of the crustacean fats are in turn largely decided by the type of fat in the food; whether, in fact, as suggested previously [Lovern, 1932], it is really the plant life of the medium which is affected by the presence or absence of salt. Experiments in progress point to this being the case and suggest that even in the crustacea the ingested vegetable fat is mainly deposited unchanged.

SUMMARY.

The fats from three freshwater and one marine species of plankton crustacea have been examined. The mixed fatty acids of the freshwater species show the same class distinction when contrasted with the acids of the marine species as is observed with the fatty acids of fish from the respective habitats.

The close correspondence in type of the fats from crustacea and fish suggest that fat ingested by the fish is largely deposited unchanged, and that the class differences observed between the fats from freshwater and marine fish as a whole have a dietary origin.

The author desires to express his thanks to Dr S. G. Gibbons and Miss H. S. Ogilvie, of the Marine Laboratory of the Fishery Board for Scotland, Aberdeen, for kindly examining the various hauls of plankton.

CI. *POST MORTEM* BREAKDOWN OF GLYCOGEN AND ACCUMULATION OF LACTIC ACID IN FISH-MUSCLE AT LOW TEMPERATURES.

By JAMES GARDEN SHARP.

From the Torry Research Station, Aberdeen, of the Department of Scientific and Industrial Research.

(*Received February 26th, 1935.*)

The temperature of maximum rate of change.

In a previous publication [Sharp, 1934] it was shown that the rate of glycogenolysis in fish-muscle after death decreased with temperature down to 0°. Lowering of temperature to −10° resulted first of all in an increased rate of change in the frozen tissue at −2° and secondly in a falling off to a barely perceptible rate at −10°. It must follow therefore that between 0° and −10° there is a temperature at which the maximum rate of breakdown occurs in the frozen muscle.

The first part of the present work shows that the maximum rate of change takes place in the temperature interval −3·2° to −3·7°. The sampling error of the technique previously given in detail is too large to permit of more accurate determination.

Experimental.

The method of experiment was slightly different from that employed previously, for no attempt was made to obtain complete curves over any period of storage. The muscle was stored for an arbitrary period at different temperatures and the loss in glycogen and the gain in lactic acid were estimated over this period. Using ten similar fresh samples from five haddocks, two were retained for immediate analysis and the remainder stored in pairs in air-tight

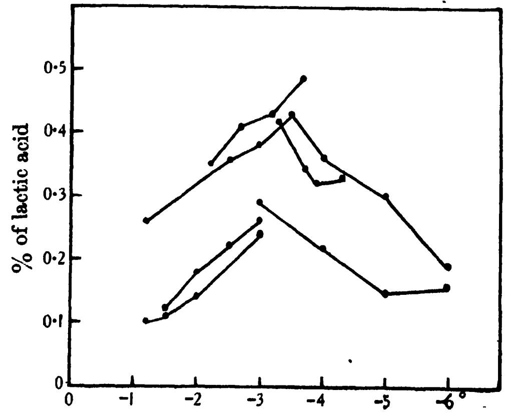

Fig. 1. Amounts of lactic acid accumulation in six lots of mixed muscle samples over arbitrary periods of 9–12 hours' storage at different freezing temperatures.

tinned containers at four temperatures for a definite period (9–12 hours) after which glycogen and lactic acid estimations were carried out by the methods given before in detail. Duplicate samples at each temperature served to reduce the sampling error and in most cases repeat experiments were done on different batches of fish. The results of six experiments are plotted in Fig. 1, and since in all cases the glycogen loss was accounted for by a corresponding increase in lactic acid, the plotted values represent either lactic acid accumulation or glycogen loss over the period of storage.

Conclusion.

In the temperature interval −3·2° to −3·7° the maximum rate of glycogen breakdown with corresponding lactic acid accumulation occurs in the frozen muscle.

In frog-muscle, Smith and Moran [1930; Smith, 1931] have shown that the increased rate of change below −0·9° is not due to oxygen starvation, but can be directly related to the amount of available water withdrawn from the muscle plasma in the form of ice. Freezing of the tissue causes increased salt concentration in the plasma, and, on the assumption that the plasma behaves like an isotonic solution of sodium chloride, it is estimated that at −2·5°, 80–82 % of the available water is withdrawn from the plasma in the form of ice, resulting in a five-fold increase in salt concentration.

In minced frog-muscle suspended in phosphate solutions of different concentrations maximum formation of lactic acid occurs in solutions freezing at −3°. Further, the solubility of rabbit-muscle globulin reaches a maximum in phosphate solutions freezing at −2° and falls rapidly in solutions freezing below −2° [Smith, 1932].

It seems therefore that the maximum rate of change takes place in the frozen muscle when a definite salt concentration is attained in the plasma, coincident with maximum solubility of the muscle globulin. Further increase in salt concentration by lowering of temperature results in decreasing solubility of the protein and decreasing rate of change.

The salt concentration of fish-muscle plasma is such that the freezing-point is approximately 0·6° lower than that of frog-muscle plasma. It follows from this that the plasma salt concentration attained in fish-muscle frozen at −3·2° would approximate to the concentration attained in frog-muscle at about −2·5°. Considered from the standpoint of the maximum rate of change occurring on the attainment of a definite salt concentration in the plasma, the present results agree closely with those obtained in the case of frog-muscle.

The critical temperature of freezing.

In frog-muscle with certain degrees of freezing, irreversible changes take place in the colloidal structure of the tissue. That such changes occur is evident on thawing the frozen muscle when it is observed that the muscle has become non-irritable and has lost the power of synthesising both glycogen and phosphagen [Moran, 1929; Smith, 1929; Kreps, 1931]. According to the intensity of freezing, muscles on thawing either return completely to normal condition or are irretrievably altered. For the gastrocnemius of the frog, these irreversible changes occur on freezing at −1·6° and storing at this temperature for a period of 24 hours. For example, on thawing at 5° muscles which have undergone different degrees of freezing, it is found that in the muscles stored at temperatures above −1·6° for 24 hours the accumulated lactic acid is resynthesised to glycogen until the normal resting level (0·05 %) is attained, whereas in muscles stored at −1·6° and lower temperatures, lactic acid continues to accumulate at a rapid rate until the rigor maximum is reached. In the latter case the synthetic mechanism for the formation of glycogen from lactic acid is irreparably damaged.

Since, in fish-muscle, there is no resting level but a comparatively rapid accumulation of lactic acid at 0° and higher temperatures, both the proof of the existence and the determination of a critical temperature of freezing present greater difficulty than in the case of frog-muscle. Experimental proof depends on comparison of the rates of formation of lactic acid on thawing muscle which has suffered different degrees of freezing. The rate of acid accumulation at temperatures in the region −2° to −4° is however so great that only short periods of storage are permissible, since an appreciable concentration of glycogen is necessary in the muscle, just before thawing, before any true comparison of rates can be made.

Experimental.

That freezing at −20° damages the lactic acid recovery mechanism in fish-muscle is evident by the results plotted in Fig. 2. Of ten similar mixed samples of muscle, five were frozen and stored separately at each of the chosen temperatures, +5°, 0°, −2·5°, −3° and −4°. The remaining samples were rapidly frozen at −20°, immediately raised to their respective storage temperatures and kept thereat, with the duplicate samples, for a period of 10 hours, after which glycogen and lactic acid concentrations were estimated. Thus, at each temperature there were two samples, one of which had been rapidly frozen to

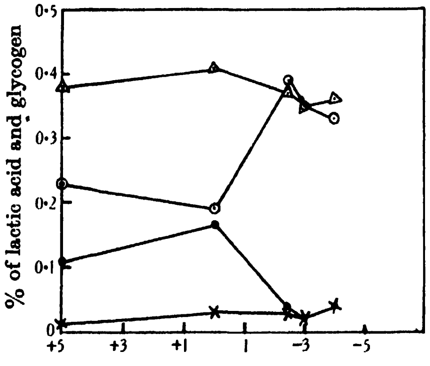

Fig. 2.

Fig. 3. Rates of lactic acid accumulation at 4° in muscle, thawed after a freezing period of 4 hours at −1·6°, −2° and −6°.

●—● −1·6°. ×—× −2°. ⊙—⊙ −6°.

−20° and immediately raised to the temperature of storage, while the other had never been subjected to temperatures below the storage temperature.

The middle curves illustrate the different rates of change in the temperature interval +5° to −4°, showing maximum change between −2·5° and −4°, but, owing to an almost total loss of glycogen in this region over the storage period, the peaks of the curves have become flattened out. The effect of preliminary freezing at −20° is apparent at 0° and +5°, at which temperatures total loss of glycogen and maximum accumulation of lactic acid have occurred in the frozen muscle samples. Since only a fraction of this difference can be accounted for by the rapid double passage through the interval where maximum rate of change occurs, it appears that in freezing at −20° the synthetic mechanism in the lactic acid-glycogen cycle has been destroyed, resulting in an increased rate of lactic acid accumulation in the thawed muscle.

It remained to be determined what degree of freezing was necessary to damage this synthetic mechanism in the muscle, and a comparison was made of the rates of lactic acid formation in thawed muscle which had undergone different degrees of freezing.

Similar lots of samples were frozen at −1·6°, −2° and −6°, and after a period of 4 hours at the freezing temperature were thawed in circulating brine at 4°. Samples were removed at intervals for lactic acid estimation. The rates of lactic acid accumulation in the thawed muscle are shown in Fig. 3, the moment at the freezing temperature just before thawing being taken as zero time. On thawing muscle which has been frozen at −1·6° the normal rate of change at 4° is resumed, whereas on thawing muscle which has been frozen at either −2° or −6° a very rapid rate of change takes place, until the lactic acid maximum is attained. Between −1·6° and −2° therefore a critical temperature of freezing similar to that obtained in the case of frog-muscle must exist, for, in freezing below this temperature the muscle is irretrievably altered, in so far as the recovery mechanism for the removal of accumulated lactic acid is broken down.

SUMMARY.

1. In fish-muscle in the frozen state the maximum rate of glycogenolysis occurs in the interval −3·2° to −3·7°.

2. Freezing at −2° and lower temperatures for a period of 4 hours causes injury to the muscle, resulting in very rapid lactic acid formation on thawing. Freezing at −1·6° has no such effect, and on thawing the normal rate of lactic acid formation is resumed. Between −1·6° and −2° a "critical" temperature of freezing exists.

CII. GLYCOGENOLYSIS IN FISH-LIVER AT LOW TEMPERATURES.

By JAMES GARDEN SHARP.

From the Torry Research Station, Aberdeen, of the Department of Scientific and Industrial Research.

(*Received February 26th, 1935.*)

Since the time of Claude Bernard it has been known that the end-products of glycogenolysis in muscle and liver are different, but whilst considerable information is now available about this process in muscle, comparatively little is known regarding the detailed mechanism of glycogenolysis in liver. Results obtained from study of the breakdown of glycogen and accumulation of lactic acid in fish-muscle at low temperatures [Sharp, 1934 and preceding paper] made it of additional interest to enquire into the *post mortem* glycogenolytic changes taking place in fish-liver under similar conditions of freezing and storage.

As in the previous work, haddocks which had been lightly hooked on lines set off-shore were put into tanks of circulating sea water and kept there until, after 7–10 days' captivity, they returned to a normal resting condition. When required for experiment the fish were netted quickly, killed by a blow on the back of the head and the livers excised immediately. In order to exclude initial changes due to the struggling of the fish during catching, only fish which had undergone a minimum of struggling were used for experiment. Preliminary work was concerned with the distribution of carbohydrate throughout the tissue, immediately *post mortem*, and with the development of a reliable technique for estimation of the free sugar fraction.

Experimental.

Methods.

Glycogen concentrations were determined by Pflüger's method, the reducing values of the final hydrolysates being estimated by the Shaffer-Hartmann reagent. In the tables all glycogen concentrations are given in glucose equivalents.

For estimation of lactic acid the tissue was extracted with ice-cold 5 % trichloroacetic acid and the interfering substances were removed from the filtrate by copper-lime precipitation, according to Holmes and Gerard [1929]. The final analyses were carried out by the method of Friedemann *et al.* [1927].

Free sugar was extracted with ice-cold alcohol and the fraction freed from protein by the technique to be described later under method A.

Distribution of carbohydrate in liver tissue.

Each liver after excision was pressed gently between filter-papers to remove adherent blood and then sliced into 2, 4 or 6 samples. The samples were immediately introduced into tared receptacles containing the necessary extractants. The results, given in Table I, show only slight differences in the distributions of glycogen, free sugar and lactic acid throughout the tissue.

Table I. *Distribution of glycogen, free sugar and lactic acid in fish-liver tissue.*

Fish	Sample	Glycogen %	Fish	Sample	Glycogen %
A	1	1·02	C	1	3·68
	2	1·27		2	3·50
	3	1·04		3	3·66
	4	1·03		4	3·72
B	1	2·54	D	1	2·85
	2	2·33		2	2·85
	3	2·42			
	4	2·39			
		Free sugar %			Lactic acid %
E	1	0·024	E	4	0·030
	2	0·024		5	0·031
	3	0·023		6	0·025

Obvious differences in the concentration of glycogen between separate livers are to be noted however, and in Table II are given the glycogen and lactic acid concentrations in the livers of seven individual haddocks. The lactic acid values do not show large individual variations and lie within the range 0·015–0·031 %. On the other hand, as previously noted, large individual variations are evident in the glycogen concentrations, the values ranging from 0·12 to 3·72 % in Tables I and II.

Table II. *Glycogen and lactic acid concentrations in seven individual fish using the whole liver for estimation.*

Fish ...	1	2	3	4	5	6	7
Glycogen (%)	0·94	0·23	1·24	0·12	0·12	0·57	1·70
Lactic acid (%)	0·031	0·02	0·02	0·015	0·015	0·02	0·02

These estimations were done in the month of May, with fish caught after the spawning season and not in very healthy condition. Although the data are too few for statistical treatment, it appears that at this season of the year very low glycogen values are to be associated with "spent" fish and the higher values with immature, "unspent" fish.

Free sugar estimation.

Before following the changes in glycogen, free sugar and lactic acid concentrations taking place during storage periods at different temperatures, test experiments were made on methods of extraction and purification of the sugar fraction. Since the concentration of sugar in the liver immediately after excision is rather low for test purposes, a higher range of values was obtained by allowing glycogenolysis to proceed for different periods before analysis of the tissue.

Results are given in Table III, the details of the several experimental methods being as follows:

A. The minced sample was stirred up in 10 volumes of alcohol of 90 % effective concentration and left to extract overnight at room temperature. The extract, after being made to known volume next morning, was filtered and an aliquot sample freed from alcohol by evaporation in a current of hot air. The residue was taken up in water and one-fifth volume of "colloidal iron" and one-tenth volume of saturated sodium sulphate were added to precipitate protein. The reducing power of the final solution was estimated by the Shaffer-Hartmann reagent.

B. The tissue was extracted three times with successive 10 volumes of 90 % alcohol, after which the collected filtrates and washings were made to known volume and an aliquot sample treated as in A.

C. To the final solutions obtained by either A or B method, the copper-lime technique of Holmes and Gerard [1929] was applied as a further precaution against the presence of non-carbohydrate reducing substances.

D. After evaporation of the alcoholic extract and solution of the residue in water an aliquot sample was hydrolysed in 2·2 % hydrochloric acid for 3 hours at 100° and after neutralisation was treated with "colloidal iron" and saturated sodium sulphate as in A.

Table III. *Estimation of free sugar in minced liver tissue by different methods.*

Liver sample	% free sugar by method A	B	C	D
1	0·24	0·25	0·27	0·27
2	0·45	0·43	0·46	0·49
3	0·45	—	—	0·47
4	0·56	0·56	—	—
5	0·60	0·59	0·59	0·67

The results demonstrated that there were no appreciable differences in the sugar values obtained by methods A, B and C, and the negligible increases in reducing values, obtained after acid hydrolysis, proved that no polysaccharides were being extracted.

In the work now to be described, as in the distribution experiments, method A (above) was adopted and the reduction values, so obtained, were further checked by Somogyi's [1928] yeast fermentation technique.

Post mortem *glycogenolysis at 0°.*

The livers excised from 9–12 haddocks immediately after netting and stunning were minced and thoroughly mixed together into a uniform paste in a cold room at 0°. Samples were stored separately in air-tight tins in a brine bath thermostatically controlled to remain at 0° ± 0·03°, and single samples removed at intervals for estimation of glycogen, free sugar and lactic acid. The results of one representative experiment are plotted in Fig. 1.

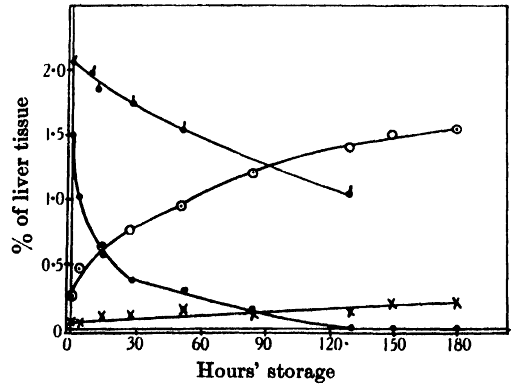

Fig. 1. Changes occurring in glycogen, free sugar and lactic acid concentrations during storage of minced liver tissue at 0°. Glycogen •—•; free sugar ⊙—⊙; lactic acid x — x; glycogen at −3° ♠—♠.

The rate of sugar accumulation was lower in all cases than the rate of glycogen breakdown, but whereas the rate of glycogen loss steadily diminished with depletion of the stores, free sugar continued to accumulate steadily until a balance was obtained between glycogen loss and gain in sugar and lactic acid.

The lactic acid concentration, although increasing steadily, remained at a comparatively low level throughout. In this particular experiment a total glycogen loss of 1·5 % of the liver was balanced by a sugar gain of 1·31 % *plus* a lactic acid gain of 0·13 %.

A comparison was made of the rates of change in oxygen and nitrogen. The samples were stored in gas-filled desiccators in a cold chamber at 0°. The results obtained (Table IV) proved that the reactions were anaerobic, similar rates of change occurring in the two gases.

Table IV. *Comparison of changes occurring in minced liver tissue during storage in oxygen and in nitrogen.*

	Stored in oxygen			Stored in nitrogen		
Hours' storage at 0°	Glycogen %	Lactic acid %	Fermentable free sugar %	Glycogen %	Lactic acid %	Fermentable free sugar %
20 mins. *post mortem*	4·50	0·03	0·04	4·50	0·03	0·04
7	4·05	0·03	0·15	4·20	0·04	0·15
12	3·76	0·03	0·18	3·85	0·04	0·19
24	—	0·03	0·30	—	0·04	0·30
55	3·18	0·07	0·54	3·20	0·07	0·54
99	2·34	0·07	0·62	2·34	0·09	0·58
169	1·33	0·20	1·14	—	0·20	1·06
247	0·95	0·13	1·30	0·90	0·18	1·20
409	0·14	0·14	1·43	0·16	0·16	1·37

With the very high initial concentration of glycogen experienced in this case, the lag in sugar accumulation was very pronounced, since after 409 hours' storage there was still a glycogen loss of approximately 3·0 % of the liver which could not be accounted for in accumulation of either free sugar or lactic acid.

From these results it appears that during glycogenolysis there is rapid accumulation of some intermediary substance which in its turn breaks down at a comparatively slow rate to form free sugar.

In a further experiment the changes in the total carbohydrate fraction were followed in addition to the changes in glycogen and free sugar. West, Scharles and Peterson's [1929] method for total carbohydrate estimation was employed. The liver tissue after hydrolysis in *N* H_2SO_4 was treated with mercuric sulphate to precipitate protein, the reducing power of the filtrate estimated by Shaffer-Hartmann reagent and the values so obtained checked by yeast fermentation. The method was tested by addition of pure glucose to several hydrolysates and in all cases 99–100 % recovery was obtained.

The changes occurring in the various fractions at 0° are given in Table V.

Table V. *Changes occurring in glycogen, free sugar and total carbohydrate concentrations during storage of minced fish-liver tissue at 0°.*

Hours' storage at 0°	Glycogen (G) %	Free sugar (S) %	Total carbohydrate (T) %	Sum $G+S$	Δ $T-(G+S)$
20 mins. *post mortem*	2·66	0·06	2·86	2·72	0·14
50	1·38	0·50	2·83	1·88	0·95
98	0·42	0·64	2·75	1·06	1·69
175	0·08	1·05	2·88	1·13	1·75
314	Trace	1·31	2·60	1·31	1·29
508	Nil	2·03	2·50	2·03	0·47

If the difference between total carbohydrate and the sum of the glycogen and sugar values be taken as a measure of the unknown intermediary fraction it is seen that this fraction was present initially only to the extent of 0·14 % of the tissue. It accumulated at a rate intermediate between the rates of breakdown of glycogen and accumulation of free sugar to reach a maximum when only 0·08 % glycogen remained in the tissue and thereafter it decreased steadily with the continued accumulation of free sugar after the glycogen store had become exhausted.

In mammalian liver similar evidence for the accumulation of an intermediary substance was brought forward by Simpson and Macleod [1927], and more recent work by Barrenscheen *et al.* [1930] indicated that *post mortem* glycogenolysis during the first 4 hours proceeded in a step-like fashion, periods of rapid change in sugar, inorganic phosphate and hexosemonophosphate concentrations being followed by periods of slower rates of change. The periods of increased hexose ester accumulation however were coincident with the periods of decreased formation of sugar and inorganic phosphate, which suggested that alternate synthesis and degradation of hexose ester occurred.

Although the plotted values obtained in the present work provide smooth curves, the possibility of a step-by-step process of glycogenolysis occurring in fish-liver is not precluded. The chosen periods of sampling were of such duration that a possible step-by-step formation might well be completely masked. The position of hexosemonophosphate in the glycogenolytic processes of fish-liver and the identification of the intermediate fraction are points which await further study.

The effect of freezing on the rate of glycogenolysis.

It is known that certain degrees of freezing bring about increased rates of glycogenolysis in fish-muscle. With more intense freezing decreased rates of change occur until at −10° very small changes are evident over long periods [Sharp, 1934].

In the liver the same conditions do not exist and lowering of temperature to below the freezing-point results in a continually decreasing rate of change in the frozen tissue. The curve of glycogen breakdown at −3°, introduced for comparison in Fig. 1, shows that the rate of change at 0° is almost three times as great as at −3°. Similar decreases are observed in the rates of accumulation of sugar and lactic acid.

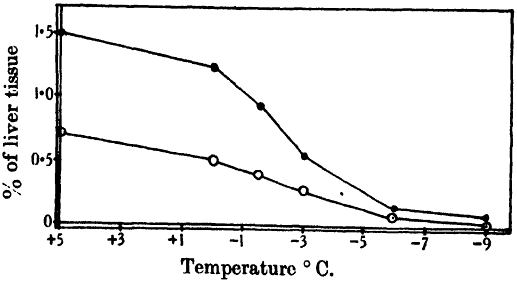

Fig. 2. Relative amounts of glycogen loss and sugar accumulation in minced liver tissue over a period of 53 hours at different temperatures. Glycogen values •; free sugar values ⊙.

In Fig. 2 are plotted the amounts of glycogen breakdown and sugar accumulation over a period of 53 hours at temperatures in the interval +5° to −9°. It is seen that the rates of glycogen breakdown and sugar accumulation decrease markedly through freezing the tissue to $-1{\cdot}5^\circ$, and continue to decrease with further lowering of temperature, until at temperatures below -6° extremely slow rates of change are observed.

SUMMARY.

1. During *post mortem* glycogenolysis in fish-liver at 0°, the following changes have been found to occur:

(*a*) An initial period of rapid loss of glycogen is followed by a period of decreased rate of loss, until the glycogen store becomes exhausted.

(*b*) No equally rapid formation of free sugar takes place. The concentration of sugar increases steadily at a lower rate and continues to increase despite total loss of glycogen. If sufficient time be allowed, a balance is eventually obtained between the glycogen loss and the gain in sugar *plus* lactic acid.

(*c*) The lactic acid concentration, although increasing steadily, remains at a comparatively low level throughout.

(*d*) No alteration in the total carbohydrate content is apparent until only a small concentration of glycogen remains in the tissue, after which point a steady decrease is observed.

These changes are independent of the presence of oxygen and indicate the rapid formation of an intermediary substance, which in its turn breaks down at a lower rate to form free sugar.

2. Investigation of the effect of freezing has shown that the conditions prevailing in liver tissue are different from those in muscle tissue, in so far as no increased rate of glycogenolysis occurs in the liver at freezing temperatures. On freezing at $-1{\cdot}5^\circ$ there is a marked decrease in glycogenolysis and further lowering of temperature causes a continually decreasing rate of change. At temperatures below -6° in the frozen tissue very small changes are evident over a period of 53 hours.

The author is indebted to the late Prof. J. J. R. Macleod for his interest and advice throughout the work.

CIII. THE ACTION OF CRYSTALLINE VITAMIN B_1 ON THE TISSUE OXIDATION OF CHRONIC AVITAMINOUS PIGEON'S BRAIN.

BY HÅKAN RYDIN.

From the Department of Biochemistry, Oxford.

(*Received February 26th, 1935.*)

GAVRILESCU AND PETERS [1931, 1, 2] showed by Barcroft's method that the oxidation *in vitro* is reduced in avitaminous pigeon's brain tissue, suspended in glucose-phosphate solution as compared with normal controls. This particularly referred to the lower parts of the brain and not to cerebellum. The reduced oxygen uptake could be restored in part by the addition of a vitamin B_1 concentrate *in vitro*. On exchanging glucose for lactate [Gavrilescu *et al.*, 1932] these effects became more marked. No significant defect in the oxygen uptake and no vitamin effect were observed in brains from normal pigeons or from avitaminous ones in absence of substrate, or in the cases where this consisted of succinate. Passmore *et al.* [1933] showed a parallelism between crystalline vitamin B_1 and the concentrate previously used. The changes in oxygen uptake so produced by vitamin B_1 do not run parallel with oxidase estimations by reduction methods. By Thunberg's methylene blue technique, Rydin [1935] was not able to show any effect of crystalline vitamin B_1 on normal or on avitaminous tissues from brain, kidneys, liver and muscle, either in presence of the substrate (lactate or succinate) or in absence of these. In order to find out whether the results obtained by the Barcroft method are specific for the avitaminosis-B_1, or whether tissue from starved animals gives the same reactions, Gavrilescu and Peters [1931, 1] carried out tissue oxidation tests in glucose-phosphate solution on brains from pigeons which had been cured of the opisthotonus symptoms with vitamin concentrate. Even before an increase of the body weight began to set in, higher values of the oxygen uptake were obtained than in the case of avitaminous birds in head retraction. Later it was shown by Meiklejohn *et al.* [1932] with addition of vitamin B_1 and further control of water intake that lactate as substrate gave the same results. The increase of the tissue oxidation in cured pigeons was parallel with the disappearance of the nervous symptoms and independent of the nutritional condition. Peters and his co-workers conclude from their investigations that the reactions obtained on avitaminous pigeon's brain are specific to avitaminosis-B_1 and independent of the nutritional condition. Further support of this view was furnished by Sinclair [1933] who showed that vitamin B_1 increases the respiratory quotient *in vitro* on avitaminous pigeons in head retraction, but does not alter the R.Q. in tests on pigeons which are fed on polished rice and show a marked loss of weight but no polyneuritic symptoms. The same conclusions were arrived at by Abderhalden and Vlassopoulos [1931] by tissue oxidation experiments with Barcroft's method on brain, liver and kidneys though their experiments are really in disagreement with those previously quoted [Gavrilescu *et al.*, 1932]. Without addition of substrate they found lower oxygen uptake for tissues from avitaminous pigeons than from starved or normal birds. The differences for brain were not large, a decrease of −12 % for starving and −23 % for avitaminous birds as compared with the normal. [See also Galvao and Florence, 1934, and comments by Rydin.]

It has generally been concluded from the work quoted above and that of Kinnersley and Peters [1930] that there is a relation between the symptoms of head retraction and deficiency in the brain, especially the lower parts, of vitamin B_1. So far however only polyneuritic birds in head retraction have been used. It should be of interest to study the tissue oxidation in polyneuritic pigeons not showing head retraction but with other nervous symptoms such as leg weakness. These symptoms are present in pigeons which show a chronic avitaminous condition, generally when they have been fed on polished rice for a period of more than 30 days. I have therefore studied the action of crystalline vitamin B_1 on the tissue oxidation of brains from these birds, partly on the whole of the brain, partly on cerebrum and the optic lobes + "the rest" separately. The result was a significant vitamin B_1 effect in experiments with the whole of the brain and with cerebrum alone. The vitamin effect on the optic lobes + "the rest," on the other hand, was generally only slight. Also the vitamin effect during the first periods of reading up to ¾ hour was only little apparent but later on became more marked. The bearing of this work upon that of Meiklejohn, Passmore and Peters will be considered after describing the experiments.

EXPERIMENTAL.

The present investigations were carried out on brain tissue with Barcroft's method under the same general test conditions as apply to other experiments in this field made in this laboratory. These conditions have been changed somewhat during the progress of the work. It is now known that the presence of Na pyrophosphate [Peters and Sinclair, 1933] and "warm" mincing [Peters *et al.*, 1935] much improve the vitamin effect and that this is always more marked in the respiration period 1–2 hours. In order to obtain some basis for comparison of this work with that of Meiklejohn *et al.*, I have not used pyrophosphate and have adopted cool conditions for mincing, because their experiments were done in colder weather. For similar reasons the cerebellum has been excluded. The pigeons were fed on polished rice and were picked out for experiments after having been on this diet for at least 30 days, showing marked leg weakness but no trace of head retraction. The birds were killed by decapitation. The brain was quickly taken out, placed on an iced plate and finely minced with a blunt bone spatula, whereupon it was transferred to the bottles. The apparatus used for the determination of the oxygen uptake was of the Barcroft-Dixon type. Into each bottle were measured 3 ml. of a solution consisting of Ringer-phosphate (p_H 7·3) together with neutralised Na lactate. The latter was added in such quantity as to make the final concentration of the Ringer-phosphate solution 0·033*M*. The bottles were weighed before and after the addition of approximately 100 mg. of tissue. The roll of filter-paper was put in place and wetted with 2*N* KOH, and finally 2γ vitamin B_1 hydrochloride were added to every second bottle. (As regards the composition and preparation of the Ringer-phosphate solution as well as the preparation and administration of the vitamin solution see Passmore *et al.* [1933]). The bottles were then evacuated twice to 70 mm. Hg with subsequent refilling with oxygen. The apparatus was then transferred to the thermostat (temp. 38°) for determination of the tissue oxidation in the usual way. In the tables all the values are the mean of two determinations. The difference between these in no case exceeded 10 %. The oxygen consumption is expressed in µl. per g. tissue per hour. The first reading was made after 12 minutes, the second after 10 minutes and the subsequent readings at intervals of half an hour.

RESULTS.

Table I shows the action of vitamin B_1 on the tissue oxidation in experiments with the whole of the brain. In these experiments 8 pigeons were used. In all the readings the value of the figures was numerically higher for the oxygen uptake in presence of vitamin B_1, but in some cases the effect of the vitamin was doubtful or not at all observable during the first two periods of reading (¾ hour). The average increase of oxygen uptake due to vitamin B_1 for all the birds amounted to 17 % for the first period and to 16 % for the second period. During the third and the fourth periods the corresponding figures were 28 and 30 %. The vitamin effect set in as usual, the oxygen uptake owing to the vitamin did not decrease in proportion to the normal control but kept on a higher level during several periods. In many cases the tissue oxidation in presence of vitamin B_1 was decidedly higher than in the controls even during the first period. If the tissue oxidation in presence of vitamin is compared with that without vitamin during all the test periods, an average increase is obtained which amounts to 21 % for the addition of vitamin B_1 *in vitro* over the 1¾ hour period.

Table II illustrates the effect of vitamin B_1 on the oxygen uptake in different parts of the brain, and shows a comparison between the effect on cerebrum on the one hand, and on the optic lobes + the rest on the other. Fifteen pigeons were used in these experiments. For the cerebrum, the vitamin effect was approximately the same as that obtained for experiments on the whole brain.

The average vitamin action on the tissue oxidation during the first period was small but later on showed a great increase amounting to 35·5 % during the fourth period. The average vitamin effect for all the periods was 18 %. It varied however very considerably for the different pigeons. For the optic lobes + "the rest," the vitamin effect was considerably less. The highest average vitamin effect amounted to 11·7 % for period 3. The tests showed great individual variations. Thus pigeons 10 and 13 showed a large vitamin effect even on these parts of the brain. The increase of the tissue oxidation in presence of vitamin B_1 was statistically significant for the last two periods, both for the cerebrum and the lower parts.

	%	14·9	21·8	34·3	8·3	11·7	11·5			

At first sight it may seem that Exps. 10, 13 and 17 contradict the hypothesis previously advanced in this laboratory that head retraction is associated with biochemical changes in the optic lobe + "the rest." If it were certain that these birds were showing no head retraction, then the hypothesis would have to be modified. However, in the case of the results for the optic lobe + "the rest" upon the pigeons with chronic leg weakness, 11–17 birds showed no larger vitamin effects during the first hour period than those which have been found for normals [Gavrilescu *et al.*, 1932]; differences between L and L + V are almost within the experimental error. It seems possible therefore that the exceptions were actually latent cases of head retraction. With weak birds, it is admittedly difficult to decide whether muscular weakness is not masking any opisthotonus. The preponderance of evidence in Table II is that the leg weakness is accompanied by negligible deficiency in vitamin B_1 in the optic lobes + "the rest," but by some demonstrable deficiency in the cerebrum. In my experiments during 1 hour period this may be reckoned as 17 %, whereas in the experiments of Meiklejohn *et al.* for cerebrum of pigeons with head retraction, which seem to be the most nearly comparable, it was 28 %. The cerebral deficiency seems therefore to be less for the chronic birds.

Discussion.

Previous work on the oxygen uptake of avitaminous pigeon's brain carried out for the purpose of clearing up the correlation between avitaminosis-B_1 and inanition, shows that these phenomena are independent of each other. The reduced tissue oxidation and the vitamin B_1 effect on avitaminous pigeon's brains seem to be directly correlated with the head retraction and independent of the nutritional condition. In my experiments on brains from avitaminous pigeons showing leg weakness but no head retraction, a clear vitamin effect was present in tests on the whole of the brain and on the cerebrum, but generally only a slight effect was observed on the lower parts (the optic lobes + "the rest"). The experiments consequently show that vitamin B_1 can increase the tissue oxidation *in vitro* even in brains from avitaminous pigeons, from which head retraction is absent but which have nervous symptoms in the form of leg weakness. So far as comparison can be made with tests in the laboratory carried out upon a different batch of pigeons at a different time, the vitamin B_1 deficiency is rather less for the cerebrum in "leg weakness" than in the "opisthotonus" cases examined. The "leg weakness" is not correlated with deficiency of vitamin B_1 in the optic lobes + lower parts, but there arises from my work the possible new point that the chronic symptoms may be partly central in origin. There is a high correlation between lowered vitamin B_1 in the cerebrum and these symptoms.

Summary.

1. The action of crystalline vitamin B_1 on the tissue oxidation of brains from chronic avitaminous pigeons showing leg weakness but no head retraction was studied by Barcroft's method in the presence of lactate and Ringer-phosphate solution.

2. Vitamin B_1 evidently increased the tissue oxidation in experiments on the whole of the brain and on cerebrum alone but generally only brought about a slight increase with the lower parts of the brain (the optic lobes + "the rest").

3. When compared with the results previously obtained in this laboratory from pigeons with head retraction, the vitamin effect was less marked. This particularly refers to the lower parts of the brain where the pigeons in head retraction showed a pronounced increase of the oxygen uptake with addition of vitamin *in vitro*.

I am very deeply indebted to Prof. Peters for his great interest and advice during the course of this work.

CIV. THE POTENTIOMETRIC TITRATION OF SOLUTIONS OF VITAMIN B_1.

By RICHARD CAYLEY GIFFARD MOGGRIDGE
AND ALEXANDER GEORGE OGSTON.

From the Department of Biochemistry, Oxford.

(*Received February 28th, 1935.*)

THIS work forms part of a programme designed to throw light upon the constitution of vitamin B_1 prepared in this laboratory [Kinnersley *et al.*, 1935]; an unavoidable delay in starting gave us the advantage of having in our hands the results of a titration of Jansen's vitamin, privately communicated by Birch and Harris [Birch, 1934], when they wrote for a specimen of our vitamin to compare its behaviour with their previous results. We understand that they have this work in hand.

They obtained preliminary evidence of a dissociation constant at p_K 5·1 and another in the neighbourhood of p_K 9; that part of the titration curve representing the p_K 9 group was characterised by the fact that, on addition of acid or alkali, equilibrium was not immediately attained; a large change of p_H was produced immediately after each addition, but the p_H drifted back to more alkaline or acid values respectively. In the course of a complete titration from p_H 3 to 11 and back, about 20 % of the p_K 9 group was destroyed, the amount of the p_K 5·1 group remaining unchanged.

The properties of the p_K 9 group suggest at once those of a pseudo-acid converted to the acid form, or of a base converted to the pseudo-base form, as p_H is increased. It was desired if possible to determine the nature of this group. If this hypothesis is correct, the equilibrium may be represented, for the case of a pseudo-acid as

$$\mathrm{PA} \overset{K_1}{\rightleftarrows} \mathrm{HA} \overset{K_2}{\rightleftarrows} \mathrm{H^+} + \mathrm{A^-} \qquad \text{......(A).}$$

The overall dissociation constant K is given by

$$K = \frac{K_1 K_2}{1 + K_1} \qquad \text{......(B).}$$

It is apparent that any method for determining the nature of the dissociating group which relies on measuring the difference of K in two media, is not directly applicable here, since the effect of change of medium on K_1 is not measurable or predictable, so that the change of K_2 cannot be determined. It has however been found possible to determine K_2 independently of K_1 in water and 90 % alcohol.

EXPERIMENTAL.

The technique of these determinations is to be described elsewhere. The titration cells were constructed to hold a solution of 0·25 mg. in 2 ml. of solvent; the liquid junctions were made in sintered plugs of finely ground glass and were found to be reproducible to within 2 mv. Titrant solutions of strength $N/10$ were added from capillary micro-burettes. The p_H scales were standardised as described by Ogston and Brown [1935]; the glass membranes used with a Macfarlane-Pye valve potentiometer were standardised with buffer solutions checked against the hydrogen electrode. Stirring of the solutions used with the glass electrode was effected by bubbling nitrogen slowly through them. Blank experiments showed that the temperature of the room remained sufficiently constant for the accuracy required (18 ± 0·5°), and that any absorption of carbon dioxide from the air, even by alkaline solutions, was negligible.

The dissociation constants were calculated from the experimental values by the method described by Ogston and Brown [1935].

RESULTS.

Experiments were conducted both at 18° and at 0° using hydrogen and glass electrodes in aqueous solutions and glass electrodes in 90 % ethyl alcoholic solutions. The form of curve obtained by Birch and Harris was confirmed, with certain minor differences. The results of various experiments may be summarised as follows.

I. Using the hydrogen electrode, neutral solutions of the vitamin dihydrochloride in water at 18° were titrated with acid to p_H 3, then with alkali up to p_H 10 and again back to p_H 3 with acid.

(1) Between p_H 3 and 7 the curve can be described by two constants of p_K 2·5 and 4·7; on the other hand the initial curve obtained on first titrating to p_H 3 was never reproduced in subsequent titration of the same solution (Fig. 1).

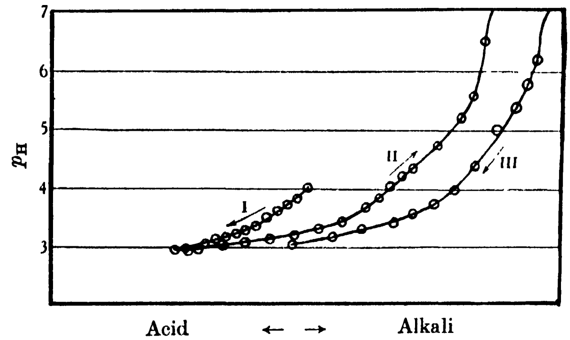

Fig. 1. Titration with hydrogen electrode at 18° (uncorrected). Curve I. Initial titration with acid. Curve II. Acid part of titration with alkali. Curve III. Return curve from p_H 10, with acid, showing shift to alkaline side.

(2) Between p_H 7 and p_H 10 the drifting of p_H after additions of titrant was confirmed; the time taken from each addition of titrant till equilibrium was established was about ¾ hour. Four such "equilibrium" curves gave values of p_K between 8·2 and 8·5, the mean being 8·3.

(3) Displacement of the curve as a whole to the alkaline side was observed on titrating back with acid, without change of its form, *i.e.* without alteration of the amount or dissociation constant of any of the groups titrated (Fig. 1). No disappearance of the p_K 8·3 group occurred.

II. Similar "equilibrium" titrations were carried out using glass electrodes in aqueous and in 90 % alcoholic solutions at 18°. The constants obtained in water were p_K 3·4, 4·8 and 9·1; in 90 % alcohol p_K 4·2 and 9·3 (values for the group having p_K 3·4 in water were not obtained since titration was not carried to a low enough p_H). The general behaviour was the same as with the hydrogen electrode with the following differences.

(1) The initial curve obtained by titrating with acid to p_H 3 (*cf.* I (1) above) was exactly reproduced on titrating back with alkali.

(2) The constants of two of the groups were different.

(3) The displacement of the curves as a whole (I (3) above) was not observed.

In 90 % alcoholic solutions the behaviour is similar to that in water except that in alkaline solution 2–3 hours are required for establishment of equilibrium after each addition of titrant.

III. Assuming the molecule of the vitamin to be $C_{12}H_{16}ON_4S.2HCl$, the amounts of the two basic groups were within 5 % of 1 equivalent per mol. The amount of the p_K 9 group was, using the hydrogen electrode, sometimes 1, sometimes 2 equivalents per mol.; using the glass electrode, always 2 equivalents per mol.

IV. Assuming the pseudo-acid or pseudo-base hypothesis to be correct, the slowness with which equilibrium is established should make it possible to titrate the vitamin in each form separately by performing rapid titrations. This was done using the glass and hydrogen electrodes; in order further to retard the attainment of equilibrium, the cell was immersed in melting ice (see Fig. 2 which illustrates the form of the curves obtained).

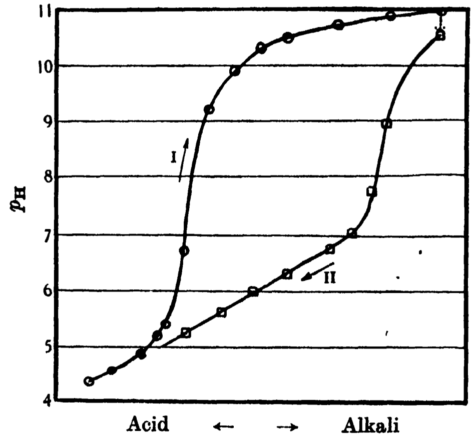

Fig. 2. Rapid titrations with the hydrogen electrode at 0° (uncorrected). Curve I. Rapid titration with alkali (identical with solvent blank). Curve II. Rapid titration with acid after establishment of equilibrium.

(1) Solutions of the vitamin dihydrochloride were titrated rapidly with alkali to p_H 11; the results were the same using either hydrogen or glass electrodes and showed the absence of any group having a p_K greater than 7 (*i.e.* the curves were identical with the water blank).

(2) Solutions of the vitamin were brought rapidly to p_H 11 with alkali and allowed to stand until equilibrium was established (as before, the p_H fell steadily during this process); they were then rapidly titrated back with acid. The resulting curves gave constants p_K 6·8 in water, and p_K 7·9 in 90 % alcohol. With the hydrogen electrode a p_K of 6·4 was obtained (*cf.* II (2)).

V. The colour reaction test was performed on the residual solutions from all runs; where the hydrogen electrode had been used the reaction showed only 5–10 % of the strength expected from the amount of vitamin in solution; where glass electrodes had been used, the colour reaction showed about 30 % of the expected value.

The constants obtained are summarised in the table.

Table I.

	p_K			$\Delta\ p_K$ (glass) H_2O - 90 % EtOH
	H_2.Pt in H_2O	Glass in H_2O	Glass in 90 % EtOH	
Basic group 1. 18°	2·5	3·4	—	—
Basic group 2. 18°	4·7	4·8	4·2	-0·6
Acid group. Equilibrium p_K 18°	8·3	9·1	9·3	+0·2
p_{K_2} 0°	6·4	6·8	7·9	+1·1

DISCUSSION.

There is a marked difference of behaviour of the vitamin solutions with hydrogen and glass electrodes; with glass, their behaviour is more reproducible, but apart from this the main differences are:

(1) The difference between p_K 2·5 and p_K 3·4 for the weaker basic group, together with the anomaly of the initial part of the curve (I (1) and Curve I); both these can be accounted for by conversion of this group by action of the hydrogen electrode into one having a lower p_K.

(2) The difference found in the colour reaction (V).

(3) The displacement of the whole curve towards the alkaline side (I (3)).

(4) The difference between p_K 8·3 and 9·1 for the constant in this region.

(5) The difference between the amounts of the p_K 8–9 group, using hydrogen and glass electrodes (IV).

Some of these anomalies are unexplained, but in view of the present scarcity of material it was thought that further work was not justified. However, it seems likely that the vitamin is reduced by the hydrogen electrode, so that the results from the glass electrode best represent its behaviour: the group concerned in the colour reaction can be none of those titrated.

It was found that the vitamin does not poison the hydrogen electrode, nor does it appear to be strongly adsorbed.

The two acid-binding groups of the vitamin have p_K values of 3·4 and 4·8 respectively; this is in accord with the chemical data on the formation of hydrochlorides and sulphates [Kinnersley *et al.*, 1935]. The change of the second from p_K 4·8 to 4·2 between water and 90 % alcohol is of the order to be expected of a basic nitrogen atom [Neuberger, 1934]. Levene and Sims [1925] and Levene *et al.* [1926] have shown that pyrimidine amino-groups have p_K values of about this amount (4·0–4·6), so that the group of p_K 4·8 might be identified with the pyrimidine amino-group of Williams's [1935] formula. However, the quaternary nitrogen demanded by his formula is in disagreement with the evidence, since this must be a third, strongly basic group which together with the groups of p_K 3·4 and 4·8 would cause the vitamin to combine with three equivalents of acid instead of the two equivalents observed.

It appears that the vitamin has also a pseudo-acid group, in view of the following facts.

(1) Apart from the two basic groups (p_K 3·4 and 4·8) the form of the vitamin stable in acid solution contains no acid or basic groups titrating between p_H 7 and 11 (IV (1) above).

(2) Alkali causes the reversible formation of a group having p_K 6·8 in water and 7·9 in 90 % alcohol (IV (2) above). This change of p_K is characteristic of an enolic acid (unpublished observations of one of the authors).

This might be ascribed to a keto-enol change but for the fact that there appear two equivalents of acid per mol. of vitamin. The splitting of an oxide ring or of a sulphide ring (as in Williams's formula) might account for the facts, provided that the dissociation constants of the two —OH groups, or of the —OH and —SH so formed, were not very different. The possibility of hydrolysis of a —CO—NH— linkage seems to be excluded. The formation of a pseudo-base from quaternary nitrogen, such as that found in nicotine derivatives by Lowry and Lloyd [1932], will not account for the present results, both in view of the amount of the group (two equivalents per mol.), and in view of the change of p_K found between water and 90 % alcohol.

The titration results can be correlated with the absorption spectra of the vitamin [Peters and Philpot, 1933; Holiday, 1935] on the assumption that the labile band observed on bringing the vitamin from acid solution to p_H 9·5 is due to the unionised pseudo-acid form; as conversion of PA (equation A) to HA and A^- occurs, this band disappears.

SUMMARY.

Potentiometric titrations have been performed on solutions of crystalline vitamin B_1 dihydrochloride. Evidence has been obtained of the existence of two weakly basic groups of p_K 3·4 and 4·8, and of a pseudo-acid group titrating in the region of p_H 9. The dissociation constant of the acid form of the vitamin has the value p_K 6·8 in water at 0°.

The authors wish to express their thanks to Mr Kinnersley and to Mr Philpot for help and advice; and to Prof. Peters, at whose suggestion this work was undertaken, for invaluable advice throughout its course and for measurement of the colour reactions.

CV. STUDIES IN THE BIOCHEMISTRY OF MICRO-ORGANISMS.

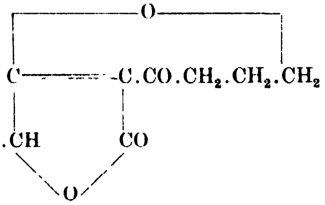
XLIII. THE METABOLIC PRODUCTS OF *PENICILLIUM CHARLESII* G. SMITH. III. THE MOLECULAR CONSTITUTION OF CARLIC AND CARLOSIC ACIDS.

By PERCIVAL WALTER CLUTTERBUCK, HAROLD RAISTRICK AND FRITZ REUTER.

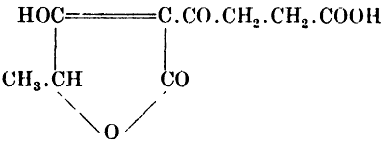
From the Division of Biochemistry, London School of Hygiene and Tropical Medicine, University of London.

(*Received February 22nd, 1935.*)

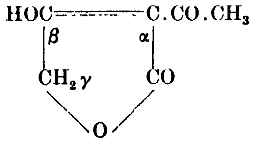
It was recently shown [Clutterbuck *et al.*, 1934] that *Penicillium Charlesii* G. Smith, a new species of *Penicillium* isolated by our late colleague, Mr J. H. V. Charles, from mouldy Italian maize, produced from glucose a number of hitherto undescribed organic acids. Of the latter, carolic acid, $C_9H_{10}O_4$, and carolinic acid, $C_9H_{10}O_6$, which were obtained in the largest yields, have been shown to have the constitutions I and II respectively [Clutterbuck *et al.*, 1935]:



I. Carolic acid.



II. Carolinic acid.



III. α-Acetyltetronic acid.

The acids may be regarded, therefore, as condensation products of *l*-γ-methyltetronic acid with γ-hydroxybutyric (butyrolactone) and succinic acids respectively, condensation with elimination of water occurring between a carboxyl group of the latter acids and an α-hydrogen atom of the γ-methyltetronic acid ring.

Both acids showed somewhat unusual properties. They were broken down quantitatively with great ease on boiling with dilute mineral acids giving 1 mol. each of acetoin and CO_2, carolic acid giving also 1 mol. of butyrolactone, and carolinic acid 1 mol. of succinic acid. Both acids on bromination gave *d*-α-bromo-γ-methyltetronic acid, the α-side-chains being removed. Both were readily reduced with Pd and hydrogen, the CO group of the α-side-chain being converted into a CH_2 group, and both gave with diazomethane methyl ethers which were attacked by NaOH with remarkable ease. They also showed rather characteristic behaviours with 2:4-dinitrophenylhydrazine. Thus carolic acid gave no visible immediate reaction with this reagent in $2N$ HCl but slowly over a period of 8 weeks a precipitate separated which at first consisted of a mixture of mono- and bis-dinitrophenylhydrazones of $C_9H_{10}O_4 + H_2O$ and later became the pure bis-derivative. The monodinitrophenylhydrazone was soluble in $NaHCO_3$ and fairly soluble in water, the bis-derivative being insoluble in either reagent. Carolinic acid immediately gave a yellow monodinitrophenylhydrazone, insoluble in water but soluble in $NaHCO_3$, which was not converted into the bis-derivative on standing with excess of reagent.

It was found that α-acetyltetronic acid (III), which also contains the α-keto-substituted-tetronic acid nucleus, reacted in a manner showing an absolute analogy with the behaviour of carolic and carolinic acids.

In our first work [Clutterbuck *et al.*, 1934], in addition to carolic and carolinic acids, two further acids, each containing ten carbon atoms, *viz.* carlic acid, $C_{10}H_{10}O_6$, and carlosic acid, $C_{10}H_{12}O_6$, were also obtained in smaller yields. These acids have now been shown to be closely related in constitution to carolic and carolinic acids, and it is the purpose of this paper to describe the investigation of the molecular constitution of carlic and carlosic acids.

Carlic acid, $C_{10}H_{10}O_6$, M.P. 176°, $[\alpha]_{5461} - 160°$ (in water), gives with $FeCl_3$ an immediate brownish yellow precipitate soluble in excess to an orange-yellow solution. It does not give a colour with $NaNO_2$. The acid blues Congo red and titrates in water as a dibasic acid. It does not however contain any active hydrogen atom, as determined in dry anisole by the Zerewitinoff method (Roth), whilst it contains two active hydrogen atoms when determined in pyridine. It appears therefore that carlic acid, like carolic acid, must contain a ring system which opens up in aqueous solution, whilst enolisation must occur in pyridine. A number of unusual enolisations of the CO groups of acid anhydrides (containing a $CH_2.CO$ group) in pyridine with activation of hydrogen have been recently reported [Ishikawa and Kojima, 1934].

Carlosic acid, $C_{10}H_{12}O_6$, M.P. 181°, $[\alpha]_{5461} - 160°$ (in water) gives with $FeCl_3$ an immediate brownish yellow precipitate insoluble in excess. It does not give a colour with $NaNO_2$. The acid blues Congo red and titrates in water as a dibasic acid. It gives an amount of methane corresponding to 2·2 (at 18°) to 2·5 (at 95°) active hydrogen atoms in dry anisole and 2·1 (at 18°) and 2·9 (at 95°) in pyridine as determined by the Zerewitinoff method (Roth).

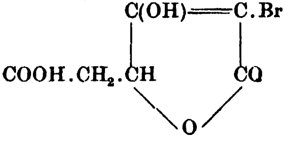
On hydrolysis by boiling with $2N$ H_2SO_4 carlic and carlosic acids, like carolic and carolinic acids, very quickly give 1 mol. of CO_2. Carlic and carlosic acids differ however from carolic and carolinic acids in that on continued hydrolysis they both slowly give a second molecule of CO_2 over a period of about 25 hours. Under these conditions of protracted hydrolysis, carlic acid gives 1 mol. each of acetoin and butyrolactone with 2 mols. of CO_2.

$$C_{10}H_{10}O_6 + 2H_2O = CH_3.CO.CHOH.CH_3 + \underbrace{CH_2.CH_2.CH_2.CO}_{O} + 2CO_2$$

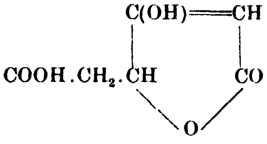
whilst carlosic acid gives 1 mol. each of acetoin and n-butyric acid with 2 mols. of CO_2.

$$C_{10}H_{12}O_6 + 2H_2O = CH_3.CO.CHOH.CH_3 + CH_3.CH_2.CH_2.COOH + 2CO_2.$$

Carlic and carlosic acids on bromination in dilute acetic acid give the same product, $C_6H_5O_5Br$, M.P. 194°, which has been shown to be very probably l-α-bromo-γ-carboxymethyltetronic acid (IV) and which on catalytic reduction with palladium and hydrogen is readily debrominated giving *l*-γ-carboxymethyltetronic acid (V).



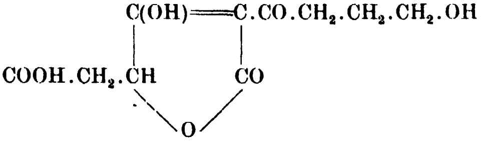
IV.



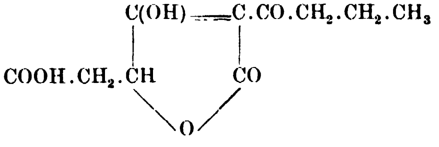
V.

This acid, on hydrolysis with 2*N* H_2SO_4, loses 1 mol. of CO_2 very readily as do carolic, carolinic and γ-methyltetronic acids, whilst a second molecule of CO_2 is lost more slowly, the behaviour being exactly parallel with that of carlic and carlosic acids. Protracted hydrolysis also results in the formation of 1 mol. of acetoin. It is therefore reasonable to suppose that the acetoin and 2 mols. of CO_2, obtained on hydrolysis of carlic and carlosic acids, arise from the *l*-γ-carboxymethyltetronic acid nuclei present in these acids and separated from them on bromination.

Carlic and carlosic acids therefore result from the condensation of 1 mol. of *l*-γ-carboxymethyltetronic acid with 1 mol. of γ-hydroxybutyric acid (butyrolactone) and 1 mol. of *n*-butyric acid respectively. Since synthetic α-acetyltetronic acid has been shown on bromination to lose the α-side-chain giving α-bromotetronic acid, and since carolic, carolinic, carlic and carlosic acids all lose their side-chains on bromination giving α-bromotetronic acid derivatives, it is reasonable to suppose that in the four metabolic acids the side-chains are attached to the α-carbon of the substituted tetronic acid ring as in α-acetyltetronic acid. This view is further supported by the complete analogy in properties between the four metabolic acids and α-acetyltetronic acid, and by their absorption spectra which have been investigated by Dr E. L. Hirst of Birmingham University, and will be reported in a subsequent publication. The following formulae have therefore been adopted for carlic acid (+H_2O) (VI) and carlosic acid (VII) respectively.

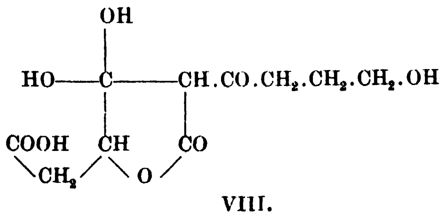


VI. Carlic acid (+H_2O).

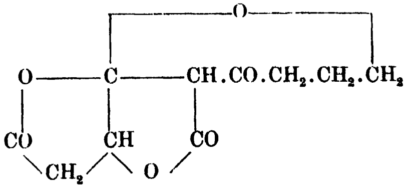


VII. Carlosic acid.

The structural formula of carlic acid then requires the removal of 1 mol. of H_2O from VI. Carlic acid titrates as a dibasic acid in water but contains almost no active hydrogen (in anisole) and two active hydrogen atoms in pyridine. The most probable formula for carlic acid, in view of these facts, is then given by IX, which is derived by hydration of the β-keto group of the tetronic acid ring (VIII) followed by double ring closure.



VIII.



IX. Carlic acid.

This structure would give practically no active hydrogen in anisole, but by analogy with the compounds investigated by Ishikawa and Kojima [1934] would show two active hydrogen atoms in pyridine due to enolisation of the two CO groups having CH_2 groups adjacent to them.

It now remains to be shown that these constitutional formulae are in full agreement with all the known properties of these acids.

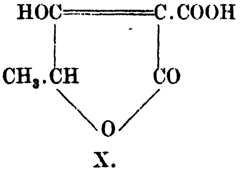
(*a*) *General properties of carlic and carlosic acids.* The above formulae for carlic and carlosic acids would obviously permit optical activity, and in view of the stable substitution of the α-carbon of the tetronic acid ring, we should not expect a colour with $NaNO_2$. The fact that both acids can be recovered unchanged after boiling with acetyl chloride is explained by the fact that all the hydroxyl groups are of the keto-enol type and revert to the ketonic form in presence of this reagent. With carlic acid we should not expect any active hydrogen in dry anisole, but there is the possibility of two enolic groups being formed in pyridine, thus accounting for the two active hydrogen atoms. With carlosic acid, two active hydrogens would be expected with certainty and a third might arise by enolisation in the side chain. The value found in anisole was 2·5. Both acids however on titration with aqueous sodium hydroxide would react as dibasic acids, if it be assumed that with carlic acid two rings open at the β-carbon of the tetronic acid ring.

(*b*) *Bromination of carlic and carlosic acids.* On bromination in approximately 50 % acetic acid under the conditions used for carolic and carolinic acids, carlic and carlosic acids gave the same bromo-derivative, $C_6H_5O_5Br$. This compound gave a red colour with $FeCl_3$ and a violet colour with $NaNO_2$, the latter reaction being characteristic of tetronic acids having the α-CH_2 either unsubstituted or substituted by an easily removable substituent, *e.g.* bromine. It titrated as a dibasic acid and on reduction with palladium-charcoal-hydrogen it readily gave the corresponding dibasic acid $C_6H_6O_5$. This acid also gave the same $FeCl_3$ and $NaNO_2$ colour reactions as did the brominated acid, and on hydrolysis with 2*N* H_2SO_4 very quickly gave 1 mol. of CO_2 and then much more slowly a second molecule of CO_2, whilst after complete hydrolysis, 1 mol. of acetoin remained. The hydrolysis therefore follows the equation

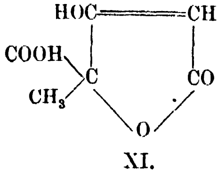
$$C_6H_6O_5 + H_2O = CH_3.CHOH.CO.CH_3 + 2CO_2.$$

The acid $C_6H_6O_5$ differs from γ-methyltetronic acid, $C_5H_6O_3$, by CO_2 and by titrating as a dibasic acid, whereas the latter acid is monobasic. The absorption spectrum of the acid $C_6H_6O_5$, as will be shown in the later publication previously referred to is almost identical with that of γ-methyltetronic acid.

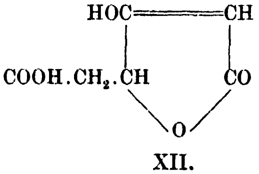
It seems reasonable to suppose therefore that the acid $C_6H_6O_5$ is a carboxy-derivative of γ-methyltetronic acid. Three formulae are conceivable, X, XI, XII.



X.

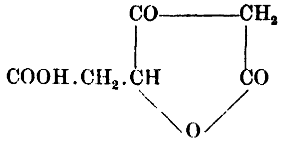


XI.



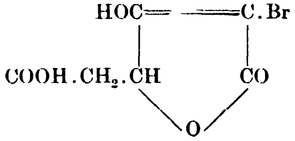
XII.

Formula X is however excluded since this acid was an intermediate substance in the synthesis of γ-methyltetronic acid and was shown to exist only as the ester or as salts, CO_2 being lost immediately on acidification [Benary, 1911; Clutterbuck *et al.*, 1935]. Our acid however is quite stable in acid solution at room temperature and is stable to heat up to its M.P. of 182°. Formula XI appears to be impossible also for a similar reason, since opening the tetronic acid ring would lead to a β-ketodicarboxylic acid. We have seen however that on hydrolysis the acid loses 1 mol. of CO_2 very quickly in the same way as γ-methyltetronic acid, whilst the second molecule of CO_2 is only lost slowly. This is best explained in terms of formula XII when the reaction becomes:



$$\begin{aligned}+\mathrm{H_2O} &= \mathrm{COOH.CH_2.CHOH.CO.CH_2.COOH}\\ &= \mathrm{COOH.CH_2.CHOH.CO.CH_3 + CO_2}\\ &= \mathrm{CO_2 + CH_3.CHOH.CO.CH_3 + CO_2.}\end{aligned}$$

Here 1 mol. of CO_2 is lost at the same rate as with γ-methyltetronic acid in each case from the COOH group in the β-position to the CO group, whilst the second molecule of CO_2 is lost more slowly from the COOH group in the γ-position to the CO group in the acid $C_5H_8O_4$. Compounds with formulae X and XI also would hardly be expected to be stable to heat up to a M.P. of 182°. The acid $C_6H_6O_5$ is therefore regarded as γ-carboxymethyltetronic acid XII, and its bromo-derivative will therefore have the structure XIII.



XIII.

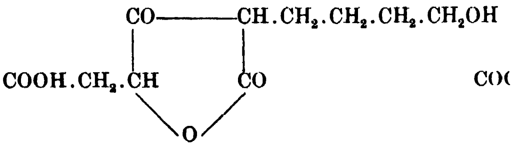
It appears therefore that during bromination of carlic and carlosic acids in dilute acetic acid the α-side-chains are removed and replaced with bromine in a way entirely analogous to that with synthetic α-acetyltetronic acid and with carolic and carolinic acids.

(*c*) *Hydrolysis of carlic and carlosic acids.* The ready hydrolysis of these acids with boiling 2*N* H_2SO_4 has already been discussed and brings them into line with carolic, carolinic and α-acetyltetronic acids. This property is undoubtedly due to the α-ketotetronic acid structure which is common to all five acids, and which on opening the tetronic acid ring represents them as derivatives of diacetylacetic acid.

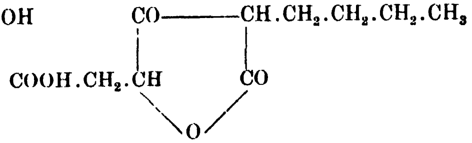
(*d*) *Reduction of carlic and carlosic acids.* Carlic acid, $C_{10}H_{10}O_6$, on reduction with palladium-charcoal-hydrogen, absorbs $2H_2$ and gives the reduced dibasic acid $C_{10}H_{14}O_6$. This result is explained, as with carolic acid, by assuming that on dissolving in water 1 mol. of H_2O is added, and that the CO group of the side-chain is reduced to a CH_2 group.

Carlosic acid, $C_{10}H_{12}O_6$, on reduction absorbs $2H_2$, giving the reduced dibasic acid $C_{10}H_{14}O_5$, and behaves exactly as do carolinic and α-acetyltetronic acids. Here again therefore the reaction is merely the reduction of the CO group of the side-chain to a CH_2 group.

Reduced carlic and carlosic acids may therefore be represented by structures XIV and XV.



XIV.



XV.

Like reduced carolic, carolinic and α-acetyltetronic acids, reduced carlic and carlosic acids give red $FeCl_3$ colours identical with the colour given by γ-methyltetronic, α-ethyltetronic and acetoacetic acids. The reduced acids, as also reduced carolic and carolinic acids, hydrolyse very slowly with boiling $2N$ H_2SO_4 and give substances which reduce Fehling's solution in the cold, slowly give bis-dinitrophenylhydrazones, and probably therefore contain the CHOH.CO grouping. This confirms the view that the tetronic acid ring itself is not reduced under our conditions and moreover, γ-methyltetronic acid itself does not reduce with our catalyst.

(*e*) *Absorption spectra of carlic and carlosic acids and of the corresponding reduced acids.* As will be shown in the subsequent publication previously referred to, the structures assigned to these acids fit the requirements of their absorption spectra. Thus carlic and carlosic acids, like carolic, carolinic and α-acetyltetronic acids, all give a double-banded spectrum in aqueous solution. On the other hand, reduced carlic and carlosic acids, like reduced carolic and carolinic acids, give a single band corresponding to that of either γ-methyl- or α-ethyl-tetronic acid. Thus reduction has resulted in the loss of the ketonic absorption band.

(*f*) *Reactions of carlic and carlosic acids with 2:4-dinitrophenylhydrazine.* In our earlier paper it was shown that α-acetyltetronic and carolinic acids immediately gave yellow monodinitrophenylhydrazones. Carolic acid, on the other hand, gave no immediate precipitate, probably owing to the solubility of the monodinitrophenylhydrazone. After 48 hours a precipitate slowly began to separate which at first consisted of a mixture of mono- and bis-derivatives and later became pure bis-dinitrophenylhydrazone.

Carlic acid gave no precipitate even after 2 weeks and only after 8 weeks showed a small separation of crystals which however proved to be the bis-dinitrophenylhydrazone of diacetyl. Carlic acid must therefore very slowly have been degraded by acid hydrolysis. A similar behaviour has been observed with γ-carboxymethyltetronic acid.

Carlosic acid, like carolinic and α-acetyltetronic acids, gave an immediate precipitate of the monodinitrophenylhydrazone. This derivative was also the only substance isolated after long standing with the reagent. Small amounts of other substances were formed, probably by degradation of carlosic acid, but were not characterised.

(*g*) *Reactions of carlic and carlosic acids with diazomethane.* Carlic acid, like carolic acid, on treatment with diazomethane in incompletely dry ether, very slowly reacted and, after standing overnight, gave a yellow oil which had a methoxyl content rather greater than that of a dimethyl derivative. The elements of water must therefore have been added, and a methyl ether methyl ester have been formed.

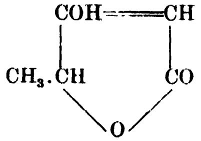
Carlosic acid under the same conditions reacted immediately, and gave an oil which had a methoxyl content also high for that of a dimethyl compound, presumably a methyl ether methyl ester.

As with the methyl derivatives of α-acetyltetronic, carolic and carolinic acids, both these oils were readily hydrolysed by N NaOH at the ordinary temperature, the methyl ether grouping again being attacked.

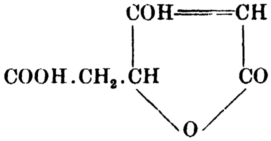
The fact that all these acids gave methyl derivatives having high methoxyl values suggests that the α-CO group of the side-chain undergoes enolisation and subsequent methylation to a slight extent.

This close similarity in behaviour between carlic and carlosic acids on the one hand and α-acetyltetronic, carolic and carolinic acids on the other hand, supported by the absorption spectra data makes it very probable that in carlic ($+H_2O$) and carlosic acids, γ-hydroxybutyric and *n*-butyric acids respectively are condensed with *l*-γ-carboxymethyltetronic acid to give the ketonic structures VI and VII similar to α-acetyltetronic acid. These formulae have therefore been allotted to carlic ($+H_2O$) and carlosic acids respectively, which may therefore be formulated as α-[γ-hydroxybutyryl]-γ-carboxymethyltetronic acid and α-butyryl-γ-carboxymethyltetronic acid.

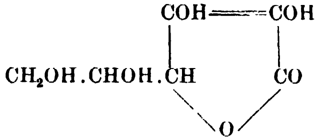
A further point of interest is the close relationship of these products to ascorbic acid (vitamin C). Thus carolic and carolinic acids both contain the γ-methyltetronic acid nucleus (XVI), carlic and carlosic acids the γ-carboxymethyltetronic acid nucleus (XVII), both of which show close analogy with the structure of ascorbic acid (XVIII).



XVI.



XVII.



XVIII.

All these acids have similar absorption spectra and show similar shifts of the absorption band in acid and alkaline solution.

EXPERIMENTAL.

Carlic acid, $C_{10}H_{10}O_6$, M.P. 176°, $[\alpha]_{5461}-160°$ (in water) gives with $FeCl_3$ an immediate brownish yellow precipitate soluble in excess to an orange-yellow solution. It does not give a colour with $NaNO_2$ but blues Congo red and titrates sharply in water as a dibasic acid. Thus 0·1214 g. required 10·70 ml. *N*/10 NaOH corresponding to an equivalent of 113·4. ($C_{10}H_{10}O_6$ titrating as a dibasic acid requires 113.) It does not contain any active hydrogen as determined in dry anisole by the Zerewitinoff method (Roth), 6·78 mg. at 28° giving only 0·04 ml. CH_4. In dry pyridine however it contains two active hydrogen atoms, 8·955 mg. at 28° giving 1·71 ml. CH_4, corresponding to 1·93 active hydrogen atoms. Carlic acid, like carolic acid, must therefore have a ring system which opens on dissolving in water and titrates, and in pyridine two carbonyl groups must enolise.

In regard to the yield of carlic acid, it was noted in our first paper that the acidified metabolism solutions after extraction 10–12 times with an equal volume of ether, and subsequently 5–6 times with chloroform, still had a negative rotation, and it was suggested that this was probably due to residual carlic acid. It has now been found that by adding still larger amounts of HCl for acidification and extracting with chloroform up to 30 times that the yield of carlic acid can be more than doubled.

Carlosic acid, $C_{10}H_{12}O_6$, M.P. 181°, $[\alpha]_{5461}-160°$ (in water) gives with $FeCl_3$ an immediate brownish yellow precipitate insoluble in excess. It does not give a colour with $NaNO_2$. It blues Congo red and titrates as a dibasic acid. Thus 0·1040 g. required 9·20 ml. *N*/10 NaOH corresponding to an equivalent of 113·1. ($C_{10}H_{12}O_6$ titrating as a dibasic acid requires 114.) In a determination of active hydrogen in dry anisole by the Zerewitinoff method (Roth) 8·46 mg. gave 1·86 ml. CH_4 at 18° and 2·10 ml. CH_4 at 95°, corresponding to 2·2 and 2·5 active hydrogen atoms respectively, while in pyridine 7·515 mg. gave 1·55 ml. CH_4 at 18° and 2·12 ml. CH_4 at 95° corresponding to 2·1 and 2·9 active hydrogen atoms respectively.

Both of these acids fail to give benzoyl-, *p*-nitro- or *p*-bromo-benzoyl-derivatives and can be recovered unchanged after boiling for 1 hour with acetyl chloride. They probably do not contain therefore under these conditions a free hydroxyl group.

It has been confirmed that carlosic acid, which is the most highly reduced of these acids, is only obtained when Czapek-Dox medium is used and not with Raulin-Thom solution. It is interesting to note that the metabolism on the latter medium proceeds twice as quickly as on the former medium.

A. *Bromination of carlic and carlosic acids. Preparation of* l-*α-bromo-γ-carboxymethyltetronic acid.*

1 g. of carlic or carlosic acid was dissolved in 15 ml. 50 % aqueous acetic acid and a standardised solution of bromine in the same solvent added. Immediate decoloration of the bromine occurred and a sharp end-point was obtained after the equivalent of 2 mols. of bromine had been added. The solution was then rapidly evaporated to dryness over sticks of KOH in a high vacuum at room temperature. A crystalline mass remained, weighing in each case 1 g. After recrystallisation from boiling ether-light petroleum the product in both cases melted at 194° (decomp.) and on mixing the two samples there was no depression of M.P. The acid gave a red $FeCl_3$ colour and a violet $NaNO_2$ colour. (Found (Schoeller): C, 30·44; H, 2·23; Br, 33·61 %. $C_6H_5O_5Br$ requires C, 30·39; H, 2·13; Br, 33·72 %.)

0·1045 g. on neutralisation in aqueous solution to phenolphthalein required 8·80 ml. *N*/10 NaOH corresponding to an equivalent of 119 ($C_6H_5O_5Br$ titrating as a dibasic acid requires 118·5). Rotation in water ($c = 0{\cdot}562$) $[\alpha]_{5461} - 117°$.

Reduction of l-*α-bromo-γ-carboxymethyltetronic acid, $C_6H_5O_5Br$, to an acid $C_6H_6O_5$ shown to be* l-*γ-carboxymethyltetronic acid.* *l*-α-Bromo-γ-carboxymethyltetronic acid, 0·25 g., was reduced catalytically using palladium-charcoal-hydrogen. The reduction, which was carried out as with α-bromo-γ-methyltetronic acid was complete in about 5 minutes and corresponded to an uptake of 1 mol. of hydrogen per mol. of substance reduced. The catalyst was filtered off and washed with 2*N* NaOH and then with water. The filtrate and washings were combined, acidified and extracted five times with an equal volume of ether, the ethereal extracts dried over anhydrous $MgSO_4$ and the ether removed *in vacuo*. A crystalline product remained which after recrystallisation from boiling ether-light petroleum melted at 182°. The acid gave a red colour with $FeCl_3$ and a violet one with $NaNO_2$. (Found (Schoeller): C, 45·61; H, 3·90 %. $C_6H_6O_5$ requires C, 45·55; H, 3·83 %.) 0·0129 g. on neutralisation in aqueous solution to phenolphthalein required 1·60 ml. *N*/10 NaOH corresponding to an equivalent of 80·6 ($C_6H_6O_5$ titrating as a dibasic acid requires 79). Rotation in water ($c = 0{\cdot}483$) $[\alpha]_{5461} - 52°$.

l-γ-Carboxymethyltetronic acid does not give an immediate precipitate with Brady's reagent, but during 6–8 weeks a precipitate slowly separated which proved however to be the bis-dinitrophenylhydrazone of diacetyl, M.P. 318°, not depressed by mixing with an authentic specimen. Complete hydrolytic decarboxylation had therefore occurred.

Hydrolysis of l-*γ-carboxymethyltetronic acid, $C_6H_6O_5$.* 0·205 g. of the acid was heated with 20 ml. 2*N* H_2SO_4 in a stream of CO_2-free nitrogen exactly as in the hydrolysis of carolic acid, the resultant gases being passed through a dinitrophenylhydrazine bubbler and then through baryta bubblers. The amounts of CO_2 collected in 3, 9 and 17 hours respectively corresponded to 27·8, 40·8 and 51·8 ml. *N*/10 baryta. The theoretical amount of CO_2 assuming that 1 mol. of

$C_6H_6O_5$ gives 1 mol. of CO_2 requires 25·95 ml. $N/10$ acid. It is obvious therefore that 1 mol. of CO_2 is very readily liberated, the time taken corresponding exactly with those for carolic, carolinic, γ-methyltetronic and α-acetyltetronic acids, whilst a second molecule of CO_2 is liberated much more slowly. The hydrolysate was cooled and after neutralisation with concentrated KOH made up to 100 ml.; aliquot portions were used for the following tests. The solution gave a positive Voges-Proskauer reaction, reduced Fehling's solution in the cold, slowly in the manner characteristic of acetoin gave the bis-dinitrophenylhydrazone of diacetyl, M.P. 318° (not depressed by mixing with an authentic specimen), and on determination of the acetoin content by the Wood-Ost method was shown to contain 0·098 g. acetoin (theory for 1 mol. acetoin, 0·1142 g.).

As happens in all the hydrolysis experiments in which acetoin is formed, a little of the acetoin passed through the condenser in the stream of nitrogen, and the dinitrophenylhydrazine bubbler on standing gave slowly a very small amount of precipitate which proved to be the bis-dinitrophenylhydrazone of diacetyl, M.P. 318°. If, however, the hydrolysis product had been diacetyl and not acetoin a very copious precipitate would have been formed in the dinitrophenylhydrazine bubbler, as control experiments have proved.

The acid $C_6H_6O_5$ behaves therefore like γ-methyltetronic acid in giving a red colour with $FeCl_3$, a violet one with $NaNO_2$ and on hydrolysis giving readily 1 mol. of acetoin and 1 mol. of CO_2, but differing in titrating as a dibasic (instead of monobasic) acid and in slowly giving on hydrolysis a second molecule of CO_2. As shown in the theoretical part of this paper, these facts fit best the view that the structure of this acid is γ-carboxymethyltetronic acid (XII), whilst the bromide is α-bromo-γ-carboxymethyltetronic acid (XIII).

B. *Hydrolysis of carlic acid.*

0·8114 g. carlic acid, M.P. 176°, was hydrolysed as with carolic and carolinic acids, by boiling with 50 ml. dilute H_2SO_4 ($\equiv$ 118·7 ml. N) in a stream of CO_2-free nitrogen, the gases evolved being passed up a reflux condenser and through a bubbler containing Brady's dinitrophenylhydrazine reagent, and then through a series of bubblers containing standardised baryta. After 3, 7, 14, 21 hours the amounts of CO_2 liberated corresponded to 73·0, 95·45, 129·45 and 138·85 ml. $N/10$ baryta respectively. Assuming $C_{10}H_{10}O_6 \rightarrow 2CO_2$, the theoretical amount of CO_2 is equivalent to 143·5 ml. $N/10$ baryta. One molecule of CO_2 was therefore readily eliminated but the second molecule only slowly. The dinitrophenylhydrazine bubbler showed a slight precipitate which increased on standing due to a little acetoin passing the condenser. The residual fluid after cooling required 119·2 ml. N alkali for neutralisation, corresponding to a residual acidity of 0·5 ml. N acid. On warming the neutral solution with excess N NaOH, a further amount of alkali was absorbed, owing to the hydrolysis and neutralisation of butyrolactone, making the total residual acidity up to 3·8 ml. N acid. Assuming that 1 mol. of carlic acid gives 1 mol. of butyrolactone, the theoretical amount of NaOH required is 3·6 ml. N. The neutralised solution was next evaporated *in vacuo* to dryness several times, the combined distillates made up to 500 ml. and investigated qualitatively and quantitatively (Wood-Ost method) for the presence of acetoin, whilst the salts remaining were acidified and the butyrolactone so obtained was isolated by continuous extraction with ether.

The distillates reduced Fehling's solution in the cold, gave a positive Voges-Proskauer reaction, gave slowly the bis-dinitrophenylhydrazone of diacetyl, M.P. 318° (not depressed by mixing with an authentic specimen) and gave a copper reduction by the Wood-Ost method corresponding to a total of 0·2767 g. acetoin (the theoretical amount assuming that 1 mol. of carlic acid gives 1 mol. of acetoin is 0·316 g.). The result is a little low, owing to the loss during the long period of bubbling, a loss detected in the dinitrophenylhydrazine bubbler.

The ether-extracted salts gave a sweet-smelling mobile oil which was identified as butyrolactone since it readily gave the beautifully crystalline phenylhydrazide of γ-hydroxybutyric acid, which crystallised in large plates from ethyl acetate, M.P. 94° (not depressed by mixing with an authentic specimen), prepared as described in our previous paper [Clutterbuck *et al.*, 1935].

Carlic acid (1 mol.) on hydrolysis with dilute mineral acid gives therefore 1 mol. each of acetoin and butyrolactone and 2 mols. of CO_2, one readily as with carolic acid, the second more slowly.

C. *Hydrolysis of carlosic acid.*

1·045 g. carlosic acid, M.P. 181°, were hydrolysed under the same conditions as with carlic acid by boiling with 40 ml. dilute H_2SO_4 ($\equiv$93·50 ml. *N*). After 3, 6, 13, 20 and 27 hours, the amounts of CO_2 liberated corresponded to 98·6, 126·0, 149·1, 165·5 and 171·7 ml. *N*/10 baryta respectively. Assuming $C_{10}H_{12}O_6 \rightarrow 2CO_2$, the theoretical amount of CO_2 is equivalent to 183·2 ml. *N*/10 baryta. One molecule of CO_2 was therefore readily eliminated and a second molecule more slowly. The dinitrophenylhydrazine bubbler again showed a precipitate due to a small amount of acetoin passing the condenser. The residual fluid after cooling required 97·90 ml. *N* NaOH for neutralisation, corresponding to a residual acidity of $97{\cdot}9-93{\cdot}5=4{\cdot}40$ ml. *N* acid. Assuming that 1 mol. of carlosic acid gives 1 mol. of a monobasic acid, the theoretical amount of residual acidity would be 4·58 ml. *N*. The neutralised solution was next evaporated *in vacuo* to dryness several times, the combined distillates made up to 500 ml. and investigated as before for the presence of acetoin, whilst the salts were acidified with 2*N* H_2SO_4, the hydrolysis acid separated by distillation in steam, neutralised and isolated as the *p*-phenylphenacyl ester by the method of Drake and Bronitsky [1930].

The distillates reduced Fehling's solution in the cold, gave a positive Voges-Proskauer reaction, gave slowly with Brady's reagent the bis-dinitrophenylhydrazone of diacetyl, M.P. 318° (not depressed on admixture with an authentic specimen), and gave a copper reduction by the Wood-Ost method corresponding to 0·3572 g. acetoin (the theoretical amount assuming that 1 mol. of carlosic acid gives 1 mol. of acetoin is 0·4035 g.). The *p*-phenylphenacyl ester of the volatile hydrolysis acid melted after recrystallisation from 95 % alcohol at 82°, and after fractional sublimation still melted at 82°. (Found: C, 76·39, 76·42; H, 6·30, 6·41 %. $C_{18}H_{18}O_3$ requires C, 76·58; H, 6·43 %.) A sample of the *p*-phenylphenacyl ester of *n*-butyric acid was synthesised and melted at 82° and did not depress the M.P. of the ester from the hydrolysis acid. It appears that Drake and Bronitsky's melting-point of 97° for the *p*-phenylphenacyl ester of *n*-butyric acid is incorrect. The *p*-phenylphenacyl ester of *iso*butyric acid was also prepared for comparison and melted both before and after sublimation at 89°. A mixture of this ester and that of the volatile acid from carlosic acid melted at 75–76°.

Carlosic acid (1 mol.) on hydrolysis with dilute mineral acid gives, therefore, 1 mol. each of acetoin and *n*-butyric acid and 2 mols. of CO_2, one readily as with carolic acid, the second more slowly.

D. *Reduction of carlic and carlosic acids.*

Carlic and carlosic acids are reduced readily under the same conditions as with carolic and carolinic acids.

Carlic acid (1 g.) was dissolved in 25 ml. of water, the catalyst prepared from 1 g. charcoal and 0·2 g. palladium chloride, as described for carolic acid, was added and the reduction started in the usual way; 2 mols. of hydrogen per molecule of carlic acid were absorbed in just over 1 hour. The catalyst was then filtered off and washed with a little NaOH and then with water, the filtrate and washings acidified and extracted several times with an equal volume of ether. After removal of the ether, a crystalline residue remained, which after recrystallisation from ether (containing a trace of alcohol)-light petroleum melted at 157·5°. (Found: C, 51·88, 51·92; H, 6·15, 6·09 %. $C_{10}H_{14}O_6$ requires C, 52·16; H, 6·13 %.)

0·1050 g. required 9·05 ml. *N*/10 NaOH for neutralisation to phenolphthalein corresponding to an equivalent of 116 ($C_{10}H_{14}O_6$ titrating as a dibasic acid requires 115).

It appears therefore that in the reduction of carlic acid $C_{10}H_{10}O_6$ (as with carolic acid), 2 mols. of hydrogen are absorbed and the reduced acid $C_{10}H_{14}O_6$ contains $2H_2$ more than carlic acid. This result is explained on the ketonic structure of carlic acid by assuming that on dissolving in water, 1 mol. of H_2O is first added in order to open the ring systems, and that the CO group of the side-chain is then reduced to CH_2, giving structure XIV.

Carlosic acid (1 g. in 90 ml. water) was reduced under exactly the same conditions as above. It absorbed 2 mols. of hydrogen in just over 1 hour. The reduced acid was almost insoluble in water and was precipitated during the reaction. The catalyst and acid were filtered off and extracted with NaOH, and the alkaline filtrate on acidification gave a crystalline precipitate which after recrystallisation from hot water melted at 217°. (Found: C, 56·01, 55·94; H, 6·61, 6·54 %. $C_{10}H_{14}O_5$ requires C, 56·06; H, 6·59 %.)

80·7 mg. required 7·50 ml. *N*/10 NaOH for neutralisation to phenolphthalein corresponding to an equivalent of 107·6 ($C_{10}H_{14}O_5$ titrating as a dibasic acid requires 107).

It appears therefore that in the reduction of carlosic acid $C_{10}H_{12}O_6$, 2 mols. of hydrogen are absorbed and that the product has the empirical formula $C_{10}H_{14}O_5$. This is readily explained by assuming that the CO group immediately outside the tetronic acid ring is reduced to CH_2, as in structure XV. The behaviour of carlosic acid on reduction is therefore completely analogous to that of carolinic acid.

The reduction of carlic and carlosic acids proceeds more slowly under our conditions than does the reduction of true unsaturated compounds, taking place at a rate almost identical with that of α-acetyltetronic acid, in which the CO group of the side-chain is reduced to CH_2 with production of α-ethyltetronic acid. The reductions of carlic and carlosic acids therefore support the ketonic structures assigned to these substances. This view, as will be shown in a subsequent publication, is strongly supported by the change of absorption spectrum on reduction, the double-banded spectra of carlic and carlosic acids giving way to single-banded spectra of the reduced acids. The behaviour of carlic and carlosic acids on reduction is therefore completely analogous to that of carolic and carolinic acids, respectively. This view is further supported by the fact that whereas carlic and carlosic acids give orange precipitates with $FeCl_3$, the corresponding reduced acids both give red colours with $FeCl_3$ indistinguishable from those given by γ-methyltetronic and α-ethyltetronic acids.

E. *Reactions of carlic and carlosic acids with 2:4-dinitrophenylhydrazine.*

Carlic acid, after standing with Brady's reagent either overnight or for a fortnight, gave no precipitate. The solution was extracted five times with ether and the ethereal solution extracted with aqueous $NaHCO_3$ when unchanged 2:4-dinitrophenylhydrazine remained in solution in the ether. The $NaHCO_3$ solution was acidified and re-extracted with ether. This ethereal solution on evaporation gave a red oil which could not be obtained crystalline. It appears therefore that carlic acid does react with the reagent, but the product is very soluble in water and has not been obtained in the crystalline condition. When a solution of carlic acid in Brady's reagent was allowed to stand for 8 weeks, a small amount of precipitate separated towards the end of this period. The precipitate proved however to be the bis-dinitrophenylhydrazone of diacetyl, M.P. 318° (unchanged on admixture with an authentic specimen), which must therefore have resulted from slow but complete hydrolytic degradation of carlic acid by the $2N$ HCl of the reagent.

An aqueous solution of carlosic acid gives with Brady's reagent an immediate orange-yellow precipitate. With strong aqueous solutions of carlosic acid, this precipitate consists of a mixture of the monodinitrophenylhydrazone of carlosic acid together with carlosic acid, the latter being only slightly soluble in the $2N$ HCl of Brady's reagent. After several recrystallisations from absolute ethyl alcohol, the monodinitrophenylhydrazone was obtained pure in orange-yellow needles, M.P. 182°. (Found (Schoeller) on a sample dried to constant weight at 128° *in vacuo*: C, 46·74; H, 3·97; N, 13·75 %. $C_{16}H_{16}O_9N_4$ requires C, 47·04; H, 3·95; N, 13·72 %.)

F. *Reactions of carlic and carlosic acids with diazomethane.*

The acids (1 g. in each case) were suspended in commercial (incompletely) dry ether and a solution of diazomethane in ether was added. With carlic acid, as with carolic acid, the reaction proceeded slowly for several hours. With carlosic acid as with carolinic, γ-methyltetronic and α-acetyltetronic acids, the reaction was vigorous and quickly complete. After standing overnight with excess of reagent, the ethereal solutions were evaporated and dried over H_2SO_4 *in vacuo* for several days. In both cases yellow oils resulted. With carlic acid the oil contained 24·1 % OMe ($C_{10}H_8O_4(OMe)_2 + H_2O$ requires 22·8 %), and with carlosic acid 27·2 % OMe ($C_{10}H_{10}O_4(OMe)_2$ requires 24·2 %).

The methylation products were then allowed to stand for 24 hours with 20 ml. N NaOH. The material in both cases passed completely into solution. After acidification and ether extraction, removal of solvent and drying, yellow oils were again obtained. The methoxyl content of the dimethyl derivative of carlic acid had fallen to 9·6 % and that of the dimethyl derivative of carlosic acid to 5·7 %.

The behaviour of carlosic acid and of the hydrated form of carlic acid on methylation with diazomethane, and of their dimethyl derivatives on treatment with cold dilute NaOH, is therefore strictly analogous to that of carolinic acid. The product of methylation in each case is a methyl ether methyl ester. In each case the carboxyl group is esterified and is relatively slowly hydrolysed, whereas the enolised carbonyl group in the β-position in the tetronic acid ring methylates to give a methyl ether which is readily hydrolysed, because there are two potentially acidic CO groups in β-positions to it.

The products resulting from the methylation with diazomethane of carlic and carlosic as well as carolic and carolinic acids all have methoxyl contents somewhat higher than the theoretical values, suggesting that the α-CO group of the side-chain is enolised to a slight extent and that the enolised portion is methylated.

SUMMARY.

Penicillium Charlesii G. Smith produces from glucose carlic acid ($C_{10}H_{10}O_6$) and carlosic acid ($C_{10}H_{12}O_6$). The molecular constitutions of these two acids have been investigated and it has been shown that they are closely related derivatives of *l*-γ-carboxymethyltetronic acid.

Carlic acid hydrate has been shown to be *l*-α-[γ-hydroxybutyryl]-γ-carboxymethyltetronic acid, and carlosic acid to be *l*-α-butyryl-γ-carboxymethyltetronic acid. Both acids are therefore closely related structurally to carolic and carolinic acids, which are also metabolic products of *P. Charlesii*, and to ascorbic acid (vitamin C).

A number of derivatives and breakdown products are described.

We gratefully acknowledge much assistance in the preparation of carlic and carlosic acids given by Messrs G. Smith and W. K. Anslow.

CVI. ANTISCORBUTIC VALUE OF LUCERNE.

By LEOPOLD FERDINAND LEVY and FRANCIS WILLIAM FOX.

From the Biochemical Department, South African Institute for Medical Research, Johannesburg, South Africa.

(*Received February 26th, 1935.*)

During the course of an investigation into the distribution of the antiscorbutic factor in some South African foodstuffs specimens of the common lucerne, or alfalfa (*Medicago sativa*) were examined, and it was found that, as judged by the indophenol reaction, this plant was an outstandingly rich source of vitamin C.

According to the report on the vitamins issued by the Medical Research Council [1932] lucerne is regarded as rich in vitamins A and B and exceptionally rich in E. More recent work, such as that described by Scheunert and Schieblich [1934] and by Hauge [1934], confirms the high values for vitamin A, though the former authors state that vitamins B and D are present only in low concentration. We have been unable, however, to find any reference dealing with the antiscorbutic value of this plant.

Lucerne is also of value since it contains no less than 1–2 % of mineral salts, of which nearly 0·5 % is calcium; in addition about 8 mg. of iron are present per g., or nearly double that found in spinach. It will be agreed, therefore, that lucerne is an interesting plant from the nutritional point of view; moreover, it is growing in favour as a forage crop and is becoming fairly readily available in many parts of the world [see monograph by Klinkowski, 1933]. In view of the foregoing it seemed desirable to investigate its antiscorbutic activity more closely.

Although it is well known that lucerne is occasionally the cause of death in animals, Steyn [1933], after careful examination of the available evidence is of the opinion that there is no experimental evidence to show that this is due to the presence of any poisonous substance in the plant. In all probability death is due to the effects of excessive fermentation, which, it appears, it likely to take place when large amounts are consumed, especially if the plant is in a young, frosted or wilted condition.

We learn from several sources that green lucerne is actually used to some small extent as a human food in parts of Russia, China and America, whilst here in South Africa it is occasionally used as a substitute for spinach. On account of its high mineral and vitamin A contents lucerne meal has been recently incorporated into the special "cereal mixture" devised by Brown and Tisdall [1933] and used by them with conspicuous success in the feeding of small children.

Determination of antiscorbutic activity by means of indophenol.

For this purpose the method of Birch *et al.* [1933] was used. The following are typical values from amongst many samples of lucerne that have been examined.

Table I. *Antiscorbutic value of lucerne as measured by the indophenol reaction.*

	mg. of ascorbic acid per g. of fresh lucerne
Young plants:	
Leaves only	3·2, 3·3, 3·3, 3·8, 3·8
Leaves and small stalks	2·7, 3·0, 3·1, 3·2, 3·2, 3·3
Shoots only	3·0, 3·8
Flowering stage:	
Leaves only	2·2, 2·2, 2·3, 2·3, 2·3, 2·4, 2·5, 2·6, 2·7, 2·7, 2·7, 2·7, 3·0, 3·1
Another specimen gave:	
Leaves only	4·5
Small stalks	1·8
Fibrous stalks	0·7

As will be seen from the above, the antiscorbutic value is of a high order, being frequently more than four times that of the same weight of orange juice.

Confirmation of antiscorbutic activity by means of animal experiments.

These experiments were carried out upon young guinea-pigs according to the method described by Bracewell *et al.* [1930]. A fresh supply of lucerne was obtained daily and the vitamin content estimated by means of indophenol. Only the leaves and young shoots were used, and the amounts weighed out and given to each animal were adjusted to correspond as nearly as possible to a definite quantity of vitamin C. The animals were divided into three groups, and the amounts of ascorbic acid given *per diem* corresponded approximately to 0·8, 1·6 and 3·2 mg. This represented a daily ration of 0·25–0·3, 0·5–0·6 and 1·0–1·2 g. respectively of the fresh leaf. A double quantity was given on Saturdays. At the conclusion of the experiment the animals were killed and

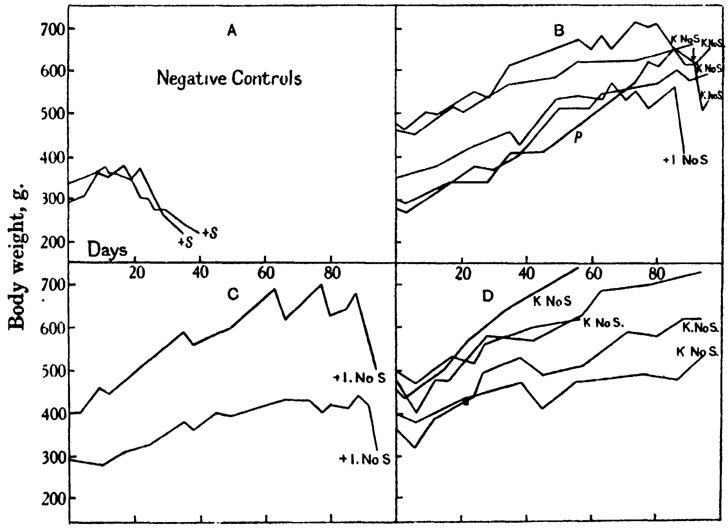

Fig. 1. A, Negative controls; B, 0·25–0·3 g. lucerne≡0·8 mg. ascorbic acid; C, 0·5–0·6 g. lucerne≡1·6 mg. ascorbic acid; D, 1·0–1·2 g.≡3·2 ascorbic acid.

+S Died of scurvy.

carefully examined for evidence of scurvy. No such evidence was obtained from any of the animals receiving the lucerne, whereas both the animals receiving the basal diet alone quickly died from this disease. These two animals showed extensive subcutaneous haemorrhages, fragile epiphyses containing numerous areas of haemorrhage in the marrow and beading of the costochondral junctions; the teeth, however, did not appear to be brittle nor was there swelling or haemorrhage into the gums. The charts of the animals' growth are given in Fig. 1.

Some difficulty arises in the quantitative interpretation of these animal experiments, owing to the uncertainty which appears to exist regarding the minimum protective dose for the guinea-pig. According to Birch *et al.* [1933] 0·9 mg. of ascorbic acid *per diem* may be regarded as sufficient to protect the animal from macroscopical evidence of scurvy, whilst Göthlin [1934] claims that protection against macroscopical scorbutic alterations can be reached with values as low as 0·5 mg. of ascorbic acid. Since 0·25–0·3 g. of lucerne leaf *per diem* protected these animals from macroscopical evidence of scurvy, it may be concluded that this amount of leaf contains at least 0·5 mg. of the vitamin. This corresponds to 2·0–3·6 mg. per g. of leaf depending on which value for the minimum protective dose is accepted; in either case the values obtained by the chemical and biological methods are seen to be in very fair agreement.

Variations in the antiscorbutic activity of lucerne.

As will be noticed from Table I, the shoots and leaves tend to be somewhat richer when young than at the flowering stage. There are a very great many different varieties of lucerne in cultivation [see Klinkowski, 1933], and it is quite possible that these varieties may differ very considerably in their antiscorbutic values and in other properties that may be of importance when considering lucerne as a possible green vegetable for human consumption. The variety used for the above experiments is known as Provence; substantially the same values were, however, obtained for a few specimens of two other varieties in common use, namely Chinese and Hunter's River. No difference was found between samples taken at the same time from a variety receiving different fertiliser treatment.

Preservation of the antiscorbutic value of lucerne.

Green lucerne. The changes that are liable to occur after cutting are seen in Table II. In the first case there is an apparent increase in concentration owing to wilting of the leaves, whilst in the second, although wilting was prevented, the lucerne became slightly yellow in colour; in such cases lower values were invariably obtained.

Table II. *Deterioration of antiscorbutic value of lucerne after cutting.*

mg. ascorbic acid per g. of leaf.

	Standing without water	Standing in water
Fresh leaves	3·2, 3·2, 3·3	3·1, 2·6, 2·5, 3·0
After 24 hours	3·8, 3·7, 3·6	2·3, 2·2, 2·3, —
After 72 hours	— — —	1·9 — — 2·1

That lucerne, when cooked like spinach, retains its antiscorbutic activity to a very considerable extent is suggested by the following experiment.

10·6 g. of carefully sampled lucerne leaves, corresponding to an ascorbic acid content of 34·0 mg., were boiled for 20 minutes with 50 ml. of water and a pinch of salt in a covered pyrex beaker. At the conclusion of the experiment very little water remained, and after the contents were cooled 31·7 mg. or 90 % of the original ascorbic acid was found to be present.

Lucerne hay. That ordinary lucerne hay of commerce may contain a good deal of ascorbic acid is seen from the following figures obtained for samples of varying quality found at the local market:

0·09, 0·28, 0·45 and 1·6 mg. per g. of hay.

Lucerne meal. Specimens of commercial meal were also examined and were found to vary considerably in their ascorbic acid contents. Two samples contained negligible amounts, whilst the best, which was of a good green colour and contained much less stalk, gave a value of 0·57 mg. per g.

A sample of meal was also prepared from a bale of lucerne obtained from the market; the leaves when removed from the stalks were found to represent about 37 % of the original weight. On grinding the meal gave a value of 0·79 mg. per g.

It was thought that the rate of destruction of the vitamin during the curing of green lucerne and the preparation of meal would be much reduced if enzyme action could be arrested at an early stage. The following rough experiments support this view and indicate possible methods for the practical preparation of meals possessing really high antiscorbutic activity.

(1) Fresh lucerne plants were plunged into boiling water for 30 seconds and then dried by exposure to air, but away from direct sunlight.

Table III. *Lucerne meal prepared from leaves scalded for 30 seconds.*

mg. ascorbic acid per g.

	Initial value		Value after scalding and drying	
	Fresh leaves	Calculated to dry weight	4 days' drying	11 weeks' storage
(*a*)	—	—	1·5	—
(*b*)	3·1	10·3	3·8	—
(*c*)	2·4	8·0	4·4	—
(*d*)	3·1	10·3	4·0	2·7

(2) Lucerne dried in an air-oven for 6 minutes at 250° gave values of over 7·0 mg. per g.

(3) Lucerne leaves and shoots were dried for 2 days over sulphuric acid *in vacuo*. The excellent preservation obtained is seen from Table IV.

Table IV. *Antiscorbutic value of desiccated lucerne.*

Initial value		Value after desiccation	
Fresh leaves	Calculated to dry weight	Immediately after desiccation	After 6 months' storage
2·3	9·2	8·3	—
2·5	10·0	7·4	3·0

These three experiments indicate that there should be no great difficulty in devising a practical method for the preparation of a lucerne meal possessing considerable antiscorbutic activity, should such a dry and comparatively non-perishable source of the vitamin be required.

SUMMARY.

1. Lucerne is an outstandingly good source of vitamin C, the concentration in the average leaf examined being about four times that found in *Citrus* juice. This conclusion was first arrived at by means of the indophenol reaction and then confirmed by the biological test.

2. Although the original activity rapidly diminishes when the cells are damaged, preliminary experiments indicate that much of the vitamin remains after cooking, and that it is possible to dry the plant in such a way that lucerne meal of high activity can be obtained.

3. Since lucerne is also a rich source of vitamins A and E and is also unusually rich in minerals such as calcium and iron, the possibility of using certain types of the young plant as a human food, either as green salad, spinach or in the form of dry meal is worthy of consideration.

We should like to take this opportunity of thanking Dr F. W. Simson, Pathologist to the Institute, for his help with the *post mortem* examination of the animals, Dr J. Daneel, Superintendent of the Rietfontein Hospital for arranging the daily supplies of freshly gathered lucerne, and Miss C. Wilson, of the Sanitation Department, Rand Mines, for suggesting and carrying out the experiment with oven-dried lucerne.

III. THE OXIDATION OF ALANINE BY *CL. SPOROGENES*.

IV. THE REDUCTION OF GLYCINE BY *CL. SPOROGENES*.

By LEONARD HUBERT STICKLAND[1].

From the Biochemical Laboratory, Cambridge.

(*Received February 16th, 1935.*)

In the first paper of this series [Stickland, 1934] it was shown that washed suspensions of *Cl. sporogenes* can catalyse reactions between various pairs of amino-acids, one amino-acid being oxidised and the other reduced. In the second paper [Stickland, 1935] the reduction of proline was shown to occur by rupture of the ring, giving δ-aminovaleric acid. The present work continues the study of the chemistry of these reactions and deals with the oxidation of alanine and the reduction of glycine.

III. THE OXIDATION OF ALANINE BY *CL. SPOROGENES*.

Experimental.

Preparation of bacterial suspensions.

The culture was the same as that previously used (*Cl. sporogenes* Bellette), and the washed suspensions of bacteria were prepared in the way described in the earlier papers.

The oxidation of alanine.

(*a*) *The degree of oxidation of alanine.* In the first paper it was proved that when alanine is oxidised by cresyl blue two molecules of the dye are reduced for each molecule of alanine oxidised. This result has now been confirmed, using the natural substrate glycine in place of the artificial dye. A series of Thunberg tubes was set up each containing a known amount of *d*-alanine (0·5 ml. of $M/20$ solution), excess of glycine (0·5 ml. of $M/5$ or 0·5 ml. of $M/2{\cdot}5$ solution), 0·5 ml. of phosphate buffer $M/2$ p_H 7·5 and 1·0 ml. of suspension of bacteria. A control series of tubes contained the same solutions with 0·5 ml. of water replacing the alanine solution. After evacuation and incubation at 40°, pairs of tubes were taken and the ammonia was estimated in 2 ml. of their contents, estimations being carried out from time to time until no further increase in the ammonia (corrected for the blank) was found. Since only the final value was required, samples were usually not taken until after 24 hours, when the reaction was practically complete. The result of one experiment is given in Table I. The ammonia production approaches a limit at 0·74 ml. of $M/10$ per tube. Of this 0·25 ml. is derived from the oxidation of the alanine, so that 0·49 ml. can be attributed to reduction of glycine. Hence 2·0 molecules of glycine are reduced for each molecule of alanine oxidised; two other similar experiments gave values

---

47	0·74

of 1·8 and 1·8. Making the assumption, which will be justified experimentally later on, that the reduction of glycine involves the taking up of two equivalents of hydrogen, this result agrees with that obtained by the oxidation of alanine with cresyl blue.

In connection with these experiments it must be mentioned that when thick suspensions of bacteria are used, and the experimental period is rather long, a significant amount of ammonia is produced in tubes containing bacteria and glycine alone, in excess of that found in the blank. This must be attributed to the reduction of a small amount of glycine by the "reducing blank" of the bacteria. This point was already apparent even in the shorter experiments in the first paper of this series (see some results in Table V of that paper [Stickland, 1934, p. 1754]).

(*b*) *The products of oxidation of alanine.* The product of reduction of proline has already been identified as δ-aminovaleric acid [Stickland, 1935], so that from an examination of the products of the reaction between one molecule of alanine and two molecules of proline the oxidation products of alanine can be found. Preliminary experiments showed that ammonia, carbon dioxide and a volatile acid were among the compounds formed.

For estimation of the volatile acid, 10 ml. of $M/10$ *d*-alanine solution, 10 ml. of $M/5$ proline, 10 ml. of $M/2$ phosphate buffer p_H 7·5 and 20 ml. of suspension of *Cl. sporogenes* were placed in a large (75 ml.) Thunberg tube, which was evacuated and incubated at 40°. A control tube with 20 ml. of water in place of the two amino-acid solutions was treated similarly. For carbon dioxide estimation, a 50 ml. bottle containing 2·5 ml. of $M/10$ alanine, 2·5 ml. $M/5$ proline, 2·5 ml. buffer and 5·0 ml. bacterial suspension was connected in the incubator with a train of three small gas wash-bottles, each containing 5 ml. of $N/10$ baryta and rendered anaerobic by the passage of a stream of oxygen-free nitrogen. A parallel control with neither amino-acid was set up at the same time. A Kjeldahl splash trap was inserted between the experimental bottles and the baryta wash-bottles and the rubber connections were made as short as possible and coated with paraffin wax. The course of the reaction was followed by preparing two sets of small Thunberg tubes containing the solutions in the same proportions as above in a total volume of 2·5 ml. (0·5 ml. $M/10$ alanine, 0·5 ml. $M/5$ proline, 0·5 ml. buffer and 1·0 ml. bacteria, and the corresponding controls) in which the ammonia was estimated from time to time until the whole of the alanine was found to be oxidised.

The reaction was usually complete in from 12 to 24 hours, after which the estimations were carried out.

For the carbon dioxide estimations, the current of nitrogen was increased and allowed to run for 2 hours or more. This was found by trial to be sufficient to remove the whole of the carbon dioxide from the solution even at p_H 7·5. The baryta was then titrated with $N/10$ hydrochloric acid to phenolphthalein.

For volatile acid estimations, 40 ml. of the contents of each large Thunberg tube were freed from chloride by adding them to a mixture of 10 ml. of N sulphuric acid and 40 ml. of saturated silver sulphate solution. Volatile acid was estimated in duplicate on 40 ml. portions of the filtrates by distilling *in vacuo* into excess of standard baryta. The manipulations of the acid solutions sufficed to remove the carbon dioxide without further treatment, as was shown by the fact that the baryta in the receiver remained free from barium carbonate.

Ammonia was estimated in duplicate in 2 ml. portions of the residues from both the carbon dioxide and the volatile acid experiments; these two values were always identical, within experimental error.

The complete results of two experiments are given in Table II. Since the product of reduction of proline (δ-aminovaleric acid) is not volatile, all these products must have arisen from the oxidation of alanine, and the figures though not exact show that by far the greater part of the alanine has been oxidised to one molecule of ammonia, one of a volatile acid and one of carbon dioxide from each molecule of alanine oxidised. (The possibility that the acid titration represents half a molecule of a dibasic acid need not be considered, as all the simpler volatile acids are monobasic.)

Table II. *Products of the reaction between 10 ml.* M/*10* d-*alanine and 10 ml.* M/*5 proline.*

Expressed as ml. *M*/10.

	Exp. 1			Exp. 2		
	Exp.	Control	Diff.	Exp.	Control	Diff.
Ammonia	9·5	0·5	9·0	9·8	0·4	9·4
Volatile acid	9·4	1·1	8·3	9·7	1·2	8·5
Carbon dioxide	10·4	0·8	9·6	8·1	0·3	7·8

(*c*) *The identity of the volatile acid.* (1) *By the* p-*toluidide.* The identification of a volatile acid is best effected by the formation of the *p*-toluidide. The yield of this derivative by the standard method is however very small, and it has proved impossible to obtain enough of the acid formed by oxidation of alanine by proline to identify it in this way.

(2) *By the lanthanum-iodine reaction.* Krüger and Tschirch [1929; 1930] described a test for acetate depending on the formation of a solution of basic lanthanum acetate, which gives a blue colour with iodine similar to that obtained with starch. The test is specific for acetate and propionate, but is modified or inhibited by many other anions. It is given strongly by the neutralised distillates from the oxidation products of alanine. When the test is carried out at room temperature, it is found that the depth of colour is by no means proportional to the concentration of acetate present but falls off very sharply between acetate concentrations of *M*/100 and *M*/500. (The original authors claim that by gradually heating the mixed solutions a positive reaction may be obtained down to *M*/6000 acetate, but the present author has not been able to detect less than *M*/1000 under any conditions.) The blue colour cannot therefore be used in the ordinary way for colorimetric estimation of acetic acid, but the sharp decrease in intensity between *M*/100 and *M*/500 may be used as the basis of a method of approximate estimation, in the following manner.

The acetic acid to be estimated is distilled over into excess of alkali, to free it from sulphate and phosphate which inhibit the reaction. The distillate is neutralised, evaporated if necessary and made up to such a volume that it contains roughly *M*/50 acetate (the correct dilution must be determined by trial). Into a series of test-tubes are measured volumes of this solution from 1·0 ml. down to 0·1 ml., and each is made up to 1 ml. Into another series of test-tubes are measured similar volumes of a standard $M/50$ solution of sodium acetate. To each of these tubes are now added 0·5 ml. of 5 % lanthanum nitrate solution, 0·5 ml. of $N/100$ alcoholic solution of iodine and three or four drops of N ammonia. From a comparison of the blue colours developed in the two series of tubes it is possible to deduce with some accuracy (probably ± 10 %) the concentration of acetate in the unknown solution.

This method was applied to the volatile acid distillates obtained from experiments on the oxidation of alanine by proline. The distillates after titration to neutrality were evaporated and made up as accurately as possible in a measuring cylinder to a volume corresponding to that which they had occupied in the original experimental tube (*viz.* 17·7 ml.). If the whole of the volatile acid were acetic acid, the concentration of acetate in this solution should now be $M/50$. The lanthanum-iodine test was carried out on a series of dilutions of this solution and simultaneously on a similar series of dilutions of a $M/50$ solution of sodium acetate. The details and results of two experiments are given in Table III. These figures show that, within the rather wide limits of experimental error, the whole of the volatile acid is acetic acid, since propionic acid, which also gives the test, is obviously impossible. The equation representing the oxidation of alanine can therefore be written

$$CH_3.CHNH_2.COOH-4H+2H_2O \rightarrow CH_3.COOH+NH_3+CO_2.$$

(*d*) *Intermediate products in the oxidation of alanine to acetic acid.* Though it is possible that this oxidation proceeds in a single step of four equivalents, it is far more likely to involve two steps of two equivalents each. The most probable course appears to be

$$(1)\ CH_3.CHNH_2.COOH-2H+H_2O \rightarrow CH_3.CO.COOH+NH_3,$$
$$(2)\ CH_3.CO.COOH-2H+H_2O \rightarrow CH_3.COOH+CO_2,$$

pyruvic acid being an intermediate compound. Experiments already quoted [Stickland, 1934] showed that pyruvic acid could not be detected at any stage of the reaction, whether the oxidant were cresyl blue, proline or glycine, within the limits of sensitivity of the nitroprusside test. Therefore if pyruvic acid is indeed the intermediate compound it must be oxidised as quickly as it is formed so that it does not accumulate in the solution. Direct proof of the occurrence of pyruvic acid has not been obtained, but evidence supporting this view has been obtained by proof of the following points:

(1) The rate of oxidation of the intermediate product is greater than that of alanine.

(2) The rate of oxidation of pyruvic acid is greater than that of alanine.

(3) The extent of oxidation of pyruvic acid is in agreement with equation (2) above.

(4) The products of oxidation of pyruvic acid are in agreement with equation (2).

(1) *The rate of oxidation of the intermediate compound.* If we consider the reaction between one molecule of alanine and one of proline, it is clear that (*a*) if the intermediate compound is oxidised at a negligible speed, then the whole of the alanine will be oxidised to this compound, and all its nitrogen will be liberated as ammonia; (*b*) if the intermediate product is oxidised very rapidly, then the proline will suffice for the complete oxidation of only one-half of the alanine, and only 50 % of the nitrogen will appear as ammonia. Thus the quantity of ammonia liberated in this reaction serves to indicate the relative velocities of oxidation of alanine and the hypothetical intermediate compound. To test this experimentally, three sets of Thunberg tubes were prepared containing (*a*) 0·5 ml. $M/10$ alanine, 0·5 ml. $M/10$ proline, 0·5 ml. phosphate buffer p_H 7·5 and 1·0 ml. suspension of *Cl. sporogenes*, (*b*) 0·5 ml. $M/10$ alanine, 0·5 ml. $M/5$ proline, 0·5 ml. buffer and 1·0 ml. suspension and (*c*) 1·0 ml. water, 0·5 ml. buffer and 1·0 ml. suspension. After anaerobic incubation at 40° for various periods, the ammonia was estimated in 2 ml. of the contents of one tube from each series, and these estimations were continued until the ammonia produced, corrected for the blank, remained constant. A typical result is shown in Fig. 1.

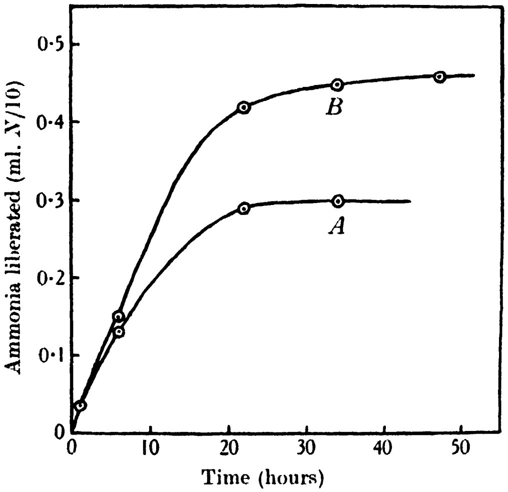

Fig. 1. The course of production of ammonia from: *A*. 0·5 ml. $M/10$ alanine + 0·5 ml. $M/10$ proline; *B*. 0·5 ml. $M/10$ alanine + 0·5 ml. $M/5$ proline.

In this case, while the reaction of alanine with two molecules of proline liberated as usual practically the whole of nitrogen of the alanine as ammonia, the reaction with only one molecule of proline gave only slightly more than half (60 %). Other similar experiments gave values of 58, 57, 68, 57, 66 and 60 % (average 61 %). It can therefore be concluded that if an intermediate compound is formed in the oxidation of alanine it is oxidised more rapidly than alanine itself.

(2) *The rate of oxidation of pyruvic acid.* In the first paper [Stickland, 1934] it was shown that, when cresyl blue is the oxidant, pyruvic acid is oxidised with a velocity about 40 % of that of the oxidation of alanine. Comparison of the rates of oxidation of alanine and pyruvic acid by glycine, however, showed that

in this case the latter is oxidised more rapidly than the former (Table IV). The rates were measured as usual by estimation of the rate of liberation of ammonia from the glycine; allowance is made for the fact that in the alanine oxidation ammonia is formed from both reactants, in the pyruvate from only one.

Table IV.

0·5 ml. $M/10$ glycine +0·5 ml. $M/10$	Ammonia produced in 5 hrs. (ml. $M/10$)	Rate of oxidation (ml. $M/10$ per hr.)	$\frac{\text{Rate of oxidation of pyruvate}}{\text{Rate of oxidation of alanine}}$
Alanine	0·32	0·021	2·1
Pyruvate	0·22	0·044	
Alanine	0·32	0·021	2·3
Pyruvate	0·24	0·048	

(3) *The extent of oxidation of pyruvate.* The extent of oxidation of pyruvic acid was measured by incubating a known amount of pyruvate with excess of glycine and determining the amount of ammonia liberated by reduction of the glycine, exactly as in the case of alanine.

Commercial pyruvic acid was distilled *in vacuo*, the fraction boiling at about 66°/15 mm. being collected. This was diluted with ice-cold water to give a roughly 10 % solution and stored in the ice-chest. Titration with alkali and titration of bisulphite-binding capacity agreed exactly, showing the product to be pure. For use in experiments portions of this solution were carefully neutralised immediately before use and diluted to $M/10$.

To measure the degree of oxidation of pyruvic acid, 0·5 ml. $M/10$ or $M/20$ sodium pyruvate solution, 0·5 ml. $M/2{\cdot}5$ or $M/5$ glycine, 0·5 ml. buffer of p_{H} 7·5 and 1·0 ml. of suspension of bacteria were placed in each of five Thunberg tubes, and in another five tubes the same solutions with 0·5 ml. of water replacing the pyruvate solution. Estimations of ammonia in experimental tubes and controls were carried out from time to time until no further increase was observed. The corrected value for the final ammonia produced showed that for each molecule of pyruvate oxidised one molecule of glycine was reduced (see Table V). This is the degree of oxidation required for the oxidation of pyruvate to acetate as in equation (2) on p. 892.

Table V. *Extent of oxidation of pyruvate.*

Pyruvate	Glycine	NH_3 corrected for blank (ml. $M/10$)	$\frac{\text{Mols. glycine reduced}}{\text{Mols. pyruvate oxidised}}$
0·5 ml. $M/10$	0·5 ml. $M/5$	0·39	0·8
0·5 ml. $M/20$	0·5 ml. $M/5$	0·21	0·8
0·5 ml. $M/20$	0·5 ml. $M/2{\cdot}5$	0·23	0·9

(4) *The products of oxidation of pyruvate.* The products of oxidation of pyruvic acid were determined exactly as in the case of alanine, by means of the reaction with proline. For estimation of volatile acid, two 75 ml. Thunberg tubes were prepared containing (*a*) 10 ml. $M/10$ sodium pyruvate, 10 ml. $M/10$ proline, 10 ml. $M/2$ buffer p_{H} 7·5 and 20 ml. suspension of bacteria and (*b*) 20 ml. water, 10 ml. buffer and 20 ml. suspension. These were evacuated and incubated at 40°. For carbon dioxide estimation two 50 ml. bottles, containing one-quarter of the above quantities of the solutions, were connected in the incubator to a series of three small wash-bottles each containing 5 ml. of $N/10$ baryta. These were rendered anaerobic by the passage of a current of oxygen-free nitrogen, with the precautions mentioned in the alanine experiment. The reaction could

obviously not be followed by estimation of the ammonia produced, so instead a series of small Thunberg tubes was set up with the same solutions in a total volume of 2·5 ml. (no controls were necessary), and the disappearance of the pyruvic acid followed by means of the nitroprusside test (2 % of the initial concentration gave a positive test, so disappearance of the test indicated that more than 98 % of the pyruvate had reacted). When the reaction was finished, the estimations of ammonia, volatile acid and carbon dioxide were carried out as before. The results of two such experiments are given in Table VI and are sufficient to show that from each molecule of pyruvic acid there arise one molecule of volatile acid and one of carbon dioxide.

Table VI. *Products of the reaction between 10 ml.* M/*10 Na pyruvate and 10 ml.* M/*10 proline.*

Results expressed as ml. *M*/10.

	Exp. 1			Exp. 2		
	Exp.	Control	Diff.	Exp.	Control	Diff.
Ammonia	0·5	0·6	0·0	0·6	0·5	0·1
Volatile acid	13·0	2·8	10·2	11·7	2·7	9·0
Carbon dioxide	8·2	0·3	7·9	10·7	0·7	10·0

The volatile acid was identified and roughly estimated by means of the reaction of Krüger and Tschirch [1929], in exactly the same manner as that arising from alanine. The result is given in Table VII, and the figures show that within the experimental error all the volatile acid is acetic acid (propionic acid may again obviously be excluded from consideration). This confirms the equation representing the oxidation of pyruvic acid given on p. 892.

The reduction of methylviologen by alanine.

In the first of these papers it was pointed out that the calculations of Wurmser and Mayer-Reich [1933] indicated that an alanine dehydrogenase system whose end-product was ammonium pyruvate should have a potential in the neighbourhood of r_H 12, while the alanine dehydrogenase of *Cl. sporogenes* actually reduced dyes down to about r_H 2 (methylviologen at p_H 8·0). This discrepancy can now be explained.

A concentration of *M*/50 *d*-alanine at p_H 7·5 gives about 10 % reduction of methylviologen. It was found on further investigation that sodium pyruvate under exactly the same conditions gave a much greater reduction, *viz.* about 70 %. The probable explanation of the reduction in the presence of alanine is that as soon as a trace of oxidation to pyruvate takes place, this product is further oxidised to acetate, and it is this second reaction which produces the measurable amount of reduction of the indicator. The final equilibrium reached, starting from alanine and methyl viologen, is a very complex one consisting of alanine-NH_4-pyruvate-acetate-bicarbonate-methylviologen-leucomethylviologen, and the quantitative relationships in a case like this have not yet been worked out, but it is evident that a qualitative explanation of the discrepancy mentioned above has been provided.

DISCUSSION.

The end-products of the oxidation of alanine by proline in presence of the enzymes of *Cl. sporogenes* are clearly ammonia, acetic acid and carbon dioxide. Attempts to show directly that pyruvic acid occurs as an intermediate stage in the oxidation have failed; for instance, the addition of sodium arsenite, used successfully by Krebs [1933] for this purpose in the case of mammalian tissue slices, completely inhibited the whole reaction. The indirect evidence obtained, however, is all in favour of pyruvic acid as an intermediate product, and it may be considered as extremely probable that the reaction occurs in the stages given in the equations on p. 892.

IV. THE REDUCTION OF GLYCINE BY *CL. SPOROGENES*.

EXPERIMENTAL.

Estimation of the products of reduction of glycine.

As the products of oxidation of alanine have already been shown to be acetic acid, carbon dioxide and ammonia, the determination of the products of the reaction between alanine and glycine would suffice to decide the fate of the glycine. Experiments were therefore carried out in which one molecule of alanine was oxidised by two molecules of glycine. The experiments were set up as before in three sections: (*a*) for volatile acid estimations, a 75 ml. Thunberg tube containing 10 ml. $M/10$ *d*-alanine, 10 ml. $M/5$ glycine, 10 ml. $M/2$ phosphate buffer p_H 7·5 and 20 ml. bacterial suspension, (*b*) for carbon dioxide estimation, a 50 ml. bottle containing 2·5 ml. $M/10$ alanine, 2·5 ml. $M/5$ glycine, 2·5 ml. buffer and 5 ml. suspension, and (*c*) for following the course of the reaction, a set of five 10 ml. Thunberg tubes each containing 0·5 ml. alanine, 0·5 ml. glycine, 0·5 ml. buffer and 1·0 ml. suspension. In each case control experiments were also prepared, differing by the omission of both amino-acids. The Thunberg tubes in (*a*) and (*c*) were evacuated in the usual way and incubated at 40°. The bottles in (*b*) were connected in the incubator at 40° to a series of three wash-bottles, each containing 5 ml. of $N/10$ barium hydroxide and rendered anaerobic by the passage of a stream of pure nitrogen, with the precautions mentioned in the previous paper. The reaction was followed by estimation of the ammonia in 2 ml. of the contents of the small Thunberg tubes (*c*), and incubation was continued until the quantity of ammonia liberated, corrected for the control, approached the theoretical for the complete reaction. In most experiments the reaction started immediately, was almost complete (about 90 %) in 24 hours and had reached 97–98 % of the theoretical value in 48 hours. Volatile acid was estimated in the contents of the large Thunberg tubes, after removal of the chloride with silver sulphate, by distillation *in vacuo* into standard barium hydroxide, and carbon dioxide by titration of the barium hydroxide in the wash-bottles, as described in the first part of this paper.

Ammonia was estimated in both the volatile acid experiment (*a*) and the carbon dioxide experiment (*b*), always with concordant results. The results of two experiments are given in Table I. The figures show that when one molecule of alanine is oxidised by two molecules of glycine, there arise three molecules of ammonia, one of carbon dioxide and three of volatile acid. Of these products, one molecule of ammonia, one of carbon dioxide and one of volatile acid (acetic) proceed from the oxidation of the alanine, so that two molecules each of ammonia and of a volatile acid must be the products of the reduction of two molecules of glycine.

Table I. *Products of the reaction between 10 ml.* M/10 d-*alanine and 10 ml.* M/5 *glycine.*

Results expressed as ml. $M/10$.

	Exp. 1			Exp. 2		
	Exp.	Control	Diff.	Exp.	Control	Diff.
Ammonia	31·8	2·6	29·2	30·6	1·2	29·4
Carbon dioxide	10·1	1·4	8·7	10·5	0·7	9·8
Volatile acid	30·8	1·8	29·0	30·5	3·7	26·8

The identification of the volatile acid.

(*a*) *By the* p-*toluidide.* The acid distillates from one experiment were collected, evaporated to dryness and dried at 110°. The solid was heated with *p*-toluidine and a little strong hydrochloric acid in the usual way, and from the mixture about 25 mg. of a toluidide were separated. After two recrystallisations from hot water, only a few milligrams of a still slightly impure product remained, and with this a melting-point determination was made and a mixed melting-point with some pure acet-*p*-toluidide. The figures obtained were:

	Melting-point
Acet-*p*-toluidide	147°
Product from action of bacteria	145°
Mixture	146°

These are sufficient to indicate that the volatile acid consisted at any rate chiefly of acetic acid.

(*b*) *By the lanthanum-iodine test.* The acid was identified and roughly estimated by the method already described, based on the reaction of Krüger and Tschirch [1929]. Table II contains the results of one such experiment, with the results of an experiment on the oxidation of alanine by proline for comparison. The results show that, within the rather large limits of experimental error, all the volatile acid produced is acetic acid.

CONCLUSION.

The formation of one molecule of ammonia and one of a volatile acid from each molecule of glycine reduced, and the identification of the acid as acetic acid, show that the reduction of glycine can be expressed by the following equation:

$$CH_2NH_2COOH + 2H \rightarrow CH_3COOH + NH_3.$$

The formation of acetic acid from glycine by the action of mixed cultures of putrefactive bacteria has already been demonstrated by Brasch [1909].

SUMMARY.

When alanine is oxidised by *Cl. sporogenes*, at the expense of the reduction of proline or glycine, it loses four equivalents of hydrogen and yields one molecule each of acetic acid, carbon dioxide and ammonia.

The reaction probably proceeds in two stages of two equivalents each, ammonium pyruvate being the intermediate product.

Washed suspensions of *Cl. sporogenes* reduce glycine, at the expense of the oxidation of alanine, to acetic acid and ammonia.

CVIII. THE ABSORPTION SPECTRA OF ACIDS FROM FISH-LIVER OILS[1].

By JOSEPH RATCLIFFE EDISBURY
AND RICHARD ALAN MORTON,
Department of Chemistry, University of Liverpool,
AND JOHN ARNOLD LOVERN,
Torry Research Station, Aberdeen.

(*Received February 28th, 1935.*)

It has already been demonstrated [*cf.* Gillam *et al.*, 1931; Edisbury *et al.*, 1933] that although most naturally occurring glycerides, whether saturated or unsaturated, or of animal or vegetable origin, are relatively diactinic, the mixed acids derived from them by prolonged saponification often show intense and highly selective absorption in the ultra-violet. This was found to apply in a particularly striking manner to fish-liver oils and their acids. In a series of acids from several species, narrow absorption bands some 10 $m\mu$ wide were repeatedly recorded at or near 270, 282, 290 (inflection), 301·5, 316·5, 332, 348, 360 (inflection), 377 and 401$m\mu$, and less frequently near 234, 259, 422, 445 and 460 $m\mu$. It was shown that (i) the bands owe their origin to unsaturation in the absorbing molecules; (ii) these highly absorbing acids, of which there appear to be at least five, are not present as the corresponding glycerides in the original freshly extracted oils; (iii) the hypothesis that the acids are open chain compounds is not in harmony with the spectrographic evidence; (iv) a change,

unsaturated acids (low absorption) → unsaturated acids (high and selective absorption),

occurs during the saponification treatment; (v) cyclisation to form polycyclic hydroaromatic compounds is the most plausible explanation of the change; (vi) this change can also occur, spontaneously and without hydrolysis, within the more unsaturated glyceride molecules and is considerably accelerated when the oil is dissolved in a hydrocarbon solvent; but it occurs at best extremely slowly and to a limited extent, involving only a minute proportion of the available material, even when the oil is allowed to stand indefinitely. The change is however quite definite, and is easily detectable if a light source giving a continuous spectrum is employed (*e.g.* hydrogen vacuum tube, or high frequency discharge under water).

We have since found, on the other hand, that the selective absorption of the mixed free acids as usually prepared undergoes little if any change with time; thus, a sample of ling-liver oil acids, which had been kept in nitrogen in a sealed tube for 1½ years, showed little difference between the absorption spectra at the beginning and end of that period, apart from a slight decrease in the persistence of the bands, due probably to the gradual development of general absorption. Richer preparations (*vide infra*) are apparently not so stable. It is entirely unknown what causes the initial development of narrow absorption bands in a neutral liver oil, or what inhibits this spontaneous cyclisation process and prevents the production of more than minimum quantities of cyclised material. For the present, therefore, our attention must be confined to the acid products.

---

[1] The substance of this paper was read at the 166th meeting of the Biochemical Society (Liverpool, Dec. 15th, 1934).

Dann and Moore [1933] and Dann *et al.* [1935] showed that although, under suitable conditions, saponification of cod-liver oil was practically complete in a few minutes, the acids so produced exhibited only weakly selective absorption, whilst by prolonging the heating with alcoholic potash the intensity and selective nature of the absorption could be greatly enhanced. They confined their preliminary observations to the middle and further ultra-violet regions. We have confirmed their observations and extended them to the near ultra-violet and the edge of the visible region, and we have found, incidentally, that herring-body oil exhibits the effect quite as strikingly as cod-liver oil. This is interesting because in our earlier work we noted that although the development of highly selective absorption by the saponification products was predominantly a characteristic of oils containing vitamin A, no quantitative connection could be traced between this absorption and the vitamin content. The herring-body oil which we examined (kindly supplied by Prof. Channon) was highly coloured, but gave no blue colour with antimony trichloride, and therefore contained no β-vitamin A. Nevertheless, the results of saponification are in no way inferior to those we have already obtained with a number of fish-liver oils and pancreatic and peritoneal fats, all of which contained vitamin A. Little selective absorption was exhibited by the oil itself in the ultra-violet. The acids obtained as a result of saponification for one minute formed a yellow oil, showing clear bands (though of small persistence) at 270 and 283 $m\mu$ and several others, more poorly defined, nearer the visible. Vigorous saponification for some hours destroyed much of the yellow colour and resulted in greatly increased persistence and definition all round, with an increase in intensity in the middle ultra-violet and a decrease in the region 300–400 $m\mu$. Some substance (possibly an acid pigment exhibiting general or weakly selective absorption in this region and giving rise to the yellow colour of the oil and of the mildly saponified product) was largely destroyed during prolonged saponification. Similar remarks apply, *mutatis mutandis*, to the 270 $m\mu$ portions of the curves for the original oil and the one minute saponification product. In any event, the generally increased persistence of the bands again proves that, despite the reduction in overall intensity above 300 $m\mu$, prolonged saponification has resulted in an increased yield of the highly absorbing acids.

In view of the success attained in securing increased yields by prolonged heating with ethyl alcoholic potash, it was decided to try the effect of saponifying cod-liver oil at different temperatures. Methyl, amyl and octyl alcohols were used as solvents, giving under reflux at atmospheric pressure, reaction temperatures of approximately 70°, 135° and 180° respectively, after allowing for the presence of oil *etc.*, in solution. The spectrographic results are summarised in the first part of Table I.

At this juncture it may be well to explain the system of notation we have adopted for this type of investigation. The figures in Table I record both the absorption intensity and the persistence of the various bands, reduced to a common basis of comparison, namely $E^{1\%}_{1\,\text{cm.}}$, which represents the extinction $\left(\log_{10}\frac{\text{incident light}}{\text{emergent light}}\right)$ of a 1 cm. layer of a 1 % solution at the particular wavelength concerned. The upper figure in each pair gives the $E^{1\%}_{1\,\text{cm.}}$ value at the head or maximum of an absorption band, whilst the lower figure shows approximately the persistence of that band, a quantity which is most conveniently

Table I.

Note. ~ denotes inflection. Figures represent $E^{1\%}_{1\,\mathrm{cm.}}$ values; intensity above, persistence (approx.) beneath, in italics, taken as difference between max. and nearest related minimum.

taken as the difference between the $E^{1\%}_{1\,\text{cm.}}$ values at the maximum and at the nearest related minimum (*i.e.* $E_{\text{max.}}-E_{\text{min.}}$). Inflections, by this definition, have no persistence. Owing to the unknown extent to which irrelevant absorption of a general (unselective) nature contributes to the observed total absorption curve, it is necessary to take into account persistence as well as gross intensity of absorption in order to form even a rough estimate of the relative quantities of selectively absorbing material present in different samples. In these experiments, many normally well-defined bands are so completely masked by other absorption as to be rendered imperceptible or reduced in some cases to an inflection with a much higher gross $E^{1\%}_{1\,\text{cm.}}$ value than that of the original band, the net intensity of which may remain indeterminate apart from the fact that an extreme upper limit is set by the observed $E^{1\%}_{1\,\text{cm.}}$ value of the inflection.

It will be seen from Table I that saponification at relatively elevated temperatures rapidly results in a surprisingly good yield of the highly absorbing acids and that temperature is an even more effective factor in their formation than time, so far at least as the acids responsible for selective absorption below 300 $m\mu$ are concerned; a rise in reaction temperature from 70° to 135° accounts for a hundredfold increase in the yield of these acids. Further prolonged heating at the same temperature causes a greater percentage increase in the acids absorbing in the region above 300 $m\mu$ than in those below 300 $m\mu$, and an increase in temperature to 180° again favours those over 300 $m\mu$. On still further prolonging the heating at 180°, a marked decrease is observed in the absorption below 300 $m\mu$, with a roughly corresponding increase above 300 $m\mu$. In the present state of knowledge it seems probable that the acids responsible for the latter are of higher molecular weight and either more complex as regards ring structure and/or more unsaturated than the acids with maxima below 300 $m\mu$.

The precise mechanism whereby cyclisation is induced is by no means clear, but it is worth noting that when the acids from the methyl alcohol saponification were heated in nitrogen for an hour at 135°—the amyl alcohol saponification temperature—the principal change was an all-round but not very marked increase in general absorption, reflected in a perceptible deepening in colour, with an increase in selective absorption only in the case of two bands, 270 and 317 $m\mu$.

An attempt was made on similar lines to cyclise the dry neutral soaps. The product showed practically the same intensity of absorption as the corresponding material from amyl alcohol saponification, but such bands as could be detected were of poor persistence, and some were entirely masked by general absorption. During the heating considerable charring occurred, which would account for much of the general absorption. The presence of a solvent evidently prevents this charring, whilst the alkali (possibly assisted in some way by the solvent) apparently plays an important if at present obscure part in the cyclisation process.

As would be expected, the iodine value steadily decreases during the cyclisation process, from 175·0 for the original oil to 137·6, 129·6 and 115·1 for the products of saponification in amyl alcohol (6 hours) and octyl alcohol (1 and 6 hours) respectively. It is interesting that the iodine value remains as high as it does, suggesting that large quantities of aliphatic unsaturated material must still be present, both in the form of unchanged uncyclised acids and also, probably, as long side-chains attached to partially hydrogenated aliphatic nuclei resulting from the cyclisation process. From the absorption data, it seems unlikely that direct polymerisation is responsible for more than a fraction of the observed decrease in iodine value, although the possibility cannot be altogether excluded that subsequent combination of already cyclised molecules may occur and give rise to polycyclic nuclei absorbing in the near ultra-violet and visible regions. This of course is pure conjecture; nevertheless, the hypothesis is attractive and is not inconsistent with the spectrographic evidence.

Most of the constituents of fish-liver oils are obviously not cyclisable to give acids of the type under discussion. Only the highly unsaturated C_{20} and C_{22} ("clupanodonic") acids, with four and five ethenoid linkages, appear to have a sufficiently long and sufficiently unsaturated carbon chain to provide a suitable starting material. Accordingly it was decided to prepare these C_{20} and C_{22} acids in as pure a state as possible and then to cyclise them. 800 g. of cod-liver oil were saponified in the normal manner, the unsaponifiable matter removed and the acids, still largely uncyclised, recovered. These were submitted once to a lithium salt/acetone separation, yielding 140 g. of highly unsaturated acids which were esterified and distilled *in vacuo*. The following fractions were collected:

Fraction	Weight g.	Boiling-point	Saponification equivalent	Iodine value
1	27·5	130–155°	285·5	212·8
2	42·2	155–165°	313·6	322·5
3	21·7	165–180°	328·1	333·0
4	35·7	180–186°	348·5	340·0
Residue	—		Not examined	

Fractions 2 and 4 were respectively fairly pure C_{20} and C_{22} esters, and were separately cyclised for 6 hours with amyl alcoholic potash; octyl alcohol might have increased the yield, but was not used since it is apt to give exceedingly intractable emulsions. On recovering the acids, the iodine values had fallen to 227·1 for the C_{20} and 251·0 for the C_{22} acids. This would represent a loss in each case of between 1 and 2 double bonds. Polymerisation is again not likely to have been extensive, and it is probable that mixtures of monocyclic, dicyclic and polycyclic products with one or more side-chains were formed. The cyclised C_{20} and C_{22} acids gave qualitatively similar absorption spectra (Table I). This may plausibly be taken to indicate that, so far at least as the major light-absorbing constituents are concerned, there is little essential difference in the nuclei derived from the two fractions—possibly the substitution of an ethyl or one or two methyl groups in the C_{22} product for hydrogen atoms in the C_{20}. The available evidence is not inconsistent with the view that hydronaphthalene derivatives with fairly long side-chains, and also, probably, polycyclic compounds with a low degree of unsaturation, predominate among the absorbing constituents and are distributed roughly equally between the two fractions. The absorption above 300 $m\mu$ further suggests that the C_{22} material is considerably richer in the more unsaturated polycyclic bodies than the C_{20} acids. These latter polynuclear substances appear, however, to be present in relatively small proportions.

There is abundant evidence that several absorbing entities are responsible for the complex absorption curve of the acids. In view of the occurrence of cyclised products it seemed possible that a repetition of the lithium salt/acetone process might effect some separation of the unchanged acids from the others, or of those less highly cyclised (hydronaphthalenic) from those more so (tricyclic *etc.*). The following fractions were obtained:

	Weight in g.	Iodine value
C_{20} acids (liquid)	14·65	231·8
„ (semi-solid)	11·85	225·7
C_{22} acids (liquid)	21·16	259·9
„ (solid)	1·95	203·2

The absorption spectra of these fractions are also shown in Table I, and it will be seen that a very material increase in the concentration of (presumably) polycyclic acids was achieved in the solid C_{22} fraction. Otherwise the degree of separation attained, while by no means insignificant, was disappointing.

Further separation was attempted on both the C_{20} fractions, but the products showed signs of decomposition and polymerisation. For example, although the products, initially clear liquids soluble in light petroleum, were kept under nitrogen, many became gummy and insoluble in the course of a week. Details of this fractionation are given in Tables II *a* and II *b*, to illustrate the type of

behaviour encountered. Fraction B, for example, would be expected to be richer in the highly absorbing acids than fraction C. This may possibly have been the case initially, but by the time (2 or 3 days) that it could be examined spectrographically it had deteriorated markedly and contained a number of flexible tubular bodies, not unlike small worms in appearance and insoluble in alcohol (B^1). These, like the other fractions, refused to crystallise, remaining flexible even at $-20°$. Little apparently is to be gained by repeating the lithium process on the C_{20} acids, and there was insufficient of the C_{22} solid acids available to render an attempt on these profitable. The C_{22} liquid acids polymerised like the C_{20} material.

Owing partly to this instability and partly to a desire to prepare solid derivatives, it was decided to brominate samples of the cyclised acids. In sharp contrast to the uncyclised acids, no precipitate was obtained on brominating the cyclised product in ethereal solution. The bromination was therefore carried out in light petroleum. The C_{20} and C_{22} acids were not in this case freed from monoethylenic esters. 76 g. of cyclised C_{20} acids, and 80 g. of cyclised C_{22} acids, were brominated. In each case, dark green sticky precipitates were obtained, and all attempts at crystallisation failed. A considerable amount of material remained in solution in the light petroleum and was recovered, 90 g. from the C_{20} and 53 g. from the C_{22} acids. Both these petroleum-soluble fractions had a strong camphor-like odour. On debromination with zinc and alcoholic hydrogen chloride, they yielded respectively 25 g. (iodine value 122·5) and 12·5 g. of ethyl esters. The C_{20} insoluble bromides weighed 111 g. and on debromination gave 43·3 g. of ethyl esters (iodine value 171) with an aromatic odour: those from the C_{22} acids resulted in a black tarry product which was not examined. The iodine values mentioned indicate respectively a mean unsaturation of two double bonds and a mixture of mono- and di-ethylenic substances, but spectrographic examination of all the available material showed that very little separation of the selectively absorbing acids had been effected, and that a considerable amount of decomposition had occurred. Bromination as a means of attacking the problem was accordingly abandoned, and other methods of preparing solid derivatives are being attempted.

With a view to confirming the presence of polynuclear ring systems in the structure of the selectively absorbing acids, attempts have been made to identify some of the products of selenium dehydrogenation (Diels's method). The acids from 1 kg. of cod-liver oil were subjected to a lithium salt/acetone separation, and 164 g. of crude highly unsaturated acids obtained. These were converted into ethyl esters and distilled, and distillation was stopped when the esters below C_{20} had come over. The residue (C_{20} and C_{22} esters) was cyclised by saponification for 6 hours in amyl alcohol; the mixture of C_{20} and C_{22} was used in order to provide an adequate quantity of representative starting material. The cyclised product weighed 109 g. During dehydrogenation there was considerable evolution of volatile oily matter (215–250°), presumably alkyl selenides resulting from removal of side-chains from the nuclei. The action then apparently ceased until the temperature was raised to 290–300°, when evolution of hydrogen selenide commenced. The product after heating for 26 hours was taken up with ether, excess selenium filtered off and the filtrate shaken with sodium carbonate to removed unchanged acid. A considerable amount of colour was removed. After washing thoroughly and removing the solvent, a dark brown tarry liquid remained, weighing 78 g. and having an iodine value of 53·8. This was extracted three times with hot alcohol, giving a brown solution with a strong green fluorescence. No solid matter could be recovered from the alcoholic extract, and

Table III *a*. *Distillation of selenium-dehydrogenation product.*

the solvent was removed, leaving an oily brown liquid. The material insoluble in hot alcohol was a black tarry solid which was not further examined.

Attempts to prepare insoluble picrates from the alcohol-soluble material failed. The picric acid, however, evidently reacted with some constituent of the material, for the green fluorescence disappeared and a red colour developed. On removal of the picric acid with ammonia the original colour and fluorescence were restored. The material was next distilled at 2 mm. pressure and the fractions shown in Table III *a* collected. It seems probable that the true fluorescence of the residue is violet, the green effect arising from a combination of this violet with the natural brown colour of the residue.

All the fractions were examined spectrographically, with the results shown in Table III *b*. An attempt has been made here to classify the types of absorption bands encountered in these fractions—the "narrow" carotenoid type, some 10–20 $m\mu$ wide (*n* in Table), the "fine" band about 5–10 $m\mu$ wide, as exhibited by anthracene and phenanthrene (*f* in Table), and the "aromatic" type, 2–5 $m\mu$ wide (*a* in Table), characteristic of naphthalenic hydrocarbons.

The characteristic absorption maxima of some naphthalenic hydrocarbons are given in Table IV. The similarity between the wave-lengths of the various materials is noteworthy, and whilst amply confirming the presence of a bicyclic aromatic ring system among the dehydrogenation products, emphasises the difficulty of specifically identifying the compound(s) responsible for the absorption. From available data on the relative intensities of absorption at the various maxima, it seems highly probable that a mixture of dimethylnaphthalenes predominates amongst the selectively absorbing products (though present only to the extent of some 5 %), but that naphthalene itself and several of its other derivatives are also likely to be present, together with upwards of 90 % extraneous material exhibiting general absorption. From the well-known inefficiency of the selenium dehydrogenation process (order of yield 3–10 %) the proportion of hydroaromatic bodies in the material before dehydrogenation must have been considerable, though it is conceivable that cyclisation might

also have occurred during the early stages of the dehydrogenation process, which appeared to have two well-defined phases.

In any event, however, the presence of aromatic compounds demonstrates that the ability to cyclise is an inherent property of the more unsaturated higher acids. The product is too complex to be worked up by the usual means of picrate or styphnate preparation, owing probably to the presence of partially dehydrogenated products and decomposition products, and also to the presence of several different nuclei in the starting material. Fraction 1, for example, probably contains something of the order of 5 % of mixed dimethylnaphthalenes.

The absence of selective absorption in the region 295–303 $m\mu$ is explicable on the grounds that the absorption curve is here relatively steep, the bands overlapping and masking each other. The bands in the region 330–400 $m\mu$ almost certainly owe their origin to more complex polynuclear systems of the anthracene, phenanthrene, or some higher type. Here again it is at present impossible to identify the substances responsible, for much work remains to be done on such compounds and their derivatives, and the bands here observed do not exactly correspond in position with those given by any polynuclear material for which spectrographic data are at present available. The absorption spectra of aromatic polynuclear materials present, however, a characteristic and unmistakable appearance on the photographic plate, and while this generic similarity increases the difficulty of specific identification of the components of a mixture, it leaves little doubt concerning the type of compound responsible for the absorption.

SUMMARY.

It was shown by earlier work that, although most natural glycerides are relatively diactinic, the acids prepared from them by saponification often show intense, highly selective absorption, particularly in the case of fish oils. Attempts have now been made to concentrate and isolate the absorbing acids and to elucidate their structure. The attempts have been only partially successful, but although the acids have not yet been isolated in a pure state, they have been obtained in much higher concentration than hitherto by prolonged saponification at fairly high temperatures. Thus, saponification for one hour at 135° increased the yield a hundredfold, compared with similar treatment at 70°. Of the methods of separation attempted, the lithium salt/acetone process has given the best results. The solid C_{22} acids from this process represent the best source at present known of the acids absorbing near 350 $m\mu$, and the liquid C_{20} acids of those absorbing near 270 $m\mu$, the concentrations achieved over the original mixed acids (70° saponification) being of the order 10,000 to 1 and 500 to 1 respectively. Cyclisation of the natural C_{20} and C_{22} polyethylenic acids to form hydroaromatic polycyclic derivatives is the most plausible explanation of the changes in absorption, and now receives further support from (1) a marked decrease in iodine values with increasing absorption, and (2) the identification of definite aromatic nuclei, mainly naphthalenic, but some undoubtedly more complex, among the products of selenium dehydrogenation.

We are indebted to the Medical Research Council for a full time personal grant to one of us (J. R. E.).

CIX. THE NON-PROTEIN NITROGEN OF PULSES.

By KAMALA BHAGVAT and MOTNAHALLI SREENIVASAYA.

From the Department of Biochemistry, Indian Institute of Science, Bangalore.

(*Received February 26th, 1935.*)

The saline extract obtained in the preparation of globulins and albumins from pulses contains a non-protein nitrogenous fraction, which is dialysable, not coagulated by heat and not precipitated by saturation with salts or even by reagents such as trichloroacetic acid. Work on foodstuffs relates chiefly to the predominant protein characterising the seed and in the case of pulses the well defined and easily characterisable globulins have received the greatest amount of attention. The methods usually employed for their isolation render recovery of the non-protein nitrogenous bodies extremely difficult and cumbersome. Further, at the moment, there are no systematic methods for investigating a mixture of the complexity represented by this fraction. It is not surprising therefore that this valuable fraction has not hitherto received adequate attention.

It has been suggested that this non-protein fraction arises during the course of the preparation of proteins and that it is not originally present as such in the seed; but experiments have shown that it persists under carefully controlled conditions which preclude its enzymic formation. Whatever be the mechanism of its origin, it has not been generally taken into account in any of the investigations carried out on pulses.

Blish [1918] has investigated the non-protein nitrogen of wheat flour and indicated the probable presence of a non-protein nitrogenous substance not precipitated by copper hydroxide, non-amino and non-peptide in character. Ranga Rao and Sreenivasaya [1933, 1] have shown that the non-protein fractions of the body fluids of the lac insect obtained by (1) salt saturation and (2) coagulation by acetic acid, contain simple polypeptides which have an average complexity (ratio of total to amino-nitrogen) of 4·7. They [1933, 2] have further demonstrated the presence of free tyrosine which occurs to the extent of about 2·5 % of the non-protein fraction. Sreenivasan and Subrahmanyan [1934] have drawn attention to the presence of non-coagulable forms of nitrogen in the saline extract of leguminous seeds which may have great nutritive value.

In view of their simpler structure these nitrogenous compounds should be among the most easily digestible and assimilable; they may help the peptisation of the associated proteins and influence their enzymic digestion by providing the necessary activators and further they may supplement the nutritional deficiencies of the associated proteins and enhance their biological value. It is therefore obvious that this non-protein fraction merits a detailed investigation from all points of view and the present study relates to a determination of the percentage and average complexity of the non-protein nitrogen lost during the preparation of proteins by various methods.

EXPERIMENTAL.

Nine of the well-known Indian pulses, after air-drying, were powdered to pass through a 40-mesh sieve; with the exception of *Cajanus indicus*, *Lens esculenta*, *Cicer arietinum* and *Phaseolus mungo* which could be easily freed from husks, the pulses were powdered along with the husk. The meal (100 g.) was extracted for 24 hours at 0° with 100 ml. of 5 % NaCl by shaking the mixture at frequent intervals. On filtering the mixture a clear solution was obtained. The entire operation was carried out in a refrigerator maintained at 0° and in presence of toluene.

Total nitrogen was determined by the Kjeldahl method and amino-nitrogen by the method of Van Slyke in all the solutions examined. Ultrafiltration was carried out through collodion membranes under a pressure of 50 kg. per cm.^{2} employing 50 ml. of the saline extract, which was kept electromagnetically stirred during the filtration. This facilitated rapid filtration and prevented clogging of the pores of the membrane.

The trichloroacetic acid filtrate was obtained by treating 20 ml. of the saline extract with 5 ml. of 20 % trichloroacetic acid. The precipitate was filtered off, washed with 2 % trichloroacetic acid and the filtrate made up to 50 ml. Aliquots of 20 and 10 ml. were used for the total and amino-nitrogen respectively.

20 ml. of the saline extract were kept in a steam steriliser for 1 hour, the coagulated protein was filtered off, washed with 5 % NaCl and the filtrate made up to 50 ml. 20 and 10 ml. were used for the total and amino-nitrogen respectively.

Dialysis was carried out in collodion bags (prepared from a 6 % solution of pyroxylin (B.D.H.) in ether-alcohol mixture) against distilled water until the dialysate was free from chloride. The contents of the bag along with the precipitated protein were transferred to a beaker and treated with a sufficient quantity of sodium chloride to redissolve the precipitate and the volume was made up to 150 ml. with 5 % NaCl. An aliquot of 20 ml. was used for total nitrogen. The difference between this value and the total nitrogen of the crude extract gave the value for the diffusible non-protein nitrogen.

Ammonium sulphate was employed for the salt saturation experiments, since it is commonly used in all preparative work. The precipitate thus obtained was centrifuged, washed with a saturated solution of ammonium sulphate, redissolved in water and reprecipitated with 10 ml. of 20 % trichloroacetic acid. The precipitate was filtered off, washed with 2 % trichloroacetic acid until free from ammonia and used for determination of the total nitrogen. The difference

DISCUSSION.

The non-protein nitrogen has been determined by five different methods each of them representing a well-defined process conventionally adopted in the study of proteins. The quantity thus lost varies from 10 to 55 % of the nitrogen extractable by saline solution, depending upon (1) the nature of the pulse under investigation and (2) the method adopted for the estimation of the non-protein fraction. Trichloroacetic acid is usually employed as a precipitant for proteins in various physiological fluids. Dialysis is a recognised method for the isolation of the globulins which are thrown out of solution as the dialysis proceeds, while saturation with ammonium sulphate offers a convenient method for the precipitation and purification of globulins and albumins. Ultrafiltration was adopted as a method of isolating the non-protein nitrogen of the saline extracts, since it offers possibilities of fractionating the nitrogenous bodies without contaminating extracts with acids and salts difficult to eliminate at a later stage. In the present study however only one grade of membrane has been used for all the pulses investigated.

Heat brings about coagulation not only of the globulins but also of the albumins and practically the same result is achieved by saturation with ammonium sulphate but with this difference, that the proteins are not denatured. There should therefore be fair agreement between the two sets of values; such agreement does indeed exist in the cases of the last three pulses in Table II. The higher the average complexity of the nitrogenous bodies in the crude extract, the less will be the nitrogen lost in the filtrate after heat coagulation. *P. radiatus*, for example, whose crude saline extract has the highest average complexity in the series (15·9), suffers the least loss of nitrogen not only during heat coagulation but also during ultrafiltration and precipitation with trichloroacetic acid. Similarly it will be observed that the last four pulses in Tables I and II, whose nitrogenous bodies in the saline extract possess lower complexities (6·4–7·4), yield high percentages of the non-protein fraction on heat coagulation and also on ultrafiltration and precipitation with trichloroacetic acid.

It will be seen that there is general agreement between ultrafiltration and trichloroacetic acid precipitation except in the case of *P. mungo*, which indicates that the membrane used for ultrafiltration is impermeable to all that the trichloroacetic acid is able to precipitate. This is born out by the fact that none of the ultrafiltrates yields any precipitate with trichloroacetic acid.

The average complexities of the "non-protein" fractions obtained by ultrafiltration and precipitation with trichloroacetic acid, in the case of the pulses examined, are always lower than the corresponding figure for the fraction obtained by heat coagulation, whose uniformly higher complexity indicates the presence or peptones and higher polypeptides in the filtrate. Further confirmation of this fact is obtained by the observation that the filtrates after heat coagulation give a further precipitate with trichloroacetic acid. Particular interest attaches to the heat-coagulated fraction since heat coagulation represents the nearest approach to the conditions of cooking and corresponds to the portion generally administered to invalids and children. It is interesting to observe that the average complexities of the fractions in general run parallel with the recognised ease of their digestibilities. The non-protein fraction of *P. aconitifolius*, for instance, has the lowest ratio of 2·8 in the heat coagulation series, a fact which is in harmony with the reputation which this pulse enjoys as a very easily digestible and assimilable source of nitrogen during convalescence. This is apparently contradictory to the findings of Niyogi *et al.* [1932] that the protein of *P. aconitifolius* is poor both as regards its digestibility and biological value. It only suggests the supplemental value of the non-protein fraction and emphasises its importance in influencing the digestibility and biological value of the protein.

The saline extracts, the ultrafiltrates and the heat-coagulated filtrates were examined to see if they contained any of the essential amino-acids in a free condition. An active preparation of tyrosinase from *Dolichos Lablab*, was employed to test for tyrosine and related compounds like 3:4-dihydroxyphenylalanine. In view of the high concentration of chlorides and carbohydrates, tryptophan could not be tested for with glyoxylic acid. Results of the tyrosine test, given in Table III, indicate that only two of the pulses examined, *P. aconitifolius* and *P. radiatus*, show the presence of tyrosine definitely, the former containing a much higher concentration of the amino-acid, in all the three different filtrates tested. In the case of *Dolichos*, tyrosine could not be detected in the heat-coagulated filtrate, while its presence was unmistakable in the crude extract and in the ultrafiltrate. This observation together with the fact that the *Dolichos* extract gradually darkens on keeping, points to the conclusion that tyrosine is gradually liberated from the proteins through the action of the associated protease which becomes inactivated during the process of heat coagulation.

P. radiatus	+	+	+
D. Lablab	+	+	–

SUMMARY.

The saline extracts obtained during the preparation of globulins and albumins from pulses, contain a non-protein nitrogenous fraction, which occurs to the extent of 10–55 % of the total nitrogen depending upon the nature of the pulse and the method of determination.

This non-protein fraction has been shown to contain the simpler, easily digestible and assimilable peptides which have an average complexity varying from 1·8 to 3·8. In some cases the existence of free tyrosine or simple derivatives thereof has been demonstrated.

Attention has been drawn to the fact that heat coagulation constitutes the nearest approach to the conditions of cooking and the fraction thus obtained represents the portion usually administered to children and invalids.

Our thanks are due to Dr V. Subrahmanyan for his kind interest in the work.

CX. THE EFFECT OF HYPNOTICS ON GLUCOSE TOLERANCE.

BY HENRY TOD[1].

From the Royal Edinburgh Mental Hospital.

(*Received February 28th, 1935.*)

IN the course of an investigation into the glucose tolerance of mental patients, four extremely abnormal curves were obtained. In these there was little or no initial rise in blood sugar after the ingestion of 50 g. glucose and the blood sugar fell to low levels. The only abnormality found in the circumstances of these curves was that in each case the patient received a dose of a hypnotic previous to the ingestion of the glucose. It was found, furthermore, that in each case the drug had been administered at such a time previous to the administration of the glucose that the patient was just coming under the influence of the drug when the test was commenced. Thereafter, hypnotics were not given before carrying out the tests, but time did not permit of a more detailed investigation of the problem.

Subsequently, this question has been examined more closely. A search of the literature shows that while numerous workers have investigated the effects of hypnotics on the fasting blood sugar, the only workers who have investigated their effects on glucose tolerance tests are Högler and Zell [1933] who state that they find that neither veronal nor chloral has any marked effect on alimentary hyperglycaemia in rabbits. An examination of their results shows, however, that eight out of nine experiments carried out with these drugs show the effect described below.

In the following research a glucose tolerance test was carried out on the fasting patient and within a few days, often the next day, the test was repeated with the patient fasting and under the influence of a drug. In a number of cases a repetition of the "normal" curve was carried out, and in each case the results were comparable.

This work has been carried out on two classes of patients: (*a*) cases showing marked lack of emotion and apathetic behaviour. These cases showed also considerable intellectual deterioration and for descriptive purposes are referred to as cases of "dementia" in this paper in contrast to (*b*) cases which showed the typical emotion consonant with their type of psychosis and had fairly well-maintained personalities. It is noticeable, however, that the phenomenon is manifested independently of the type of disorder.

The drugs used were:

(1) Nembutal, gr. iii;
(2) Veronal, gr. vii or x;
(3) Chloral, gr. xx;
(4) Morphine sulphate, gr. $\frac{1}{4}$ or $\frac{1}{6}$;

i.e. the ordinary clinical doses used in hospital practice.

No very profound variations were found in the fasting levels whether the patient was under the influence of the drug or not, and for clarity the fasting levels of the two curves have been made equal. Blood sugar estimations were carried out on oxalated-fluorided blood by the Hagedorn-Jensen technique.

---

[1] Walter Smith Kay Research Fellow in Psychiatry, University of Edinburgh.

The tables show the fasting level, the maximum level attained and the 2 hour level or the minimum if that is attained before 2 hours. In addition, the hyperglycaemic index (H.I.) and the hyperglycaemic area (H.A.) are shown for, in each case, first the normal curve and, second, the curve after the drug has been administered. In each case the age, sex and diagnosis for the patient are given.

It will be seen that in most cases following the administration of the drug there is a fall in the H.I., excepting where the "normal" was zero. In each case, however, the hyperglycaemic area shows a fall. This is expressed as a percentage decrease, calculated from the formula:

$$\%\ \text{decrease} = \frac{(\text{Area}_{(\text{no drug})} - \text{Area}_{(\text{drug})}) \times 100}{\text{Area}_{(\text{no drug})}}.$$

The hyperglycaemic area was found by actual measurement by counting squares when the curves were plotted on 1/10 in. graph paper. The hyperglycaemic index (H.I.) is that of McCowan and Quastel [1931]:

$$\text{H.I.} = \frac{(2\ \text{hour level} - \text{fasting level}) \times 100}{(\text{maximum} - \text{fasting level})}.$$

Where a minimum is reached before 2 hours this value is used. In addition to the H.I. and decrease in H.A. the change in the curves may be seen from the maxima and minima in the tables. In the following tables the curves marked (*a*) are the "normal" curves and those marked (*b*) are those obtained when the patient was under the influence of the drug.

Table I.

A. *Nembutal.*

Case	Blood sugar mg./100 ml.			H.I.	H.A.	% decrease in H.A.	Sex	Age	Diagnosis
	Fasting	Max.	Min.						
i (*a*)	70	80	72	20	9	—	M	45	Mania
(*b*)	70	(40)	55	—	0	100			
ii (*a*)	80	105	92	50	32	—	M	56	Melancholia
(*b*)	80	100	75	0	18	56			
iii (*a*)	75	115	60	0	24	—	M	66	Inv. Mel.
(*b*)	75	95	45	0	17	29			
iv (*a*)	80	150	135	80	152	—	M	57	Acute Dep.
(*b*)	80	130	65	0	52	66			
v (*a*)	120	240	210	75	280	—	F	64	Dementia
(*b*)	120	220	170	50	194	31			
vi (*a*)	70	120	80	20	64	—	F	68	Dementia
(*b*)	70	95	70	0	32	50			
vii (*a*)	75	151	120	60	130	—	M	76	Dementia
(*b*)	75	120	120	100	63	49			

Inv. Mel. = Involutional melancholia, Dep. = Depression.

In case (i) the hyperglycaemic rise is entirely abolished, the blood sugar content falling to a minimum at 1 hour and then rising slowly. Case (i) was very excited at the time of the test. The other cases show the typical lowering of the curve. Case (vii), however, shows a rise in H.I., although the H.A. shows a 49 % decrease.

Owing to lack of space, it is not possible to show the individual pairs of graphs and accordingly the following method has been used for a graphic representation. At each time period, *i.e.* ½, 1, 1½, 2 and 2½ hours after the ingestion of glucose the blood sugar level for the curve on the drug was subtracted from the blood sugar level on the control curve, and the difference was termed the "depression" for that time. The means of these "depressions" for each time and for each drug were determined and are shown in Table V together with the maximum and minimum depressions.

Table II.

B. *Veronal.*

	Blood sugar mg./100 ml.								
Case	Fasting	Max.	Min.	H.I.	H.A.	% decrease in H.A.	Sex	Age	Diagnosis

(*b*)	80	125	35	0	38	44			
xiii (*a*)	75	140	90	23	70	—	F	59	Dementia
(*b*)	75	105	70	0	30	57			
xiv (*a*)	60	140	130	88	161	—	F	49	Dementia
(*b*)	60	125	95	54	102	37			

Ag. Depr. = Agitated depression.

In case (viii) also, the hyperglycaemic rise is abolished; a small transitory rise may however have been missed between the fasting sample and the sample drawn 30 minutes after the ingestion of the glucose. No case showed a rise in H.I. and the other cases show the typical increase of tolerance.

Table III.

C. *Chloral.*

	Blood sugar mg./100 ml.								
Case	Fasting	Max.	Min.	H.I.	H.A.	% decrease in H.A.	Sex	Age	Diagnosis
xv (*a*)	80	175	110	32	130	—	F	54	Inv. Mel.
(*b*)	80	150	105	36	94	28

Sen. Hyp. = Senile hypochondriasis, Schiz. = Schizophrenia, Sen. Dem. = Senile dementia.

In this series only one case showed a fall in H.I., four showed a rise and two did not change (H.I. = 0). A reason for this will be suggested later. The areas, however, show a marked decrease with the drug.

Table V. *Differences in blood sugar content due to hypnotics.* (mg./100 ml.)

	Max.	-50	-55	-35	-25	-10
	Min.	- 5	-15	+ 5	+ 5	+25

A normal blood sugar curve [Stewart and Dunlop, 1932] was taken as a standard, and the mean "depressions" were subtracted from its values for each drug. Figs. 1–4 show the depressed curves so obtained.

From Fig. 4 it will be seen that at 2 hours the depression is small and at 2½ hours an increase is actually found. Further, the maximum of the curve (½ and 1 hour) is heavily depressed (Table V). This accounts for the elevation of the H.I. in so many of the morphine cases.

Seven cases of schizophrenia were used, and an interesting point was shown. In all cases but one (xxiii) the drugs had no clinical action whatever, and in each case the two curves obtained were identical. Case (xv), for some reason had no clinical reaction to the drug in the first instance and two identical curves were obtained. On a subsequent occasion the drug was effective with the results shown above. This fact is particularly clear and seems to indicate that the biochemical manifestations run closely parallel with the clinical effects.

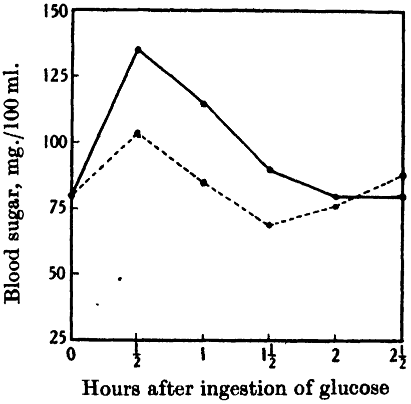

Fig. 4. Morphine.

SUMMARY.

1. It has been shown that hypnotics in clinical doses show a marked effect on the results of the glucose tolerance test.
2. This effect is shown by lowered maxima or shortened hyperglycaemia, or both, with markedly decreased hyperglycaemic area. The effect on the H.I. is less constant.
3. This effect is shown by chloral and morphine and is, therefore, not peculiar to drugs of the barbituric group.

I wish to thank Prof. D. K. Henderson for providing me with facilities to carry out this work, Dr T. A. Munro for his helpful cooperation in handling the case material, and the Medical Research Council for a personal grant enabling me to finish the work.

CXI. THE KINETICS OF ALCOHOLIC FERMENTATION OF SUGARS BY BREWER'S YEAST.

I. EFFECT OF CONCENTRATIONS OF YEAST AND SUGAR.

By REGINALD HAYDN HOPKINS
and RICHARD HENRY ROBERTS.

From the Department of Industrial Fermentation, University of Birmingham.

(*Received February 28th, 1935.*)

The kinetics of alcoholic fermentation of sugars by living yeast was established by the work of Brown [1892] and Slator [1906; 1908]. These workers showed that the rate of fermentation is approximately constant over a wide range of sugar concentration and remains constant during the main part of the fermentation. Brown used a high seeding rate which, in the absence of added nutrients other than the sugar, remained fairly constant during the observations, and measured the rate of fermentation by the rate of disappearance of the sugar. On the other hand Slator used a low seeding rate and measured in a specially devised apparatus the velocity of CO_2 evolution over short periods of time during which no yeast increase could take place. He calculated the value of "n" in the equation

$$\frac{d\,[CO_2]}{dt} = k\,[\text{sugar}]^n,$$

and showed that it was approximately zero between the limits of sugar concentration 0·5 % and 10 %. Slator and Sand [1910] concluded that "...it is unlikely that conditions could be experimentally realised under which diffusion becomes a controlling factor in the rate of fermentation". Their deductions also indicated the importance of uniform shaking or stirring of the fermenting mixture.

Nord and Weichherz [1929] criticised Slator's apparatus and considered that,

(1) it had no adequate stirring device whereby continuity of reaction could be secured;

(2) it exhibited large temperature fluctuations;

(3) readings could not be made soon enough after the commencement of the fermentation.

Using the Iterson-Kluyver apparatus to measure the rate of evolution of carbon dioxide they investigated the effects of varying stirring rates and found that with 21 turns per minute or more the rate of fermentation exhibited three phases:

(1) a fairly rapid rise to a maximum;
(2) a short quasi-stationary period;
(3) a rapid asymptotical decrease to zero.

Phase (2) was absent when no stirring took place. The constancy of fermentation rate over a relatively long period of time, observed by Brown and Slator, was not observed in these experiments.

The method of stirring or agitation is important. Slator shook vigorously by hand at intervals. Nord and Weichherz assumed that all diffusion gradients in the sugar solution are eliminated by stirring at the rate of 21 turns per minute, and attributed the further increase in maximum rate of fermentation consequent upon increased rate of stirring to an apparent increase in the membrane surface due to the motion of the cells relatively to the medium. But in the fermentations performed by them, the yeast rate was so high (2 g. of pressed yeast in 20 ml. total volume) that the cells, if uniformly distributed, would be separated from each other by a distance considerably less than one diameter. It seems probable that diffusion gradients and vortex effects would occur even at higher stirring rates. However, by maintaining a steady stirring rate, comparable results were obtained. Weichherz [1929; 1931] from mathematical considerations concluded, among other things, that proportionality between rate of reaction and dry weight of yeast employed does not necessarily hold. It may not hold in such cases as the above, but it was found by Slator to hold for low concentrations of yeast, and this has been confirmed by us (Exp. 2) over a wide range of yeast concentration.

In further experiments, Nord and Weichherz, using a stirring rate of 100 turns per minute, investigated the effect of glucose concentration on the maximum rate of fermentation and found the latter to increase up to 10 % glucose, whereas Slator had found little deviation over the range 0·5–10 %, and the maximum at 4 %.

A closer examination of the results, however, indicates that they may be interpreted to agree with those of Slator. In each of the fermentations recorded by Nord and Weichherz, a large yeast rate was employed and a large time lag (phase (1)) ensued before the maximum rate was attained. During this lag an appreciable amount of sugar was decomposed, and this amount can be calculated from the graphical data furnished. For example, in the case of 0·5 % initial glucose, the maximum rate was attained after fermentation had decreased the sugar concentration to 0·31 %. The maximum rate may therefore be taken to apply to this concentration and not to 0·5 %. Similar results calculated from the other cases are included in the table below.

Table I.

Initial glucose %	Time taken to attain maximum rate (mins.)	Glucose remaining at time of maximum rate (%)	Rate of fermentation ml. CO_2/min.
0·5	10	0·31	1·40
2·0	30	0·96	2·45
5·0	38	3·48	2·85
10·0	70	6·14	3·05
30·0	82	26·11	2·90

By plotting these maximum fermentation rates against the appropriate concentrations of glucose, a curve is obtained (Fig. 1) which shows close agreement with the corresponding curve of Slator [1906] and, in fact, demonstrates the "approximate independence" of sugar concentration more clearly than Slator's original curve. A deduction in support of this may be made from the equation derived from first principles by Weichherz [1929; 1931] who found that the velocity of fermentation

$$f = \frac{\mu k}{k-\mu} \cdot S_0 \left(e^{-\mu t} - e^{-kt}\right),$$

where S_0 = the initial substrate concentration in the outer medium,
k = the unimolecular constant of the reaction proceeding in the cell,
and $\mu = \frac{F\alpha D}{v\delta}$,

in which F = cell (membrane) surface,
δ = membrane thickness,
αD = diffusion coefficient of the substrate within the membrane (this diffusion coefficient is derived from the free diffusion coefficient (D) in the total system filled with solution, and α the degree of permeability of the membrane),
and v = cell volume.

The above equation can be solved for k and μ if sufficient values of f and t are known. Let us suppose the following values are known:

$$t=1 \quad f=f_1$$
$$t=2 \quad f=f_2$$
$$t=3 \quad f=f_3.$$

By substituting these values in the equation, followed by usual algebraical methods, it can be shown that

$$e^{-\mu}+e^{-k}=f_2/f_1$$
$$e^{-\mu}\times e^{-k}=(f_2/f_1)^2-f_3/f_1,$$

whence we can calculate k, the true unimolecular constant of the reaction proceeding inside the cell. Application of this theorem to the results of Nord and Weichherz revealed that the value of k decreased with increase in initial concentration of glucose. Although the reaction proceeding within the cell is unimolecular, it does not proceed unimolecularly in the presence of any appreciable external sugar concentration since the velocity of reaction, $f=ka$, is maintained by continuous replacement of sugar by diffusion.

It was considered desirable to investigate the following points which arise out of the above discussion;

(1) the effect of stirring or shaking (Exp. 1);

(2) the relationship between concentration of yeast and rate of fermentation (Exp. 2);

(3) the relationship between concentration of sugar and rate of fermentation (Exp. 3).

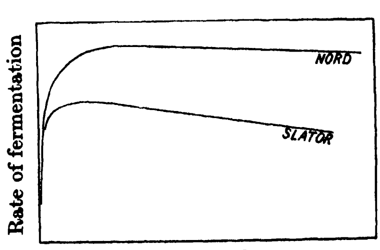

Fig. 1.

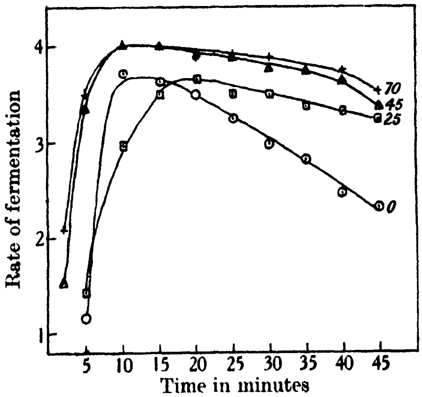

Fig. 1a.

EXPERIMENTAL.

The apparatus used was essentially that described by Slator [1906] in which the fermentation vessel is connected with an exhaust pump and a mercury manometer, change of pressure being observed as fermentation proceeds. Modifications, some of which were designed to overcome the objections advanced by Nord and Weichherz, included a two-way tap connecting to the exhaust pump or the air, and a shaking device for rocking the vessel to and fro and imparting a jerk, the rate of shaking being controlled by a rheostat in conjunction with the motor. Shaking was adopted in preference to stirring. The fermentation vessel, 250 ml. in capacity, was completely immersed in a constant temperature bath and the sugar, in solution (mutarotated), contained in a small beaker supported on a float on the surface of the yeast suspension previously placed in the vessel. Glass beads were present to assist dispersion of the yeast. When the whole system had settled down to the required temperature (30° in most experiments, as also adopted by Slator and Nord and Weichherz) the apparatus was exhausted and the shaking commenced; the beaker discharged its contents into the yeast suspension and readings on the manometer scale were taken from the beginning of the fermentation. These readings were plotted against time in each experiment, the rates of fermentation at selected arbitrary times deduced from the slope of the curve and calculated to the units, mg. of CO_2 per minute, as expressed in the various tables[1]. For this purpose the apparatus was calibrated as follows. 2 ml. of solution of pure sodium carbonate containing 65·8 mg. of CO_2 were placed in a small beaker floating on the surface of 98 ml. of sulphuric acid, of such concentration as to be exactly equivalent, contained in the fermentation vessel of the apparatus. When the system had attained the desired temperature, the pressure was reduced, the reaction flask shaken and the change of pressure on liberation of CO_2 was observed. In the case described, 100 ml. of solution in the flask in liberating 65·8 mg. of CO_2 at 30° brought about an increase of pressure equal to 5·8 cm. of mercury. Similar calibrations were performed for other volumes of liquid in the reaction vessel and for other temperatures as required.

Pressed washed brewer's (top) yeast from the same source was used in all experiments. By using yeast one day old, autofermentation was invariably found to be negligible.

Exp. 1 a. Variation of rate of shaking.

Glucose 0·5 g. (1 %). Yeast, 8 g.
Temp. 35°. Total volume 50 ml.

Table 1 A. *Progressive rates of fermentation expressed as mg. CO_2 per minute.*

Time (mins.) ...	2	5	10	15	20	25	30	35	40	45
No shaking	—	1·17	3·76	3·63	3·50	3·24	2·98	2·72	2·46	2·32
25 shakes per minute	—	1·43	2·98	3·50	3·63	3·50	3·50	3·37	3·32	3·24
45 shakes per minute	1·55	3·37	4·02	4·02	3·94	3·89	3·76	3·76	3·63	3·37
70 shakes per minute	2·09	3·50	4·02	4·02	3·89	3·89	3·89	3·89	3·76	3·50

It can be seen from the graph (Fig. 1*a*) that the rate of shaking is important. The effect of shaking is presumably most marked when high yeast rates are employed, as in this case. However, 70 and 45 shakes per minute gave similar results. It is reasonable to suppose that intermediate rates would do the same, but in all subsequent experiments shaking was maintained at approximately 70 shakes per minute.

The quasi-stationary periods were much longer than the corresponding ones observed by Nord and Weichherz, although the yeast rate was even higher than that employed by them.

---

[1] An experimental error of, *e.g.*, 1 mm. in the scale reading, spread over 30 mins. in the graphical procedure outlined above, amounts to less than 0·04 mg. CO_2 per minute.

Exp. 1b. Effect of intermittent shaking.

Parallel fermentations were performed:

(*a*) with continuous shaking at 70 shakes per minute;

(*b*) with alternate periods, without shaking and with vigorous shaking (over 70 per minute);

(*c*) without shaking.

In all cases of intermittent shaking, the shaking periods were continued until the accelerated rate of gas evolution had ceased and the normal rate with shaking was attained.

Glucose 0·5 g. Yeast 5 g.
Temp. 30°. Total volume 50 ml.

The results are shown graphically in Fig. 1 *b*.

Exp. 1c. The Exp. (1 *b*) was repeated for conditions (*a*) and (*b*), but in the case of (*b*) longer time intervals, 14 minutes, were allowed to elapse between the periods of shaking. The object of this was to exaggerate any effect due to intermittent quiescent periods. The concentration of glucose adopted in the latter experiment was 2 % instead of 1 % whereby a greater rate of fermentation was secured (*vide* Exp. 3). This also exaggerates the difference between continuous and intermittent shaking. The results are shown graphically in Fig. 1 *c*.

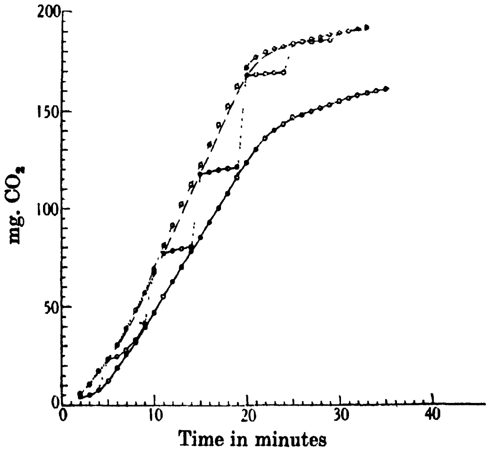

Fig. 1*b*.

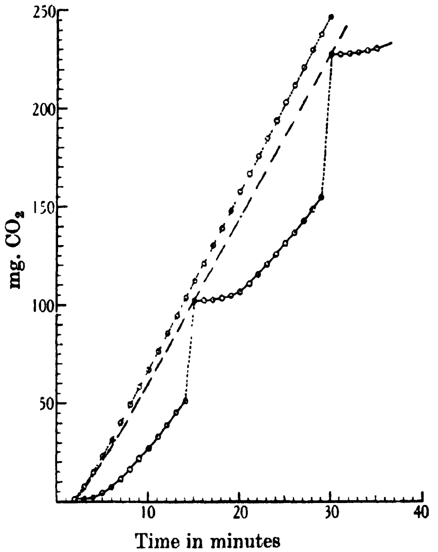

Fig. 1*c*.

Fig. 1*b*. -⊙—⊙- Periods without shaking. -⊙···⊙- Periods with shaking.
—•—•— Apparent curve for conditions (*b*).

Fig. 1*c*. -⊙—⊙- Periods without shaking. -⊙···⊙- Periods with shaking.
—•—•— Apparent curve for conditions (*b*).

It will be seen that intermittent shaking with only short time intervals, Exp. 1 *b*, the conditions adopted by Slator, gives results almost identical with those obtained by continuous shaking at 70 shakes per minute. The fermentation is proceeding at about the same rate in each case; a certain amount of supersaturation occurs between the shakings, but after a short agitation the readings approximate to those obtained with continuous shaking. Far more serious errors are involved if continuous shaking at the rate of, *e.g.*, 25 per minute, is adopted (Exp. 1*a*). Apparently this rate is inadequate to prevent a certain amount of supersaturation. If conditions are exaggerated as in Exp. 1*c* the results obtained after each agitation indicate a somewhat low rate of fermentation.

Exp. 2. Variation of yeast rate.

Glucose 0·5 g. (1 %). Yeast 2, 3, 4, 5 g. respectively.
Temp. 30°. Total volume 50 ml.

Table II. *Progressive rates of fermentation expressed as mg.* CO_2 *per minute.*

Time (mins.) ...	1	2	3	4	5	10	15	20	25	30	35	40	45	50	55	60	65	70	75	80	90	100
2 g. yeast	—	1·30	2·34	—	3·43	3·51	3·48	3·43	3·38	3·38	—	3·15	—	2·99	—	2·62	—	1·98	—	1·30	0·86	0·52
3 g. „	—	2·60	4·42	—	5·07	5·20	5·20	5·20	4·94	4·42	3·90	3·51	3·07	2·60	2·13	1·69	1·30	0·78	0·26	—	—	—
4 g. „	—	—	5·59	6·63	6·97	6·97	7·02	6·36	5·66	4·94	4·16	3·48	2·73	2·00	1·25	0·52	—	—	—	—	—	—

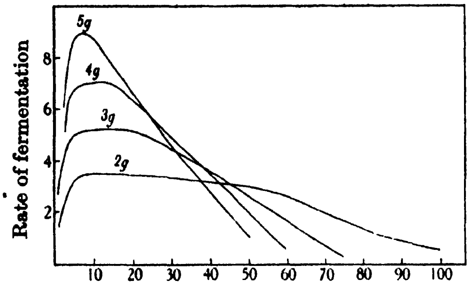

Fig. 2*a*.

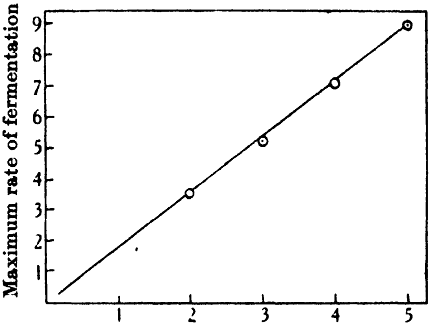

Fig. 2*b*.

The graph, Fig. 2*a*, shows the rate of fermentation plotted against time, and Fig. 2*b* the maximum rates plotted against yeast concentrations. It will be seen that the latter show exact proportionality.

Exp. 3a. Variation of initial glucose concentration.

Glucose 0·25–20 %. Yeast 4 g.
Temp. 30°. Total volume 40 ml.

Table III A. *Progressive rates of fermentation expressed as mg.* CO_2 *per minute.*

Time (mins.)...	1	2	3	4	5	8	10	15	20	25	30	35	40
0·25 %	2·29	2·80	—	—	3·57	3·31	2·80	1·43	0·25	—	—	—	—
0·50 „	2·55	3·31	—	—	4·13	—	3·97	3·16	2·14	1·17	—	—	—
1·0 „	3·31	4·08	4·84	5·10	5·25	—	5·20	4·74	4·28	—	—	—	—
2·0 „	—	4·84	5·35	—	5·81	—	5·86	5·81	5·61	5·25	5·10	—	—
5·0 „	—	—	—	—	6·02	—	6·37	6·37	6·37	6·24	6·12	5·99	5·86
10·0 „	—	—	—	—	6·37	—	6·84	7·04	7·14	7·14	7·14	7·14	7·19
20·0 „	—	—	—	—	5·10	—	5·56	5·61	5·66	5·71	5·71	5·76	5·86

In this experiment the yeast rate was the same as that employed by Nord and Weichherz. If the rates of fermentation are plotted against time it will be seen that with 0·25 % glucose the curve is typically compound exponential, but with increasing concentrations of glucose it flattens out and becomes quite flat with 5 % and 10 % glucose. With this yeast rate the highest maximum and constant rate was exhibited by the 10 % glucose solution and when at most only 0·6 % had been removed by fermentation.

Exp. 3 b.

Glucose 1·0–30 %. Yeast 2 g.
Temp. 30°. Total volume 40 ml.

Table III B. *Progressive rates of fermentation expressed as mg. CO_2 per minute.*

Time (mins.)...	5	10	15	20	25	30

10·0 „	4·38	4·93	4·93	4·93	4·93	4·98
15·0 „	4·24	4·44	4·44	4·44	4·49	4·49
20·0 „	2·74	3·12	3·12	3·12	3·18	3·18
30·0 „	1·37	1·53	1·64	1·70	1·70	1·75

The results of Exp. 3 *b* resemble those obtained in Exp. 3 *a*. The highest maximum and constant rate was apparently at a concentration of glucose approaching 10 %. In Exp. 3 *c* the yeast rate corresponded to that employed by Slator. At all concentrations of glucose from 1 % to 30 %, approximate constancy of rate of fermentation was observed over a period of time. By graphical procedure it can be seen that the concentration of glucose corresponding to maximum rate is about 6–8 %.

Exp. 3 *d.*

Glucose 0·1–15 %. Yeast 1 g.
Temp. 30°. Total volume 100 ml.

Table III D. *Constant rates of fermentation expressed as mg. CO_2 per minute.*

Initial concentration of glucose %	0·1	0·2	0·3	0·4	0·5	1·0	2·0	4·0	6·0	8·0	10·0	15·0
Rate of fermentation	0·71	1·10	1·31	1·44	1·55	1·77	1·95	2·10	2·17	2·12	2·05	1·85

(The progressive rates of fermentation in this experiment are stated in Part II, Exp. 2.)

With this low concentration of yeast the rate of fermentation became definitely constant for long periods of time. The maximum rate was exhibited by the solution of which the initial concentration of glucose was 6 %.

Exp. 3 e. Concentrations of glucose below 0·10 %.

For this experiment a different apparatus and procedure were required, as Slator's apparatus is not sufficiently sensitive. Indeed it was at the suggestion made privately by Dr Slator that this experiment was performed. The fermenting vessel and stirring arrangements employed were similar to those described by Nord and Weichherz [1929] and consisted of a 200 ml. flask with a stirrer passing through a mercury seal. The evolved CO_2 was swept out of the fermenting vessel by a current of CO_2-free air and passed through Pettenkofer tubes containing standard baryta. By the judicious use of two-way taps the CO_2 evolved was estimated at regular intervals by back-titration, the current of gas being diverted through a second tube while the first was being titrated and replaced. A control autofermentation was performed side by side with each experiment in an exactly similar apparatus, the fermenting vessel being immersed in the same thermostat, the appropriate deductions being made from each titration.

Table III E.

Glucose 0·04–0·08 %. Yeast 9 g.
Temp. 30°. Total volume 165 ml.
(Results in ml. 0·0944 *N* HCl.)

	30	10	35·6	37·6	2·0	10·4	0·0327
	40	10	36·9	38·4	1·5	11·9	0·0354
	50	10	37·8	38·2	0·4	12·3	0·0332
	60	10	37·8	38·0	0·2	12·5	0·0311
	70	10	38·3	38·5	0·2	12·7	0·0337

Graphical inspection of the results given in Table III E indicated, as was anticipated, that the reactions were proceeding unimolecularly, provided that the induction period of about 7 minutes was neglected. To calculate the values of *k*, the constant, involved a little difficulty in deducting from the values of *t* the appropriate allowance for this induction period. This period could not be judged exactly enough from the graphs. The allowances made in the respective experiments, 7·3, 7·0 and 7·5 minutes, were judged by inspection. The reasonable constancy in the values of *k* justifies the allowances made and also the conclusion that at initial concentrations of glucose between 0·04 and 0·06 % if not also 0·08 %, the fermentation proceeds unimolecularly.

DISCUSSION.

The initial concentration of glucose corresponding to maximum constant rate of fermentation varies between 9 % or over in the case of the highest yeast rate (Exp. 3 *a*) and 6 % in the case of the lowest yeast rate (Exp. 3 *d*). With the low yeast rates, the rate of fermentation varies comparatively little between 2 % and 10 % glucose, whereas with the high yeast rates greater variations and more definite maxima are exhibited.

The results of Exp. 3 *d* lend themselves to mathematical treatment in two ways.

(1) *Theory of enzyme action of Michaelis and Menten* [*1913*].

Assuming a single enzyme action to limit the rate of fermentation within the yeast cell, application of the theory gives us the relationship

$$\frac{1}{v}=\frac{K_m}{V}\cdot\frac{1}{x}+\frac{1}{V},$$

where v = velocity of breakdown of enzyme-substrate compound, *i.e.* velocity of fermentation,

V = value of v when the enzyme is fully saturated with substrate and wholly combined with it,

K_m = dissociation constant of the enzyme-substrate compound (ES),

x = concentration of substrate.

In this equation V and K_m are constants. Hence if the fermentation conforms to the equation, the graph obtained by plotting $\frac{1}{v}$ against $\frac{1}{x}$ should be a straight line. In Table IV are tabulated values of x, v, $\frac{1}{x}$ and $\frac{1}{v}$ from the data in Table III D and interpolations from a graph drawn from them.

Table IV.

x = conc. %	v = rate	$1/x$	$1/v$
0·2	1·09	5·0	0·917
0·4	1·44	2·5	0·695
0·6	1·62	1·67	0·617
0·8	1·72	1·25	0·582
1·0	1·77	1·00	0·565
1·2	1·83	0·83	0·547
1·4	1·87	0·71	0·535
1·6	1·90	0·63	0·526
1·8	1·92	0·56	0·521
2·0	1·95	0·50	0·513
2·5	2·00	0·40	0·500
3·0	2·04	0·33	0·490
3·5	2·07	0·29	0·483
4·0	2·10	0·25	0·476
4·5	2·12	0·22	0·472
5·0	2·14	0·20	0·468
8·0	2·12	0·125	0·472
10·0	2·05	0·10	0·488

The results are plotted in Fig. 3 *a*. Between the limits 0·2 % and 5·0 % the graph is a straight line. From this it may be deduced that the Michaelis and

Menten theory holds for alcoholic fermentation of glucose within this range of conditions.

According to Haldane [1930] if an enzyme action follows the Michaelis and Menten equation three cases can arise.

(*a*) The substrate concentration remains so high until very near the end of the reaction that the enzyme is fully saturated.

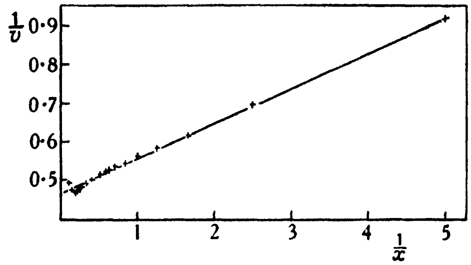

Fig. 3*a*.

Here, if the products of the reaction do not inhibit, y (the amount of substrate transformed in time t) $= Vt$. The curve for 2 g. yeast (Fig. 2 *a*) illustrates this case.

This is actually the condition under which Slator examined fermentation kinetics, and under which it is also easy to understand that the rate of fermentation is proportional to the concentration of yeast.

(*b*) The substrate concentration is so low that the amount of enzyme combined is proportional to the substrate concentration. Here

$$dy/dt=(a-y)\ V/K_m,$$

i.e.

$$t=K_m/V\,.\log_e\,(a/a-y)$$

$$(a=\text{initial substrate concentration}),$$

and the reaction is unimolecular. These are the conditions investigated in Exp. 3 *e*.

(*c*) The substrate concentration varies so that neither of these conditions is fulfilled.

Here

$$dy/dt=(a-y)\ V/(K_m+(a-y)),$$

therefore

$$\begin{aligned} Vt&=\int_0^y((a-y)+K_m)/(a-y)\,.dy\\ &=y+K_m\,.\log_e\,(a/(a-y))\\ &=y\left(1+\frac{K_m}{a}\right)+y^2\frac{K_m}{2a^2}+y^3\frac{K_m}{3a^3}+\dots\end{aligned}$$

If a is large compared with K_m the logarithmic term is at first negligible and the reaction proceeds uniformly, slowing down when y becomes appreciable. These are the conditions investigated by Nord and Weichherz. The curves for 5 and 4 g. yeast (Fig. 2 *a*) illustrate this case.

Hence, by application of the Michaelis and Menten theory, the results of Nord and Weichherz and those of Slator, apparently contradictory in part, are reconciled.

(2) *Mathematical treatment adopted by Slator.*

According to Slator the fermentation of sugars by yeast could be represented by the equation

$$\frac{d\,[CO_2]}{dt}=k\ [\text{conc. of sugar}]^n$$

(the yeast factor being kept constant),

or $$v = k\,[\text{sugar}]^n$$

i.e. $$\log v = \log k + n \log\,[\text{sugar}].$$

By plotting $\log v$ against log [sugar] we can, from the slope of the curve produced, derive the value of n. From the data of Exp. 3 *d* the values of $\log v$ and log [sugar] are tabulated in the following table (V) (first two columns) and plotted in Fig. 3*b*. From the slope of the curve are calculated the values of n tabulated in the fourth column, corresponding to concentrations in the third column, and plotted in Fig. 3 *c*.

Table V.

log (concentration) (log [sugar])	log (rate of fermentation) (log v)	Concentration %	n
-0·699	0·037	—	—
-0·523	0·117	0·30	0·381
-0·398	0·158	0·40	0·323

1·0	0·312	10·0	-0·13
1·176	0·274	—	—

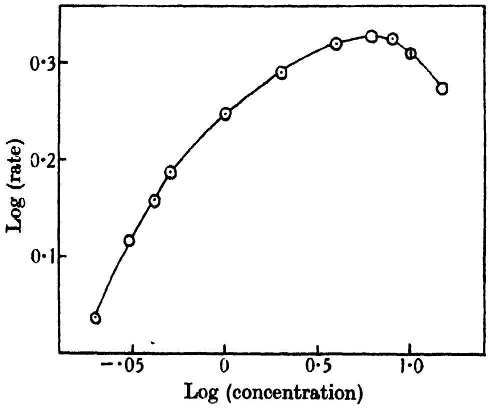

Fig. 3*b*.

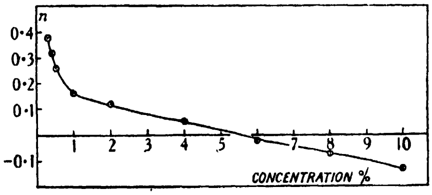

Fig. 3*c*.

It can be seen from Fig. 3 *c* that between the concentrations 1 % and 10 % of glucose the value of n approaches zero, *i.e.* the "approximate independence" of Slator holds good. At very low concentrations of sugar, however, the value of n approaches unity and the reaction becomes one of the first order with respect to sugar (*cf.* Exp. 3 *e*), which has been explained on the basis of the Michaelis and Menten theory.

SUMMARY.

1. It has been shown that if all the conditions which influence the rate of alcoholic fermentation of glucose by living yeast are carefully considered the kinetics are precisely similar to those of an ordinary enzyme reaction. The fermentation conforms to the theory of Michaelis and Menten and the mathematical deductions made from the theory apply under their special conditions.

Thus the apparently contradictory results of Slator and of Nord and Weichherz were obtained from experiments investigating respectively two special cases out of three possible cases under the theory. Relatively low concentration of yeast leads to saturation of the enzyme and constancy of reaction velocity over a wide range of substrate concentration (Slator). Relatively high concentration of yeast and sufficiently low concentration of sugar, 0·04–0·07 % glucose in the case investigated, yield a unimolecular reaction. Conditions intermediate between these yield a maximum rate of reaction followed sooner or later by a slowing down (Nord and Weichherz). In all cases an induction period precedes the attainment of the maximum rate.

2. The rate, if not also the nature, of the stirring or shaking is important, particularly when high yeast rates are employed. To attain uniform results shaking was preferred to stirring and was adopted whenever possible, from 45 to 70 shakes per minute being adequate. Slower shaking, *e.g.* 25 shakes per minute, gave a low rate of fermentation. On the other hand, intermittent vigorous shaking gave good results provided that the intervals between the shakes were not more than three or four minutes in duration.

3. In the case of glucose concentration as low as 1 % proportionality between yeast concentration and rate of fermentation was observed over a wide range.

CXII. THE KINETICS OF ALCOHOLIC FERMENTATION OF SUGARS BY BREWER'S YEAST.

II. THE RELATIVE RATES OF FERMENTATION OF GLUCOSE AND FRUCTOSE.

By REGINALD HAYDN HOPKINS
AND RICHARD HENRY ROBERTS.

From the Department of Industrial Fermentation, University of Birmingham.

(*Received February 28th, 1935.*)

The rate of fermentation of fructose by brewer's yeast was found by Slator [1908] to be the same as that of glucose over the range of conditions investigated. Hopkins [1931], however, observed that in low concentrations, less than 0·5 %, fructose was fermented appreciably more slowly than glucose at 30°. It was decided to extend the investigations on the effects of yeast rate and sugar concentration respectively (Exps. 2 and 3 reported in Part I of this series) to fructose, under conditions which permitted of comparison with glucose.

Experimental.

The apparatus and technique employed were exactly as described in Part I. Washed pressed yeast from the same source was used, and in Exp. 2 the glucose and fructose were fermented successively with yeast from the same sample.

Exp. 1. Variation of yeast rate.

Fructose 0·5 g. (1 %). Yeast 0·5–5·0 g.
Temp. 30°. Total volume 50 ml.

Table I. *Maximum rate of fermentation of fructose.*

Rates expressed as mg. CO_2 per minute.

Yeast rate (g.)	0·5	1·0	1·5	2·0	2·5	3·0	3·5	4·0	4·5	5·0
Maximum rate of fermentation	0·68	1·53	2·05	2·78	3·48	4·06	4·63	5·07	5·49	5·80

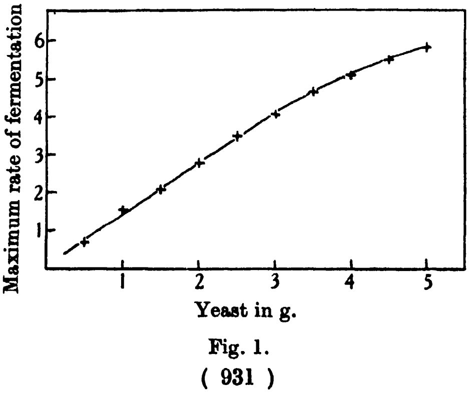

Fig. 1.

The graph, Fig. 1, shows proportionality between rate of fermentation and concentration of yeast only up to 3 g. in 50 ml., above which the fermentation rate is less than the proportional rate. This difference between the behaviour of fructose and that of glucose, which exhibited proportionality up to higher yeast rates, suggests that the yeast enzyme has a greater affinity for glucose than for fructose.

Exp. 2. Variation of initial concentration of glucose and fructose.

Glucose or fructose 0·1–15 %. Yeast 1 g.
Temp. 30°. Total volume 100 ml.

The rates of fermentation in solutions of various initial concentrations are set out in Table II. The results given correspond to certain arbitrary time stages and the constant rates calculated from the manometer readings over the period of approximate constancy are summarised in Table II *a*.

Table II. *Progressive rates of fermentation of glucose and fructose at varying initial concentrations.*

Rates expressed as mg. CO_2 per minute.

Table II*a*. *Constant rates of fermentation of glucose and fructose at varying initial concentrations.*

Rates expressed as mg. CO_2 per minute.

Concentration of sugar %	0·1	0·2	0·3	0·4	0·5	1·0	2·0	4·0	6·0	8·0	10·0	15·0
Rate, glucose	0·71	1·09	1·31	1·44	1·55	1·77	1·95	2·10	2·17	2·12	2·05	1·85
Rate, fructose	0·45	0·71	0·90	1·05	1·15	1·55	1·78	1·94	1·96	2·00	1·77	1·42

The results in Table II *a* are recorded graphically in Fig. 2 in which rates of fermentation are plotted as ordinates and concentrations as abscissae.

The results confirm those of Slator [1906] and Hopkins [1931]. Maximum rates of fermentation were obtained in solutions in the neighbourhood of 6 % initial concentration, and it is to be observed that whilst the maximum rates for the respective sugars differ but little, nevertheless the fructose curve lies below that of glucose throughout its length.

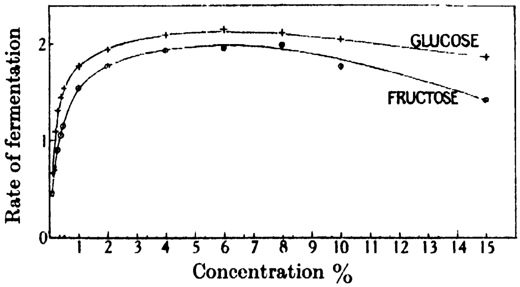

Fig. 2.

Discussion.

Application of the Michaelis and Menten [1913] equation,

$$\frac{1}{v}=\frac{K_m}{V}\cdot\frac{1}{x}+\frac{1}{V}$$

(see Part I), to the fructose results yielded the values recorded in Table III and plotted in Fig. 3 *a*.

Table III. *Fructose.*

x = conc. %	v = rate	$1/x$	$1/v$
0·2	0·71	5·00	1·408
0·4	1·06	2·50	0·943
0·6	1·27	1·67	0·787
0·8	1·43	1·25	0·699
1·0	1·54	1·00	0·649
1·2	1·60	0·83	0·625
1·4	1·66	0·71	0·602
1·6	1·70	0·63	0·588
1·8	1·74	0·56	0·575
2·0	1·78	0·50	0·562
2·2	1·80	0·45	0·556
2·4	1·82	0·42	0·550
2·6	1·85	0·38	0·541
2·8	1·87	0·36	0·535
3·0	1·89	0·33	0·529
3·5	1·92	0·29	0·521
4·0	1·95	0·25	0·513
6·0	2·00	0·17	0·500
10·0	1·84	0·10	0·544
15·0	1·42	0·07	0·704

As with glucose, the results of which were similarly dealt with in Part I (Table IV, Fig. 3 *a*), the graph is a straight line over a large part of its length. In the case of fructose this is true between the abscissa values corresponding to 0·4 % and 6 % concentration, indicating that the theory is valid over this range. In the case of glucose the corresponding limits were 0·2 % and 5·0 %.

In the cases of both glucose and fructose, it is possible to deduce the values of V, the maximum velocity of fermentation, and of K_m, the dissociation constant of the enzyme-substrate compound.

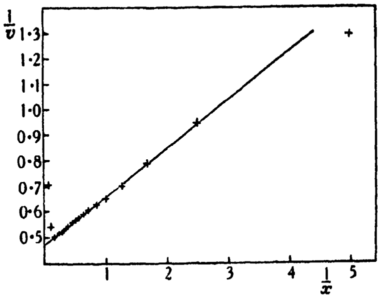

Fig. 3 *a*.

When x is large, *i.e.* when $\frac{1}{x}$ becomes zero, then

$$\frac{1}{v}=\frac{1}{V} \text{ and } v=V.$$

The value of $1/V$ can be read off from the graph where $1/x$ equals zero.

In the cases of both fructose and glucose the value of $1/V$ is the same and equals 0·47.

V is therefore 2·13.

Since K_m/V represents the slope of the curve, then

(*a*) Glucose

$$\text{Slope of line}=\frac{0\cdot92-0\cdot47}{5}=0\cdot090=\frac{K_m}{V}.$$

Hence $K_m=0\cdot090\times2\cdot13$

$=0\cdot192$, corresponding to $0\cdot01067M$.

(*b*) Fructose

$$\text{Slope of line}=\frac{1\cdot23-0\cdot47}{4}=0\cdot190\doteq\frac{K_m}{V}.$$

Hence $K_m=0\cdot190\times2\cdot13$

$=0\cdot405$, corresponding to $0\cdot0225M$.

These values of K_m, 0·192 and 0·405 for glucose and fructose respectively are in fairly close agreement with those deduced by Dawson [1932] from the results of Hopkins [1931], 0·2 and 0·4, assuming the applicability of the Michaelis and Menten theory to fermentation by living yeast.

The values of K_m and V have significance in that from them can be calculated the so-called "selectivity constant," *i.e.* that which is derived from the results of selective fermentations of mixtures of the two sugars, Hopkins [1931]. Thus it was shown by Michaelis and Menten [1913] that the relative rate of reaction of two substrates competing for the same enzyme is given by the equation

$$\frac{V_a}{V_b}\cdot\frac{K_a}{K_b}=K \text{ (selectivity constant)},$$

where K_a, K_b = the Michaelis constants of the two substrates, V_a, V_b = the theoretical maximum velocities with each substrate alone.

Substituting the values of V and K obtained above for glucose and fructose we get

$$K=\frac{2\cdot13}{2\cdot13}\cdot\frac{0\cdot405}{0\cdot192}=2\cdot10=K_{G/F},$$

which is again in close agreement with the value (2) calculated by Dawson from the experimental results of Hopkins.

The value of V, the maximum rate of fermentation deduced above (2·13, the number of mg. of CO_2 evolved per minute under the conditions of Exp. 2) is the same for both glucose and fructose. This means that for both sugars the theoretical maximum rate of fermentation is the same. In practice this is not attained since apparently hypertonic and other effects supervene.

Application of the equation, $\log v = \log k + n \log [\text{sugar}]$ as applied to fermentation of glucose (see Part I, Table V), gives the results in Table IV, columns 1 and 2, which are plotted in Fig. 3*b*. From the slope of the curve are calculated the values of n given in column 4, corresponding to the concentrations of fructose in column 3. These values are represented graphically in Fig. 3*c*. In both Figs. 3*b* and 3*c* the corresponding curves for glucose are reproduced for comparison (from Figs. 3*b* and 3*c* of Part I).

Table IV.

Log (concentration)	Log (rate of fermentation)	Concentration %	n
-0·699	-0·149	—	—
-0·523	-0·046	0·30	0·52
-0·398	0·021	0·40	0·49

0	0·190	1·0	0·30
0·301	0·250	2·0	0·16
0·602	0·288	4·0	0·045
0·778	0·301	6·0	-0·035
0·903	0·292	8·0	-0·16
1·000	0·265	10·0	-0·30
1·176	0·152	—	—

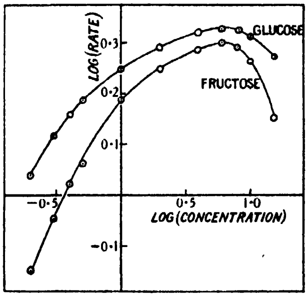

Fig. 3*b*.

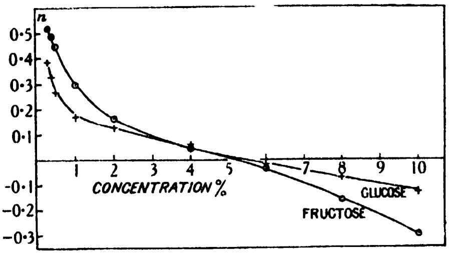

Fig. 3*c*.

Between concentrations of 2 and 8 % fructose the value of n approximates to zero, and the rate of fermentation as given by the equation $v = k [\text{fructose}]^n$ is approximately independent of the concentration of sugar. The corresponding limits for glucose concentration are 1 and 10 %.

Certain interesting differences between the behaviours of the two sugars are illustrated by these curves. The dependence of rate of fermentation on concentration of sugar is, at low values of the latter more marked in the case of fructose than of glucose. This is in agreement with the higher deduced value of K_m for fructose, for which sugar the yeast enzyme has less affinity than for glucose. This is confirmed by the results of the experiments on the effect of yeast rate. At high concentrations of sugar the rate of fermentation of fructose never quite equals that of glucose, since, apparently, hypertonic and/or other effects supervene. It is, however, evident that there exists a greater difference between the kinetics of fermentation of glucose and fructose than would be supposed from a superficial consideration of the results obtained by earlier workers.

SUMMARY.

1. Proportionality between the yeast rate and rate of fermentation of fructose exists up to a certain concentration of yeast, above which the fermentation rate is less than proportional. With glucose proportionality exists up to higher yeast rates.
2. Under selected identical conditions glucose is fermented at approximately the same rate between 1 and 10 %, and fructose between 2 and 8 % concentration, the rate for fructose being slightly less than that for glucose. Below these concentrations fructose is fermented much more slowly than glucose.
3. Under the conditions of experiment adopted, the theory of Michaelis and Menten is valid for the fermentation of glucose between 0·2 and 5 % and of fructose between 0·4 and 6 % concentration.
4. The values of the dissociation constants (K_m) of the compound of enzyme and substrate are 0·01067 and 0·0225 for glucose and fructose respectively, and the ratio of these gives the value for $K_{G/F} = 2{\cdot}10$ for the selectivity constant in agreement with the known value of this constant derived from experiments on selective fermentation of mixtures of the sugars by similar brewery yeasts.

CXIII. LACTOFLAVIN IN MICRO-ORGANISMS.

By LIONEL BRADLEY PETT[1].

From the Biochemical Institute, University of Stockholm, Sweden.

(*Received March 1st, 1935.*)

In three years very rapid development has taken place in the study of the water-soluble, nitrogen-containing pigments, commonly called flavins or lyochromes, which occur in widely varying plant and animal tissues. In this time several members have been identified and their derivatives synthesised, especially by Karrer [1934, 1] and Kuhn [1934], lactoflavin has been suggested as identical with vitamin B_2 by György *et al.* [1934], and it has been shown in yeast to be bound to protein, forming an oxido-reduction enzyme, the "gelbes Ferment" of Warburg and Christian [1933]. As yet, however, almost nothing is known as to the method of production of lactoflavin in living material and the changes it undergoes. Although widely distributed in animals, it seems probable that flavin comes originally from plants. Lactoflavin has been found in yeast and in a few bacteria. The present work shows that yeast forms the flavin itself, that under various conditions it forms amounts of flavin different from normal, that some bacteria do not contain flavin, and that under various conditions blue-fluorescing substances may arise which are possibly related to flavin.

A review of early work on this subject by Wagner-Jauregg [1934] and preliminary reports by Pett [1935, 1, 2] should be consulted. The chemistry of lactoflavin may be briefly reviewed. Kuhn *et al.* [1933] obtained from milk a yellow-coloured, green-fluorescing substance which received the name lactoflavin, and around which the chief interest now centres. Lactoflavin has the formula $C_{17}H_{20}O_6N_4$. It easily accepts hydrogen thereby losing its colour and fluorescence. Oxygen from the air readily oxidises the reduced form. Under the influence of alkali and strong light it loses a carbohydrate group and the resulting yellow pigment, called lumilactoflavin, has the formula of 6:7:9-trimethyl*iso*alloxazine, which has been synthesised. The carbohydrate is probably in position 9. If lumilactoflavin is heated with alkali, urea is split off. A blue-fluorescing photo-derivative, 6:7-dimethylalloxazine, has been described by Karrer [1934, 2].

Flavin has been found in brewer's yeast in amounts varying between 18 and 30γ per g., and in slightly higher amounts in baker's yeast. In bacteria the amounts vary from the low value of 2γ per g. for *Thermobacterium helveticum* [Adler and Euler, 1934] and 10γ for *Bacterium pasteurianum* to the high values of 77–115γ for *Bact. delbrückii* and 91–136 for *Clostridium butyricum* [Warburg and Christian, 1933]. The present paper reports some further analyses for different organisms. Euler and Adler [1934, 1] showed that flavin in yeast is chiefly present in undialysable, or bound, form.

EXPERIMENTAL.

The yeast was grown in a medium containing per litre: 30 g. glucose, 5 g. $(NH_4)_2SO_4$, 3 g. Na_2HPO_4, H_2O, 3 g. KH_2PO_4, 2 g. NaCl, 0·1 g. $MgSO_4, 7H_2O$, and about 0·1 g. marmite; initial p_H about 6·5, final 4·5 to 5·0 unless controlled. To this control solution additions were made in the following amounts: urea,

---

[1] Overseas Scholar (Canada) of the Royal Commission for the Exhibition of 1851.

10 g. per litre; $FeSO_4$, $FeCl_3$, 0·01 g. per litre; $CuSO_4,5H_2O$, 0·001 g. per litre; nucleic acid, 2 g. per litre; S, 3 g. per litre; Na_2S, 5 g. per litre. Cyanide and pyridine solutions, sterilised by filtration, were added after autoclaving the medium.

The yeast used for inoculation was a specially isolated strain of bottom yeast from a Stockholm brewery. Bacteriological technique was used throughout. An inoculum of 5 ml. per flask was used and contained about 1γ of flavin.

After maximum fermentation had been reached (about 5 days) the yeast was centrifuged and washed twice with distilled water. Part was then taken for moisture determinations and the remainder weighed in a small Erlenmeyer flask and treated with 6–10 ml. of 95 % ethyl alcohol. After some hours the mixture was heated at 70° for 2 minutes, under a condenser, and filtered. The yeast and filter were returned to the flask and re-extracted with a few ml. of 60 % alcohol. After 2–3 hours the mixture was again heated, filtered and re-extracted. If allowed to stand 12 hours or more the extract may be filtered without heating. Usually two treatments with 60 % alcohol were sufficient. The volume of the combined extracts was taken and a portion filtered through a hard paper. After one or more filtrations the solution was clear enough to be examined using a carbon arc lamp, the beams of which were concentrated by a lens. Comparison of the intensity of the green fluorescence is made with standard tubes of lactoflavin. Often a cloudiness prevents measurement, but is sometimes removed by shaking with light petroleum. This method is essentially that described by Euler and Adler [1934, 2].

More exact measurements, necessitated by the small amount of material available, were also made. The extracts were made alkaline, until equal to 0·5N NaOH, and exposed under a 500 watt lamp for 3 hours, using a special system of cooling and aeration. This solution was acidified to Congo red paper and extracted with chloroform. Several extractions remove the lumilactoflavin; the chloroform was then dried with sodium sulphate and filtered, and the fluorescence intensity was determined in a Zeiss "Stufenphotometer", previously calibrated by standard solutions.

All experiments were done two or more times. Results are expressed in γ of flavin per g. dry weight of substance. With any given solution the results usually agreed within ±3·0, but sometimes the error was about 6·0 %. Thus considerable differences are necessary to be significant.

RESULTS.

Flavin of yeast grown in different solutions.

The results shown in Table I indicate that the only method of influencing the amount of flavin was to affect the metabolism of the yeast, especially in relation to the physiological functioning of oxidation-reduction systems.

Table I. *The amounts of lactoflavin in yeast grown in different solutions.*

Flavin is expressed as γ per g. dry weight.

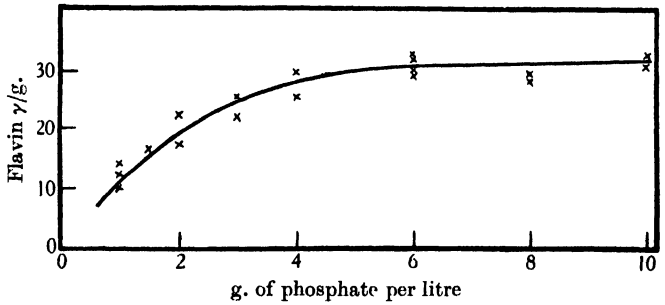

Fig. 3. The relation between the flavin content of yeast and the concentration of phosphate in which it was grown.

Discussion of flavin changes in yeast. Since only 2–3γ of flavin per flask were present at the start, and after some days' growth the yeast present contained 15γ or more, yeast must form flavin. The lower content of flavin resulting when yeast is grown with much malt extract suggests that favourable conditions for growth in the medium depress the development of flavin.

Under aerobic conditions, produced by a flow of air through the medium, the amount of flavin was lower than normal. Such conditions have long been known to depress fermentation and to promote reproduction and spore-formation. Since flavin was also depressed, some connection with fermentation is suggested.

Fig. 3 shows that a certain concentration of phosphate was necessary for normal flavin production. This seems clear in spite of some undetermined factor which caused considerable variation in the flavin contents of yeasts grown with little phosphate. This observation has great interest in view of the recent suggestion by Theorell [1934] that phosphate forms part of the active group of lactoflavin, when attached to protein to form the yellow enyzme. Since free phosphate was still present, the effect cannot be due to lack of phosphate. The explanation possibly lies in a lowering of the phosphatase activity of the yeast [Pett, 1934].

Of great interest is the increase of flavin in the presence of potassium cyanide, cysteine and pyridine (Table I, Figs. 1, 2). That flavin-enzyme has some kind of respiratory function was suggested as its properties became known in the original work of Warburg and Christian. It is, however, usually considered that iron-containing haemin compounds are chiefly concerned in cellular respiration, and the precise function of the yellow enzyme is still not clear, being possibly more related to fermentation. Nevertheless, when the normal, iron-containing oxidation mechanism is poisoned by the yeast being grown in cyanide, more flavin than normal is produced. Thus flavin can be considered an alternative system, developed to aid the cell's respiration, and it may be the only system left in cyanide-yeast.

Yeast grown in cyanide shows the characteristic spectrum bands of haemochromogen compounds, showing that these are present to some extent, even though not active. No evidence of utilisation of the cyanide by yeast was found: quantitative determinations at the beginning and end of several fermentations yielded about the same values.

Fermentation and respiration of cyanide-yeast.

For these experiments 5-litre flasks containing 4 litres of medium were used. Of the centrifuged yeast, washed free from KCN, part was used directly for flavin and moisture determinations, part was dried for dialysis in collodion, to determine the bound flavin, and part was suspended in water. This last portion was aerated according to the method of Ambrus *et al.* [1931], to remove easily oxidisable substances, and was then used for fermentation and respiration estimations and for Thunberg methylene blue reduction tests.

Fermentation was carried out, according to the well-known methods of Euler and Myrbäck, in small tubes using 0·5 ml. of 2 % KH_2PO_4 solution, 1 ml. of 10 % glucose and 0·5 ml. of yeast suspension. Results are expressed as ml. of gas evolved in one hour by 1·0 g. (dry) of yeast. The Thunberg test was performed with a final methylene blue concentration of $M/20{,}000$, and results are expressed in minutes required for decoloration, using fresh yeast equivalent to 0·01 g. The same amount of yeast was used for the Warburg respiration and results give ml. of oxygen per hour. Table II shows the results obtained with yeasts grown normally, with added iron and with added cyanide.

Table II. *Some properties of yeasts grown with added iron and cyanide.*

	Flavin					Thunberg MB reduction		
First experiment:	Total	Bound	Bound %	Fermentation	Warburg respiration	Without subst.	Glucose	Alcohol
Control	32	27	84	252	128	24	25	19
plus Fe	28	18	72	160	162	38	44	31
plus KCN	55	51	93	248	110	20	27	13
Second experiment:								
Control	30	25	81	170	190	—	—	—
plus Fe	26	21	81	118	246	—	—	—
plus KCN	46	44	95	178	140	—	—	—

The respiration of yeast grown in cyanide is somewhat less than normal but normal fermentation is maintained. The respiration was reduced from 140 only to 128 in the presence of $M/500$ KCN in the apparatus, indicating that the increased flavin content is chiefly responsible for the respiration observed, since under these conditions normal yeast respiration is inhibited 70 to 90 % [see Dixon and Elliott, 1929].

The alternative action between iron-compounds and flavin is supported by the observation of Malkov [1933] that phosphates inhibit respiration and stimulate fermentation by forming insoluble iron compounds. The work of Elvehjem [1931] had already shown that yeast grown with iron in the solution has an increased cytochrome content and respiration, the latter being clearly indicated also in Table II. Elvehjem also indicated that the longer yeast is grown the less its fermentation is inhibited by cyanide in the Warburg apparatus, and that the cyanide-stable system is concerned in glucose metabolism. Kuhn and Meyer [1929] have, on the contrary, suggested that this system is concerned in fat, not carbohydrate, metabolism. Zuckerkandl and Messiner-Klebermann [1932] have suggested that the cyanide-insensitive system concerned in fermentation also contains iron. From our work it might appear that this cyanide-stable part is flavin.

Effect of continuous culture of yeast in KCN.

When yeast was grown in a medium containing $M/1000$ KCN apparently normal gas production took place. Also, as shown above, the lactoflavin content was higher than normal. If yeast was taken from such a flask and added to another, also containing KCN, the same effect was observed. But when these transferences were continued a yeast was obtained, usually after the third to fifth culture, giving an extract with a blue fluorescence. In some cases all the fluorescence was blue, but more commonly some green (lactoflavin) fluorescence was also present. This blue persisted in subsequent transferences. It was not reducible by hydrosulphite. Inoculation into medium free from cyanide brought the green fluorescence back to normal, though sometimes some blue was present in the first transference.

It seems possible that during long-continued growth in cyanide yeast develops a special mechanism involving a blue-fluorescing substance which may or may not be related to lactoflavin.

Flavin contents of various organisms.

An examination of the quantity of lactoflavin found in various yeasts and bacteria, as shown in Table III, shows that flavin is not as generally distributed in bacteria as in higher organisms. All determinations were made as previously described.

Table III. *The amounts of flavin in various organisms.*

	γ per g.		γ per g.
Bottom yeast	20–25	*Aspergillus*	Nil (blue)
Top yeast:		*Penicillium*	Nil (blue)
Baker's (Stockholm) ...	25	*Proteus vulgaris*	Nil
Race "M"	33	*Staphylococcus albus* ...	Nil (blue)
Race XII	38	*Bacterium coli* A	Nil (blue)
Wild yeast:		*Bacterium coli* B ... ... (pathogenic)	Trace <1
Torula utilis	27		
Mycoderma cerevisiae ...	12	*Bacterium aerogenes* ...	9·8
Pichia membranifaciens ...	30	*Bacillus subtilis*	7·5

The idea that flavin is an alternative to actively aerobic, iron-containing systems and that it has a relation to fermentation finds some support in Table III. Thus a weakly fermenting, strongly aerobic yeast like *Mycoderma* has a very low content of flavin. *Pichia* and top yeasts are aerobic, but strongly fermenting, and have higher amounts. *Torula* is not so strongly fermenting, but has a fairly high flavin content, possibly because it is not strongly aerobic and is said to have incomplete haemin systems.

Moulds, like *Aspergillus* and *Penicillium*, of which the species were unfortunately not known, although containing green-fluorescing substances, showed only blue fluorescence after the treatment for the preparation of lumilactoflavin. They are, of course, strongly aerobic, but according to Frei *et al.* [1934] they contain neither cytochrome nor haematin compounds in general.

Flavin and bacteria.

No systematic study of flavin distribution in bacteria, such as that made for haemin compounds by Frei *et al.* [1934], has been made, but the results in Table III, together with previously mentioned determinations, give some idea of the situation. Undoubtedly also many older observations of colours in bacteria, especially of yellow colours, are significant in this connection. While some of these are undoubtedly carotenoids, the work of Ingraham and Baumann [1934] shows that this is true only in aerobes. Anaerobes, such as *B. butyricus*, do not contain carotenoids, but contain much lactoflavin.

That many bacteria do not contain flavin is also evident. While flavin is undoubtedly present in many kinds of tissue, it is thus not universal. Some bacteria contain other respiration pigments, like the pyocyanin of Wrede and Strack [1929], or the chloraphin of Kögl *et al.* [1932].

The possibility that some bacteria not only do not contain flavin but can actually transform it was indicated by Pett [1935, 1]. In that communication it was pointed out that an organism had been isolated from a lactoflavin solution which had become blue-fluorescing; and that this organism if placed in very small amount in a flavin solution caused the disappearance of the green fluorescence, and the development of a blue fluorescence. A few more facts can be presented. The use of fresh centrifuged, washed bacteria has been found more convenient. Dried bacteria in extremely minute quantity also effect the change described above. Their activity is about the same from p_H 6·5 to 8 but falls off in the more acid and alkaline ranges. The blue-fluorescent substance, either extracted from bacteria or developed as above, and then purified a little by extractions, fluoresces between 330 and 370$m\mu$; some preparations showed a faint absorption band about 264$m\mu$.

Of the organisms mentioned in Table III only *Bact. coli* A and *Bact. aerogenes* can act like the organism described by Pett [1935, 1], but *Bact. coli* acts much more slowly, and *Bact. aerogenes* produces a blue fluorescence reducible by hydrosulphite.

DISCUSSION.

This work contributes to two interesting points in the study of flavins: (1) the function of lactoflavin and (2) the importance of blue-fluorescing substances possibly related to lactoflavin.

The function of flavin in yeast might seem to be similar to that of the many other intermediate carriers for the oxidation-reduction activities, such as cytochrome or glutathione, assisted by the fact that it is autoxidisable. The increase of flavin in yeast grown in cyanide, shown in this paper, suggests that it is an alternative mechanism to iron-containing catalysts, but it is known that most of the normal respiration of yeast is not effected through flavin. The evidence advanced for a function in fermentation rather than respiration is not very strong for yeast but receives considerable support by analogy with bacteria.

In considering the function of lactoflavin in bacteria, as well as yeast, it must be remembered that the transference of oxygen is slower by way of flavin than by way of haemin compounds. Thus any cell containing haemin would not use flavin-enzyme for the same purpose. Using a lactic acid organism, which contained no haemochromogen, Warburg and Christian observed simultaneously the respiration and the amount of reduced flavin. They considered their results to show that all the respiration occurred by means of flavin. However, the spectrographic method of estimating the oxygen-transporting enzyme has been criticised as unreliable by Keilin [1933]. Adler and Euler [1934] showed an increase in respiration of bacteria in the presence of flavin, and especially if cozymase was also present.

In considering these results there is involved the old problem of what distinction must be made between fermentation and respiration. The respiration of lactic acid bacteria in the presence of fermentable substrate is quite different from the respiration of the bacterial cells themselves [Davis, 1933; Bertho and Glück, 1932]. Stimulation of the respiration of lactic acid bacteria by methylene blue is observed only if fermentation is taking place, and this may be true of flavin. An association with cozymase is of interest in this connection, though this appears to be related simply to the dehydrogenase system [Euler and Adler, 1934, 3]. The fact that the highest content of lactoflavin is found in anaerobic bacteria may be related to the strong fermenting ability of these bacteria rather than to their anaerobicity.

The present paper has shown that some organisms do not contain flavin, that other organisms contain it in only very small amounts, and that these results can be related to the fermentative power of the organisms. It has also been shown that if haemochromogen compounds are poisoned, the flavin system can develop and carry on suitable respiration. The function of flavin is, therefore, still obscure, except in the latter specific case.

Blue-fluorescing substances, possibly related to flavin, have been indicated from time to time by most of the workers in this field. These observations are complicated by the fact that many normal cell constituents, such as proteins or nucleotides, give a blue fluorescence in ultra-violet radiation, though not so many with a carbon arc lamp as used in this work. Karrer [1934, 1, 2] has described certain chemically prepared flavin derivatives with blue fluorescence. The chief example, lumichrome, loses its colour in the presence of hydrosulphite. Other apparent derivatives [see Euler and Adler, 1934, 4] are stable to hydrosulphite. Reduction by hydrosulphite is probably not a good criterion of lactoflavin but is of interest.

Pett [1935, 2] showed that a blue fluorescence appears during autolysis of yeast and during starvation of yeast. The present paper reports a blue fluorescence developed in yeast after continuous culture in cyanide, as well as from bacterial sources. The explanation of these observations cannot at present be given, but blue-fluorescing substances related to lactoflavin seem to be a promising field for future work.

SUMMARY.

Using a standard nutrient solution with the addition of various substances an attempt was made to vary the lactoflavin content of bottom yeast. The chief effect was observed by influencing the metabolism of the yeast, especially the functioning of redox systems. The following observations were made:

1. The presence of cyanide, cysteine or pyridine, which can poison the iron-containing catalysts, produced a flavin content much higher than normal.

2. Yeast grown in cyanide has a normal fermentation but a respiration below normal.

3. A certain amount of phosphate must be present in the medium for normal flavin development.

4. Under strongly aerobic conditions, which depress fermentation, the amount of flavin is also lowered. Some other evidence of a relation to fermentation is adduced.

5. Continued subculture of yeast in media containing cyanide resulted in the development of a blue-fluorescing substance, which partially or wholly replaces flavin.

6. The flavin contents of various organisms are reported.

The results are discussed in relation to flavin function and to blue-fluorescing substances.

The author wishes to express his appreciation to Prof. Hans von Euler for providing facilities, for suggesting the problem and for helpful interest during the work. Thanks are also due to Dr E. Adler for an introduction to the methods involved and to Dr H. Hellström for spectrographic work.

CXIV. THE HEMICELLULOSES.

I. ALCOHOLIC SODIUM HYDROXIDE AS A PRETREATMENT TO EXTRACTION.

By ARTHUR GEOFFREY NORMAN.

From the Biochemistry Section, Rothamsted Experimental Station.

(*Received March 1st, 1935.*)

INTRODUCTION.

THE hemicelluloses of plant materials form a group of polysaccharides, the investigation of which presents many difficulties. Neither their rôle nor their genesis is at present understood, and yet, in mature materials, they may amount to as much as 30 % of the whole, and they rank next to cellulose in quantitative importance. The name hemicellulose, due originally to Schultze [1892], is unfortunate, as it implies a close relationship to cellulose which, so far as most types of hemicellulose are concerned, does not appear to be justifiable. Hawley and Norman [1932] have discussed the occurrence and properties of hemicelluloses of plant materials and woods and differentiated them into two main groups differing in structure, distribution and function. For that type of polysaccharide intimately associated with the cellulose they have suggested the name "cellulosan". In most sources examined the cellulosan has proved to be a xylan, save in the Gymnosperms where a mannan also is found. The larger group of hemicelluloses is, however, not associated with the cellulose, but forms the incrusting material on the cell wall. Almost invariably has this type of polysaccharide been found to be a polyuronide. The two main groups of hemicelluloses, therefore, are the cellulosans and the polyuronides. In these papers it is proposed to deal more particularly with the incrusting polyuronides. Researches on the cellulosans will appear separately.

The isolation of hemicelluloses, and in particular those of the polyuronide group, in a pure condition is not easy. Extraction must be made with dilute alkali under conditions that result also in the solution of lignin and proteins, and the final preparation obtained after acidification and precipitation with alcohol or acetone is almost invariably contaminated with lignin, though this is rarely determined. The estimation of this group is still very unsatisfactory and inaccurate. Hydrolytic methods are of little use owing to the instability of uronic acids in hot mineral acids. Preece [1931, 2] produced a scheme for the evaluation of hemicelluloses in boxwood, depending on direct isolation and weighing, and Buston [1934; 1935] extended this to such materials as grasses and leaves in which the protein content is much higher. All the hemicellulose fractions obtained have to be corrected for the presence of protein.

To minimise the amount of lignin likely to pass into the preparation, Norris and Preece [1930], in isolating the polyuronides from wheat bran, carried out a pretreatment of the material with 50 % alcohol containing 1 % NaOH. Two extractions were given under a reflux for 2 hours each. This same pretreatment was also used and was then followed by further extraction with hot neutral 50 % alcohol in other preparations [Preece, 1930; 1931, 1, 2]. It was apparently assumed that because hemicelluloses are insoluble in cold 50 % alcohol under acid conditions, they will also be equally insoluble in hot 50 % alcohol under alkaline conditions. Later, in putting forward his quantitative method for boxwood, Preece [1931, 2] recommended one treatment for 1½ hours with boiling 50 % alcohol containing 1 % NaOH, followed by two extractions with neutral alcohol. Buston [1934], in preparing the polyuronides from cocksfoot grass, modified this treatment, giving instead a cold extraction overnight with the same concentration of alcoholic soda, and in his quantitative method he gave a similar pretreatment in the cold for 24 hours. Though the extraction with alcoholic soda was designed originally to remove lignin, it also reduces the amount of protein carried through into the subsequent alkaline extract and consequently into the hemicellulose preparation.

In some work on the delignification of straws and similar materials the effect of extraction with alcoholic soda of this and other concentrations was determined. It was found that while the removal of lignin was but partial, the material sustained heavy losses which could only be ascribed to the hemicelluloses. The results obtained caused the effect of alcoholic soda to be examined in more detail and show that its use in the heat is inadvisable prior either to preparation or estimation of hemicelluloses, and that even in the cold it is not without action on this group.

EXPERIMENTAL.

(a) *Extractions with NaOH in various alcohol concentrations.*

One gram samples of oat straw (60 mesh) were extracted in duplicate with various concentrations of alcoholic NaOH. After thorough washing with alcohol of the same concentration, containing a little acetic acid, then with 50 % alcohol to remove sodium acetate and finally with 95 % alcohol, the residue was determined. The two extractions were bulked and ground up, prior to duplicate lignin determinations, after hydrolysis with 5 % H_2SO_4 as described by Norman and Jenkins [1933]. The results are given in Table I, from which it is apparent that the loss in lignin forms only a small part of the total loss. Since a mature material was concerned, the three constituents, cellulose, hemicelluloses and lignin, account for about 90 % of the whole, and inasmuch as it is unlikely that true cellulose would be affected, the inference was that hemicellulose material, either polyuronide or cellulosan, or both, was extensively removed. As mentioned previously, no method for the estimation of the polyuronides is really satisfactory and accordingly no attempt at direct estimation was made, reliance being placed instead on the yield of furfuraldehyde as a measure of the hemicellulose present. The furfuraldehyde due to cellulosan may readily be determined and the difference between that and total furfuraldehyde represents that from the polyuronides.

Table I. *Extraction of oat straw (A) with alcoholic NaOH.*

Initial lignin content 11·39 %.
Lignin contents expressed on original material.

NaOH concentration %	Alcohol concentration %	Time in hours	Temperature	Residue %	Lignin content %	Delignification %
1	90	1	B.P.	56·9	4·61	59·6
1	90	¼	B.P.	62·9	4·74	58·4
1	90	2	60°	63·4	6·57	42·2
1	90	2	15°	70·9	8·07	29·2
0·2	90	1	B.P.	61·8	6·41	43·7
0·02	90	1	B.P.	75·8	9·84	13·6
1	60	1	B.P.	57·4	3·75	66·8
5	60	1	B.P.	57·2	3·92	65·3

A series of experiments was carried out on another sample of oat straw which proved to be rather less susceptible to alcoholic soda. Extractions were made with 100 ml. of a solution of 1 % NaOH in alcohol concentrations of 90 %, 70 %, 50 %, 30 % and with 1 % of NaOH in water. Each was carried out in duplicate and both hot and cold. The former were made at the boiling-point of the mixture for 1 hour and the latter at approximately 16° for 2 hours. The alcoholic soda extract in each case was acidified with H_2SO_4 and diluted so that the final volume was 600 ml. and the acid concentration 3 %. This was then hydrolysed by boiling for 2 hours, and the lignin, which remained insoluble, was filtered off, dried and weighed. The residue, after appropriate washing, was weighed, the duplicates bulked together, ground up finely and analysed. Cellulose determinations were made by the method of Norman and Jenkins [1933], furfuraldehyde determinations by the usual phloroglucide procedure and lignin determinations by treatment with 72 % H_2SO_4 for 2 hours and subsequent hydrolysis after dilution to 3 %. The results obtained are summarised in Table II, all the analyses being calculated on the original material.

Considering first the hot extractions, it is seen that there was an appreciable fall in the yield of furfuraldehyde from both polyuronides and cellulosan with even the 90 % alcoholic soda, and that with the lower concentrations of 50 % and below, the apparent loss of the former was very extensive. The 30 % solution appeared, rather surprisingly, to remove more of the polyuronides than an aqueous solution, though less of the xylan in the cellulose was extracted. The 50 % solution, as recommended by Preece [1931, 2] for the lowering of the lignin content, did in fact remove about 65 %, but this was accompanied by roughly 40 % of the polyuronides, if the furfuraldehyde yield may be taken as a direct measure, and 5 % of the xylan.

In the cold, the action of alcoholic soda was less drastic and in 90 % alcohol 1 % NaOH removed very little either of the polyuronides or the lignin. With lower concentrations there was some loss of polyuronides, and again it was noted that the 30 % alcoholic solution caused a greater loss of this constituent than did the aqueous solution. The figures for xylan in cellulose were unaccountably high in this group of extractions, and no apparent loss occurred save in aqueous solution. Delignification was in no case very effective and did not exceed 26 %. The recovery of lignin from the extract did not appear to be quite quantitative.

From Table II as a whole it is quite clear that any treatment which brings about a considerable lowering of the lignin content also extracts appreciable quantities of polyuronide material.

The preliminary experiments given in Table I indicated that a NaOH concentration of much less than 1 % would extract considerable amounts of material from straw, and accordingly the losses with 0·1 % NaOH in various alcoholic solutions were determined for oat straw B.

Table III. *Extraction of oat straw B with 0·1 % NaOH in various alcohol concentrations for 1 hour at boiling-point.*

Alcohol %	Residue %
90	80·4
70	77·9
50	76·6
30	72·8
—	77·3

The loss with 0·1 % NaOH in 90 % alcohol was found to be almost identical with that caused by 1 % NaOH, but at lower concentrations of alcohol the more dilute alkali did not prove to be such an efficient extracting agent. The curious difference between the effect of the 30 % alcoholic and the aqueous solutions was more marked in this series, the total loss being greater in the slightly alcoholic solution. Detailed analyses were carried out on the residues from these two extractions (Table IV) and the results showed that the extra loss in alcoholic solution was due to each of the three chief extractable groups, cellulosan, lignin and polyuronides. With hot 1 % NaOH as given in Table II only the polyuronides showed a greater loss in 30 % alcohol than in water.

(*b*) *Extraction of various materials with 1 % NaOH in 50 % alcohol.*

Because of the apparent difference in susceptibility noted between the two samples of oat straw employed, a survey was made on a number of plant materials of widely different composition. Extractions were carried out with 1 % NaOH in 50 % alcohol for 1½ hours at the boiling-point, as recommended by Preece [1931, 2] for quantitative work, and also overnight in the cold with the same reagent, as used by Buston [1934], with the minor, and probably unimportant, difference that the time of standing was 16 hours instead of 24 hours. The materials were oak wood, jute fibre, old bean straw, mature hay, wheat plants just before harvest, green wheat plants six weeks before harvest (1·4 % N), mature vetches (2·53 % N) and young green vetches (4·88 % N), thus giving a range from highly lignified to young green materials.

Analyses were carried out on the extracted residues as described before. The results are given in Table V.

Table V. *Extraction of various materials with 1 % NaOH in 50 % alcohol; hot extractions 1½ hours at boiling-point, cold extractions 16 hours at room temperature.*

The mature materials suffered less total loss than the younger tissues, as might have been expected. In the case of the latter, much of the material removed was protein in nature. The cold treatment was not very effective in the removal of lignin, the percentage delignification only exceeding a third in one case. In some materials, though not in all, there was a distinct fall in the furfuraldehyde from polyuronides as a result of the extraction in the cold. The amount of hemicellulose removed, as judged by this figure, seemed to be larger in the case of the immature materials than in the mature; there was also a loss of xylan in some cases, though certain discrepancies occurred in these analyses. The figures obtained after the hot extraction, on the other hand, indicated in every sample an appreciable loss of polyuronide material and a fall also in the xylan associated with the cellulose. Delignification, of course, was more effective under these conditions, particularly in the less mature materials. However, in no experiment was it complete, and in oak and bean it was far from extensive.

There is no doubt that if the procedure of Preece [1931, 2] be followed, and a hot extraction with 1 % NaOH in 50 % alcohol be given, prior to the extraction of hemicelluloses, the values for that group will be low to an extent which varies with the nature of the material. It happened that Preece [1931, 2] worked with boxwood in which the hemicelluloses seemed rather more resistant to the action of alcoholic soda than those of some of the materials investigated in this work. While the treatment in the cold adopted by Buston [1934] has not such a drastic effect, it cannot be said to be without action on the polyuronides in all cases.

(c) *Extraction of isolated hemicellulose with alcoholic NaOH.*

Hemicelluloses once isolated are known to be rather more easily soluble than when *in situ* in the plant, and for example, go slowly into solution on boiling with water and readily in dilute alkali. Despite this change in properties, it was thought to be worth while to determine the solubility of a preparation in alcoholic NaOH. A crude sample of hemicellulose A was prepared from oat straw by the usual means but omitting the pretreatment with 50 % alcoholic soda. Without attempt at purification a cream-coloured product was obtained with a furfuraldehyde yield of 37·0 % and a lignin content (determined by boiling with 3 % acid for 4 hours and weighing the residue as lignin) of 14·7 %, both on an ash-free basis. Corrected for the presence of lignin, the furfuraldehyde yield represents 43·4 %. Small samples were treated with 1 % NaOH in 50 % and 90 % alcohol, both hot and cold, the hot extractions being continued for 1½ hours and the cold for 16 hours. The residues were filtered off, weighed and ashed, and the filtrates in the case of the hot extractions were taken for furfuraldehyde determinations. The results are given in Table VI.

Table VI. *Extraction of isolated hemicellulose with alcoholic NaOH.*

Results given on ash-free basis.

1 % NaOH in alcohol	Hemicellulose taken mg.	Residue mg.	% extracted	Furfurald. on extract mg.
90 % hot	300·3	258·3	14·0	Trace
	293·6	265·1	9·8	Trace
90 % cold	299·4	300·9	—	—*
	298·6	289·8	2·9	—*
50 % hot	295·4	211·2	28·5	10·9
	303·2	220·8	27·2	9·7
50 % cold	303·9	263·8	13·2	—*
	300·4	264·4	12·0	—*

Not determined.

The process of isolation did not produce any apparent increase in susceptibility to attack by alcoholic soda. While the 90 % solution in the cold removed little or nothing, some material went into solution in the heat. This was largely no doubt contaminating lignin since only a trace of furfuraldehyde was given by the extract. With the 50 % solution more than a quarter dissolved on boiling and about half this amount in the cold. The quantities available were too small to make possible any investigation of the nature of the material removed. If it be assumed that the hot extraction with 50 % alcoholic solution removed all the lignin from the hemicellulose, then the hemicellulosic fraction also removed had a furfuraldehyde yield of about 25 %, significantly lower than that of the parent product. This suggests the possibility of some partial fractionation or fission. These experiments are only of a preliminary nature, and this point will receive further attention.

DISCUSSION.

In his paper on the composition of boxwood, Preece [1931, 2] noted that the 50 % alcoholic soda treatments removed in addition to lignin some furfuraldehyde-yielding material which he described as a "lignosaccharide," though he showed that it resembled the hemicelluloses in properties and composition. The chief demonstrable difference appeared to be that the "lignosaccharide" fraction was rather more resistant to hydrolysis than the main "free hemicellulose" fraction, though not very much more so than a portion of the latter. The experiments described here may be taken to support the existence of "lignosaccharides" if by that term is implied only hemicellulosic material going into solution in alcoholic soda. No evidence has however been adduced for the view that "lignosaccharides" represent an entirely new group of plant polysaccharides, and nothing in this work could be held to support such an opinion. The term seems unfortunate and likely to confuse even further the nomenclature of hemicelluloses. There does not appear to be any clear-cut fraction removable by 1 % NaOH in 50 % alcohol; the amount of material removed may be increased by heating or decreased by raising the alcohol content, and there is no indication that a different type of product is obtained in such cases. The behaviour of the polyuronides with this reagent seems to be precisely the same as that of lignin or the cellulosans, part of both of which is removable by 50 % alcohol.

The data presented make it plain that the employment of a pretreatment by boiling with 1 % NaOH in 50 % alcohol prior to a hemicellulose preparation will result in a lowering of the yield by an amount which may reach 50 %. As a preliminary to quantitative work this procedure is clearly inadmissible. In the cold its effect is less drastic and on mature materials seems to be slight. However, the effectiveness of such a cold treatment as a delignifying process is so low that it is hardly worth while carrying out. On young green materials cold alcoholic soda seems to produce some lowering of polyuronide material, and if it is desirable to give such a treatment as a means of removing much of the protein, the magnitude of the hemicellulose losses should be determined for each individual material.

If in the preparation of polyuronides purity rather than yield is the main object, there may be some justification for a pretreatment with hot alcoholic soda as a delignifying agent, though it has not been unquestionably shown that the product is wholly unchanged by this treatment. The separation of lignin and hemicellulose is at present under investigation, and preliminary results suggest that it may be better to revise the present procedure and to obtain by alkaline extraction an impure hemicellulose product contaminated with lignin, and then subsequently to remove the lignin by other means.

SUMMARY.

1. As a pretreatment to the preparation or direct estimation of hemicelluloses, an extraction of the material with 1 % NaOH in 50 % alcohol is employed as a delignifying process. The effect of this and other concentrations of alcoholic soda has been studied in this connection.

2. In the heat, 1 % NaOH in alcohol concentrations up to 90 % extracts a considerable amount of polyuronide material, the amount increasing as the alcohol concentration is decreased. In the cold, the action is less drastic in 70 and 90 % alcohol, but quite appreciable in 50 % and lower.

3. The polyuronide hemicelluloses of different materials vary in the degree of susceptibility to alcoholic soda. Those of immature tissues seem to be rather more easily removed than those of older lignified materials.

4. No indication has been obtained that the material removed by alcoholic soda represents a special group of the polyuronides.

CXV. STUDIES ON THE ANAEROBIC DECOMPOSITION OF PLANT MATERIALS.

II. SOME FACTORS INFLUENCING THE ANAEROBIC DECOMPOSITION OF RICE STRAW (*ORYZA SATIVA*).

By CADAMBI NARASIMHA ACHARYA.

From the Fermentation Department, Rothamsted Experimental Station, Harpenden.

(*Received March 1st, 1935.*)

In a previous communication dealing with the anaerobic decomposition of rice straw [Acharya, 1935], it was noted that several factors such as temperature and reaction of medium greatly influenced the rate and course of the decomposition. An examination of some of these factors is reported in the present paper.

The experimental procedure and methods of analysis adopted were the same as used previously [1935], except for the changes and modifications noted in the experiments described below.

Exp. 1. Influence of temperature. To 20 g. portions of rice straw were added a mixture of 2 g. $KHCO_3$ and 2 g. NH_4HCO_3 in order to neutralise the acids formed, 0·2 g. K_2HPO_4, 0·05 g. $MgSO_4,7H_2O$, 10 ml. of a 2 % extract of a rice soil and water to make up 200 ml. The bottles were stoppered and paraffined and after evacuation were incubated at the desired temperatures. At weekly intervals the accumulated gaseous products were tapped off into a Hempel's burette, measured and samples taken for analysis. The liquid and solid residues in the bottles were analysed at the end of 6 months, according to the procedure already described. The data obtained, calculated per 100 g. straw taken, are given in Table I.

Total weight of products	13·80	17·94	27·61	28·82	19·42	9·66

As the aim of the present investigation was to extend it to a study of anaerobic decomposition in the soil, the examination of the changes was confined to those taking place between 20° and 45°. The data show that the optimum amount of decomposition, as judged by loss of dry matter and total weight of products obtained, occurs between 30° and 35°. Outside this range there is an accumulation of acids and an increasing retardation in gas production. Hence in the experiments described below the temperature was maintained within this range. The figures given in Table I also show that though the amount of decomposition varies considerably at the different temperatures, the proportion of the net volume of CO_2 evolved, after correction for that evolved from carbonates, to that of methane produced is roughly unity.

Exp. 2. Influence of reaction of medium. Ammonium carbonate equivalent to 1 % N on the straw and K_2HPO_4, $MgSO_4,7H_2O$, soil extract and water in the quantities specified in the previous experiment were added to 20 g. portions of rice straw. The initial reaction of the medium was adjusted to the desired level by additions of H_2SO_4 or NaOH. All p_H determinations were made colorimetrically with the Hellige apparatus. Twice a week in the initial stages and at weekly intervals later, the accumulated gases were tapped off and 0·5 ml. of the reaction liquid was taken out for analysis, without the admission of air, by fitting a capillary of known volume into the exit tube, inverting the bottle and carefully unscrewing the pinchcock till the capillary was filled. The sample taken was diluted and titrated colorimetrically from a micro-burette to the desired p_H and the equivalent amount of acid or alkali was added to the contents of the bottle. On account of the buffering action of the organic acids formed, the method was found to give a reliable control of the p_H at the time of operation correct to ±0·1. Owing to the rapid formation of acids in the early stages, however, difficulty was experienced in maintaining the p_H at the desired figure over a number of days, though an effort was made to keep to the approximate level by frequent checks and additions of alkali when necessary. It has already been noted that the use of buffers was rendered impossible on account of the high concentration of acids formed.

The data obtained (Table II) show that the maximum loss of dry matter occurs at about p_H 8, at which level there is also the maximum evolution of methane and the minimum accumulation of acids. Above and below this p_H there is an increasing tendency for an accumulation of acids and a retardation of methane production, showing that the initial stage of acid formation is much more tolerant of changes in the reaction of medium than is the second stage of methane production. Very little methane production takes place below p_H 6 and above p_H 9; the rate is optimum at p_H 8 and falls rapidly on either side of this value. The accumulation of acids at p_H 9–10 suggests a method for the conversion of straw into acids, mainly acetic and butyric, by anaerobic digestion

Table II. *Decomposition of rice straw at different* p_H *values.*

g. per 100 g. of straw

p_H ...	5	6	7	8	9	10
At the end of 6 months:						
Loss of dry matter less ash	15·2	25·3	35·5	56·6	50·5	48·2

CH_4 evolved and in solution	0·14	2·43	3·75	6·94	3·67	1·39
Acetic acid present	5·35	3·57	3·13	2·11	10·85	16·05
Butyric acid present	1·89	1·02	0·85	Nil	1·76	3·21
Total weight of products	8·99	15·29	21·13	31·92	30·40	33·57

at this range. For gas production a range of p_H 7·5 to 8 seems to be optimum. The concentration of CO_2 in solution is high at the higher p_H levels which may be due to the chemical action of alkali at high concentrations on rice straw.

Exp. 3. Influence of different proportions of water. According to the hypothesis [Symons and Buswell, 1933; Boruff and Buswell, 1934; Tarvin and Buswell, 1934] that anaerobic degradation is an oxidation-reduction reaction involving the addition of water and scission of the molecule into simpler compounds, a higher proportion of water would probably be necessary than if water played no part in the decomposition. Langwell and Lymn [1932] noted that a mobile liquid medium was necessary for successful thermophilic digestion of plant materials. A concentration of 8–10 % solids has been found optimum for the anaerobic digestion of sewage solids and garbage [Keefer and Kratz, 1934]. It was therefore thought interesting to examine the effect of adding different proportions of water on the rate of decomposition of rice straw.

The experimental details were the same as in Exps. 1 and 2, except that the ratio of straw to water was varied to give the following proportions: 1 : 4, 1 : 6, 1 : 8, 1 : 10, 1 : 15 and 1 : 20.

The results obtained (Table III) show that gas production is much impeded below a straw : water ratio of 1 : 8. The optimum concentration appears to be about 1 : 10, above which further additions of water are of no advantage. On the other hand, at a concentration of 1 : 20 there is actually a decrease in gas production. The optimum proportion of straw to water of 1 : 10 may be compared with the proportion of 1 : 4 or 5 generally found to be favourable for aerobic decomposition.

Total weight of products	11·01	22·51	28·21	29·81	29·76	29·40

Exp. 4. Effect of inoculation with soil. The object of this experiment was to examine the differences if any between the rate and course of decomposition in presence of soil extract and in its absence. It is well known that natural products, *e.g.* straw, carry a microflora able to bring about their rapid decomposition. The experimental details were the same as before but no soil extract was added.

The data (Table IV) show that the rate and course of fermentation are the same both in presence and absence of soil inoculant, proving that the straw itself carries the micro-organisms necessary to bring about its decomposition.

Exp. 5. Effect of addition of phosphate. The present sample of straw contained 0·42 % P_2O_5 and the question as to whether addition of phosphate assisted anaerobic decomposition was examined by fermenting samples with and without the addition of phosphate (1 g. K_2HPO_4 per 100 g. straw).

The results (Table IV) show that the phosphate requirement for anaerobic digestion is quite small and is apparently satisfied by the phosphate present in the straw itself. Additions of phosphate, *e.g.* K_2HPO_4, do not exert any stimulating effect except by way of improving the reaction of the medium where the initial reaction is unfavourable for anaerobic digestion. Excess of phosphate at concentrations of 5 % and above on the straw taken was found greatly to impede the decomposition.

Table IV. *Exps. 4, 5, 6 and 7.*

Results in g. per 100 g. straw.

After 6 months:	Control	Exp. 4 Omission of soil inoculum	Exp. 5 Omission of phosphate	Exp. 6 Powdered straw	Exp. 7 Inoculation with vigorous culture

Net CH_4 evolved	6·87	7·10	6·52	5·82	7·32
Butyric acid present	0·23	Nil	0·86	0·98	Nil
Acetic acid present	1·07	0·83	1·82	3·22	0·42
Total weight of products	27·61	27·65	27·98	26·88	27·72
Preliminary lag period (days)	12	10	12	14	12

Exp. 6. Influence of powdering the straw (Table IV). This was tested by using 20 g. portions of straw ground so as to pass a 60-mesh sieve. The powdered sample in presence of excess of water formed a compact layer at the bottom, which did not ferment so readily as when chaffed straw was used. The total amount of decomposition is of the same order as with chaffed straw, but more acid is present. The amount of methane evolved is 8110 ml. as compared with 9585 ml. in the control.

Exp. 7. Effect of inoculation with an old culture (Table IV). A period of preliminary incubation or lag period is generally associated with anaerobic digestion and is attributed to the time taken for the development of the specific microflora necessary for effecting decomposition. The object of the present experiment was to see whether the lag period could be shortened by the addition to the medium of a small quantity of an inoculant from a vigorously growing culture. To 20 g. portions of rice straw, 5 ml. of the inoculant from an actively fermenting culture were added in place of the soil extract. The results show that the addition of such a small quantity of inoculant has no appreciable effect in shortening the period of incubation or hastening the rate of decomposition. It has been found that a fairly high proportion of seed is necessary to carry on successful digestion of fresh sewage solids [Whitehead and O'Shaughnessy, 1931].

Exp. 8. Use of different neutralising agents (Table V). Attention has already been drawn to the large amount of acids formed and the difficulty found in maintaining an alkaline reaction by the use of buffers. As the aim was to keep the reaction at about p_H 7·5 to 8, various weak neutralising agents were tried.

Table V. *Decomposition of rice straw in presence of different neutralising agents.*

g. per 100 g. straw after 6 months.

	Neutralising agent	Loss of dry matter less ash	Net CO_2	Net CH_4	Acetic acid	Butyric acid	Total weight of products
1.	$CaCO_3$, no N added	18·6	1·15	0·22	8·62	2·82	12·81
2.	Ammonium carbonate	35·2	19·44	6·87	1·07	0·23	27·61
3.	$NaNO_3$	31·8	16·01	4·19	3·64	Nil	23·84
4.	$NaHCO_3$, no N added	26·2	13·62	4·96	1·32	Nil	19·90
5.	$KHCO_3$, no N added	33·4	17·82	6·21	2·46	0·82	27·31
6.	NH_4HCO_3	34·6	18·62	6·46	2·26	0·84	28·18
7.	$CaCO_3 + NaHCO_3$, no N added	30·4	15·42	5·41	2·92	1·04	24·79
8.	$CaCO_3 + NH_4HCO_3$	31·8	16·26	5·61	3·40	1·12	26·39
9.	$NH_4HCO_3 + KHCO_3$	34·6	19·16	6·42	1·92	0·60	28·10
10.	$NH_4HCO_3 + NaHCO_3$	36·1	17·66	6·24	2·86	0·96	27·72

The figures show that $CaCO_3$ alone is not a satisfactory neutralising agent but it may give good results in combination with other reagents such as NH_4HCO_3, $KHCO_3$ or $NaHCO_3$. By itself $NaHCO_3$ is probably too alkaline (p_H 8·4–8·5) and impedes decomposition; it is not definitely known, however, whether the effect is due to the p_H of the system or to the high concentration of the salt. A mixture of NH_4HCO_3 and $NaHCO_3$ has given good results, as has also a mixture of NH_4HCO_3 and $KHCO_3$. The use of ammonium carbonate and sodium nitrate as neutralising agents has been examined in a previous communication [1935]. The degree of decomposition obtained by the use of $KHCO_3$, $NaHCO_3$ and $NaHCO_3 + CaCO_3$, in each case without the addition of nitrogen, further confirms the low nitrogen requirement for anaerobic digestion.

The neutralising agents described above are useful in that they can be added in advance along with the material in sufficient amount to neutralise the acids formed and so lead to successful decomposition without having recourse to frequent adjustments of the reaction of the medium. The acids formed may of course be neutralised from time to time as already described in Exp. 2. The degree of decomposition and the products formed are about the same in both cases.

Exp. 9. Use of different sources of nitrogen (Table VI). The parts played by ammonium carbonate and sodium nitrate in influencing anaerobic decomposition have previously been considered. The aim of the present experiment was to examine whether other nitrogenous compounds, easily reducible to ammonia under anaerobic conditions, could replace ammonium carbonate as neutralising agents. For this purpose, urea, calcium cyanamide, caseinogen, blood-albumin and egg-albumin were tried. 2 g. of each were added to 20 g. of straw, no other neutralising agent being added. The other experimental details were as before.

Table VI. *Decomposition of rice straw in presence of different forms of nitrogen.*

g. per 100 g. straw after 6 months.

	Ammonium carbonate	$NaNO_3$	Urea	Cyanamide	Egg-albumin	Blood-albumin	Caseinogen
Loss of dry matter less ash	35·2	31·8	32·8	29·6	23·8	22·4	18·2
Net CO_2 evolved	19·44	16·01	15·61	13·46	3·46	2·58	1·22
Net CH_4 evolved	6·87	4·19	5·32	4·52	1·12	0·84	0·38
Acetic acid present	1·07	3·64	3·12	4·24	7·29	7·52	4·72
Butyric acid present	0·23	Nil	0·96	1·12	6·60	5·66	8·18
Total weight of products	27·61	23·84	25·01	23·34	18·47	16·60	14·50

The figures show that urea and cyanamide are in a different category from the proteins and more closely resemble ammonium carbonate in their ability to neutralise the acids formed from straw.

An interesting point is the high proportion of butyric acid to acetic acid in cultures containing proteins. Possibly the butyric acid is derived from the anaerobic degradation of the added protein. The proportion of butyric acid to acetic acid is comparatively low where straw is digested by itself or in presence of ammonium carbonate, sodium nitrate, urea or cyanamide.

Expt. 10. Influence of the volume of the culture vessel (Table VII). The volume of the available free space above an anaerobic culture medium may sometimes markedly influence the rate of decomposition, *e.g.* a small vessel may produce high concentrations of CO_2 which may be directly toxic to the bacterial population [Kliewe and Kindhäuser, 1933] or may indirectly impede their activity by lowering the p_H. The use of culture vessels of different capacities may, in the present case, also throw some light on the mechanism of formation of methane.

In order to examine these points samples of 20 g. of rice straw were packed in bottles of different sizes as specified in Table VII and the decomposition was allowed to proceed for a period of 6 months.

In series I, one of the exit tubes of the bottle (300 ml. capacity) was connected to a receiver containing a known amount of sodium hydroxide to absorb the CO_2 formed as soon as liberated. The gas accumulating in the system was therefore almost wholly methane and was tapped off once every week. In series II, 400 ml. bottles were used and the gaseous products were removed weekly but the sodium hydroxide attachment was omitted and hence the CO_2 evolved was in contact with the culture medium for a week. In series III, with 1000 ml. bottles, the accumulated gases were removed monthly. 4-litre bottles were used in series IV and all the gases evolved were allowed to remain until the end. A mixture of 2 g. NH_4HCO_3 and 2 g. $KHCO_3$ per 20 g. straw, was added to all the bottles so as to neutralise the acids formed and maintain an alkaline reaction throughout the experiment.

Table VII. *Decomposition of rice straw in bottles of different sizes.*

g. per 100 g. straw after 6 months.

	Series I 300 ml. bottles with NaOH receiver	Series II 400 ml. bottles	Series III 1000 ml. bottles	Series IV 4000 ml. bottles
Loss in dry matter less ash	34·2	35·4	36·1	36·8
Net CO_2 evolved	18·94	19·70	20·40	21·52
Net CH_4 evolved	6·71	7·15	7·46	7·61
Acetic acid present	1·87	1·62	1·52	0·92
Butyric acid present	0·82	0·58	0·26	0·24
Total weight of products	28·34	29·05	29·64	30·29
	ml.	ml.	ml.	ml.
Volume of CO_2 evolved corrected for carbonates	9580	9965	10320	10725
Volume of CH_4 evolved	9365	10115	10410	10610

The results obtained show that the size of the interacting vessel has comparatively little influence on the course of the decomposition, provided the reaction of the medium is properly maintained. In all cases about 10,000 ml. of methane and an equal amount of CO_2 are evolved, confirming the observation made in a previous communication that a particular sample of straw produces an approximately constant quantity of methane. This is ascribed to the formation of a definite amount of acids from straw which are later decomposed into CO_2 and CH_4. It is worth pointing out that in all the series the proportion of CO_2 to CH_4 is roughly unity even though in some cases the CO_2 was removed as soon as it was liberated while in others it was allowed to be in contact with the medium for as long as 6 months. This lends additional support to the above hypothesis regarding the formation of methane and is opposed to the view that the methane is formed by reduction of carbon dioxide.

DISCUSSION.

An examination of the above results shows that the mechanism of anaerobic degradation of straw offers several points in marked contrast to aerobic fermentation. The former is much more restricted in its tolerance of changes in reaction than the latter. This may be explained as being due to the differences in the micro-flora in the two cases. The decomposition under aerobic conditions is brought about by a wide group of different species of microorganisms including fungi, bacteria and actinomycetes, which exert their optimum activity at different p_H levels. Under anaerobic conditions, however, the population is probably wholly bacterial and is possibly restricted to a few types operating within a narrow range.

Of the two stages in the decomposition of straw, *viz.* the first of acid formation and the second of gas production, it is noteworthy that the former is more tolerant to changes in reaction than the latter. The production of methane is active only in the range of p_H 7·5–8·5, whereas acid formation can go on between p_H 6 and 10. Anaerobic digestion at p_H 9–10 results in a rapid formation of organic acids which are stored up as salts and hence this might form a convenient method for the conversion of straw into acids, principally acetic. As the speed of acid formation is much more rapid than of gas production and since it is possible to calculate from the amount of acids formed the potential methane-producing capacity of straw, digestion at the above p_H range might also act indirectly as a method for the rapid determination of the methane-producing capacity of raw materials like straw.

Another interesting point of difference between aerobic and anaerobic decomposition of straw lies in the much larger amount of water required for successful decomposition in the latter case. Whereas a proportion of straw to water of 1 : 4 or 1 : 5 is sufficient for aerobic decomposition, over twice this amount is necessary for successful anaerobic decomposition. Part of the extra water required in the latter case is probably used up in the chemical reactions involving the degradation of straw material into acids and gases, but part of it may serve also to dilute the acids and other products of the fermentation which at high concentrations impede the progress of the decomposition.

The low nitrogen requirement for anaerobic digestion as compared with aerobic decomposition has been examined in detail in a previous communication [1935].

The presence of an active microflora on the straw itself and the absence of the need for extraneous inoculation, such as soil extract, confirms the observations of previous workers [Fowler and Joshie, 1920; Langwell and Lymn, 1932; Boruff and Buswell, 1929]. The absence of any response to the addition of a small amount of inoculum from a vigorously fermenting culture does not apparently support the hypothesis that the initial lag period is due to the need for the development of the specific microflora necessary to start the decomposition. Further work on this point is required before any conclusion can be drawn.

The low requirement for phosphate in anaerobic digestion could, as in the case of the low nitrogen requirement, be explained by assuming that a portion of the phosphorus in the straw dissolves and undergoes a continuous cycle of bacterial synthesis and disintegration sufficient to meet the needs of the bacterial population; thus the phosphorus would not be locked up in comparatively unavailable forms as it is under aerobic conditions.

SUMMARY.

1. For the anaerobic digestion of rice straw by mesophilic organisms, a temperature range of 30 to 35° is found to be optimum.

2. The p_H of the medium exerts a controlling influence on the course of the fermentation. The preliminary stage of acid formation is more tolerant to changes of reaction, but gas formation is greatly impeded outside the range of p_H 7·5–8.

3. The water requirements for anaerobic digestion are much higher than for aerobic decomposition. A proportion of straw to water of 1 : 10 is found optimum for the former.

4. The organisms required to decompose the straw are present on the straw itself and further inoculation is unnecessary and does not shorten the preliminary lag period.

5. The phosphorus requirement of anaerobic digestion is satisfied by the amount contained in the straw itself (0·42 %). Additions of phosphate have no appreciable stimulating effect. Excess of phosphate actually depresses the rate of decomposition.

6. Finely ground straw does not ferment more quickly than chaffed straw; the rate of gas production is in fact slower.

7. Of the different reagents tried for neutralising the acids formed during anaerobic digestion, NH_4HCO_3 and $KHCO_3$ are the best; they could be used singly or better still in admixture. It is possible also to control the reaction of the medium by additions of alkali or acid from time to time. Urea or cyanamide can replace ammonium carbonate but proteins cannot.

8. The amounts of CO_2 and CH_4 produced are approximately the same irrespective of the volume of free space above the culture medium, provided the accumulated gases are removed from time to time so as not to produce high concentrations of CO_2 or lower the p_H of the medium.

The author's thanks are due to Sir E. J. Russell for placing the facilities of the Rothamsted Experimental Station at his disposal, to Mr E. H. Richards for guidance and to Dr S. H. Jenkins for helpful suggestions.

CXVI. THE HYDROLYSIS OF HEXOSEDIPHOSPHORIC ESTER BY BONE PHOSPHATASE.

II. (*a*) THE PARTICIPATION OF PHOSPHOHEXOKINASE; (*b*) THE ISOLATION OF PURE FRUCTOSE-I-PHOSPHATE[1].

BY BÉLA TANKÓ AND ROBERT ROBISON.

From the Biochemical Department, The Lister Institute, London.

(*Received March 1st, 1935.*)

THE study of the hydrolysis of phosphoric esters by bone phosphatase may serve two purposes, to gain knowledge of the chemistry of the esters and to throw light on specific properties of the enzyme. The present investigations were planned with both these objects in view.

When hexosediphosphoric ester (fructose-1:6-diphosphate) is hydrolysed by acids, the two phosphate groups are split off at very unequal rates. The velocity constants for the reactions in *N* HCl at 100° have been determined as 52×10^{-3} for the group in position 1 and $4{\cdot}2 \times 10^{-3}$ for that in position 6 [Macleod and Robison, 1933], the latter value giving the velocity after the first group has been removed. The marked difference in behaviour of the two groups towards acids enabled Neuberg [1918], by partial hydrolysis of the diphosphoric ester, to obtain a fructosemonophosphate in which the phosphate group is now known to occupy position 6.

The relative rates of hydrolysis of phosphoric esters by bone phosphatase may differ widely from those of their hydrolysis by acids. By the action of this enzyme on hexosediphosphoric ester Macleod and Robison [1933] obtained the second fructosemonophosphate containing the phosphate group in position 1. They did not succeed in freeing this compound entirely from the Neuberg ester. Its isolation in pure condition is described in the present paper.

A point of much interest had emerged from earlier experiments [Martland and Robison, 1929], namely, that in the hydrolysis of fructosediphosphate by preparations of bone phosphatase, some of the sugar undergoes intramolecular change, producing a mixture of aldoses and ketoses; similar changes were also observed in the hydrolysis of glucosemonophosphate [Robison and King, 1931].

The more detailed investigations of Macleod and Robison [1933] appeared to confirm these findings. The proportion of aldose formed during hydrolysis of hexosediphosphate varied with the phosphatase preparation employed and with the experimental conditions; but no explanation of this variation was, at the time, forthcoming. By stopping the hydrolysis when 50 % of the phosphate had been set free they obtained, in addition to unchanged diphosphate and free sugar, a mixture of glucose-6-phosphate (possibly containing mannose-6-phosphate), fructose-6-phosphate, and a new ester characterised by its strong laevorotatory power and its very rapid hydrolysis in *N* HCl at 100°. From the hydrolysis curve of the mixed monophosphates it was calculated that the above esters were present in the approximate proportions 3 : 2 : 5. After removal of the aldosephosphates by oxidation with bromine and separation of the sparingly soluble barium phosphohexonates, the residual mixture contained 75 % of the new ester and 25 % of fructose-6-phosphate. Further purification was not attained at that time, but the properties of the new ester were calculated from those of the mixture and provided strong evidence that its constitution was that of fructose-1-phosphate. The suggestion was then made that the two phosphate groups of fructose-1:6-diphosphate are removed at equal rates by bone phosphatase but that, during removal of the group from position 1, intramolecular change occurs, resulting in the formation of a mixture of fructose-6-phosphate, glucose-6-phosphate and mannose-6-phosphate. These three esters would together constitute 50 % of the monophosphate fraction, the remaining 50 % being fructose-1-phosphate which could not undergo such intramolecular change.

---

[1] A brief report of these results was communicated to the Hungarian Physiological Society in May 1934 and an abstract was published in *Ber. ges. Physiol.* (1934), 81, 563.

The main objects of the work now to be described were (*a*) the discovery of factors controlling the conversion of ketose into aldose derivatives, (*b*) the isolation of fructose-1-phosphate in pure condition and the further study of its properties.

EXPERIMENTAL.

The fructosediphosphate used in these experiments was prepared by allowing a mixture of 50 g. dried yeast, 30 g. fructose and 100 ml. H_2O to ferment at 25° with gradual addition of a phosphate-sugar solution ($0{\cdot}5\ M$ $Na_2HPO_4 + M$ fructose); the hexosephosphates were separated by the method previously described [Robison and Morgan, 1930]. The fructosediphosphate obtained from five fermentations was purified by repeated precipitation of the acid barium salt from its aqueous solution by alcohol [Macfarlane and Robison, 1935] until a small portion, after conversion into the neutral barium salt, gave satisfactory figures on analysis (Table III). The phosphatase was prepared by the method of Martland and Robison [1929].

The methods of procedure for the hydrolysis and for the separation and examination of the products were similar to those employed in the later experiments of Macleod and Robison [1933] with slight modifications. All solutions were prepared with water which had been freed from dissolved air by boiling. The hydrolysis was carried out at 28° in presence of chloroform and was stopped by addition of H_2SO_4 to lower the p_H to 5; organic and inorganic phosphates were precipitated with basic lead acetate[1]. The solution, after removal of lead as $PbSO_4$, was examined for the free sugars. The basic lead precipitate was decomposed with sulphuric acid and converted into barium salts, which were separated in the usual way.

It was first sought to discover whether the relative rates at which the two phosphate groups are set free or the extent to which the conversion of fructose into aldose occurs during hydrolysis could be influenced by such factors as differences in the proportion of phosphatase, the p_H of the solution, or the concentration of magnesium.

Controls. As controls for these experiments a series of 8 solutions was prepared containing sodium phosphate and fructose but no phosphoric ester; phosphatase was added to 4 of these. Two of each group were adjusted to p_H 7·0 and two to 8·4, while $MgSO_4$ was added to one of each pair. A similar series was also prepared containing glucose in place of fructose. The proportions of the various constituents were equivalent to those in Exp. 1. The solutions were kept at 28° during 10 days, estimations of total and inorganic phosphate and reducing power (Hagedorn and Jensen (H.J.) and iodimetric) being carried out at intervals. No evidence was obtained of esterification of phosphate or of significant change in the amount or character of the sugar present in any of the solutions. Two of each series (p_H 8·4, without $MgSO_4$, with and without phosphatase) were finally evaporated to dryness and the residues were extracted with boiling 85 % alcohol; over 95 % of the sugar originally present was recovered in each case. The sugars recovered from each of the two fructose solutions had $[\alpha]_{5461} - 103°$, calculated on the H.J. values, and I values of 4 %, calculated as glucose; those recovered from the glucose solutions had $[\alpha]_{5461} + 60°$ and I values of 98 %. Fructose and glucose have $[\alpha]_{5461} - 110·8°$ and $+62°$ respectively. It was thus evident that very little, if any, conversion of free sugar occurs under these experimental conditions.

---

[1] The very alkaline solution "25 % $Pb_3O(C_2H_3O_2)_4$" (B.D.H.) was not used, since, as previously noted, it causes changes in the dissolved sugars.

Exp. 1. Rapid hydrolysis. A solution (140 ml.) of sodium fructosediphosphate, prepared from the acid barium salt, was divided into 4 equal portions, each containing 200 mg. P; two of these were brought to p_H 7·0 and two to p_H 8·6; magnesium sulphate was added to two of the solutions, one at each p_H, to give a final concentration of 0·005 *M*. 5 ml. of a phosphatase suspension containing 200 mg. of the dry preparation A_1 were added to each of the four solutions; the volume was made up to 40 ml., and the p_H was adjusted to 7·0 and 8·4 respectively; at intervals, portions were removed for analysis. Hydrolysis proceeded more rapidly than had been anticipated and had reached approximately 90 % in the solutions at p_H 8·4 when tested after 24 hours. In the two solutions at p_H 7·0 hydrolysis was stopped after 51 and 68 hours respectively, when slightly more than 50 % of the phosphate had been set free. The H.J. reducing power increased in all the solutions proportionately to the amount of hydrolysis. The initial iodimetric reducing power, equivalent to about 75 mg. aldose and mainly attributable to the phosphatase, was not significantly changed in any of the solutions. Conversion of ketose into aldose derivatives could not, therefore, have occurred to an appreciable extent during the hydrolysis. Analyses of the products are given in Table I; none showed more than a small iodimetric reducing power and it was concluded that the free sugars consisted almost wholly of fructose and that the monophosphate fractions contained over 90 % of the two fructose esters in approximately equal proportions. The differences found between the products of hydrolysis at p_H 7·0 and p_H 8·4 with and without added magnesium salt were not very marked or consistent.

Exp. 2. Slow hydrolysis. A further hydrolysis was carried out at p_H 8·4, using only 20 mg. phosphatase per 200 mg. organic P, *i.e.* one-tenth of the amount of phosphatase employed in the previous experiment. Hydrolysis reached 50 % in 19 days and was then stopped; the monophosphate fraction gave analytical values corresponding closely with those calculated for a mixture of fructose-6-phosphate and fructose-1-phosphate in equal proportions. The amount of aldosephosphate did not exceed 6 % and was probably less[1].

While the results of these experiments justified the conclusion that the two phosphate groups of fructosediphosphate are removed by bone phosphatase at nearly equal rates, they showed that the conversion of fructose into aldose, previously observed, is not a necessary consequence of this hydrolysis.

It seemed possible that an explanation of these varying results might lie in the difference in purity of the phosphatase used. Preparations obtained by addition of alcohol and ether to aqueous extracts of bone had been employed for most of the earlier hydrolyses; but the phosphatase A_1 used in the above experiments had been purified further by re-extracting the first precipitate with 30 % aqueous alcohol and again precipitating the phosphatase with alcohol and ether[1]. This process of purification might have brought about the destruction or removal of some agent present in the cruder phosphatase and responsible for the change in the molecule of fructose.

---

[1] Fructosephosphates have a small iodimetric reducing power.

Further evidence on this point was obtained by hydrolysing fructosediphosphate with other preparations of purified bone phosphatase (Exps. 3 and 4) and with crude bone extract (Exp. 5). These hydrolyses were carried out at 28° and p_H 7·6–7·8, without addition of magnesium salt. Analyses of the products and descriptions of the phosphatase preparations are given in Table I.

Fructose has $[\alpha]_{5461}$ − 110·8°; $C_6H_{11}O_5PO_4Ba$ requires P 7·85 %.

Phosphatase preparations:

A, B, C, precipitates by addition of alcohol and ether to filtered aqueous extracts of rabbit bones.

A_1, purified by extraction with 30 % aqueous alcohol and reprecipitation with alcohol and ether in presence of potassium acetate.

B_1, purified by extraction with 50 % aqueous alcohol and reprecipitation with alcohol and ether.

C_2, purified twice by extraction with water and reprecipitation with alcohol in presence of sodium sulphate.

D, E, crude aqueous extracts of rabbit bones.

The monophosphate fraction produced by crude extract had an I value of 14·4 %, equivalent to 31 % of aldosemonophosphate; the free sugar appeared to contain about the same proportion of aldose[2]. The monophosphates obtained with purified phosphatase had I values of only 3 % and probably contained less than 6 % of aldosephosphate, while the proportion of aldose in the free sugars was equally low. Clearly, therefore, the crude bone extract contained an active agent which was not present in the purified phosphatase.

The phosphohexokinase of bone and marrow.

Presence of the active agent in bone marrow. In preparing the phosphatase most, but not all, of the marrow was removed before the bones were extracted with water. Tests were made with two extracts, one prepared from the heads of long bones without removing the marrow, the other from specially cleaned fragments of hard bone from the shafts. When allowed to act on hexosediphosphate both extracts produced monophosphate mixtures containing about 30 % of aldo-esters. Experiments were next carried out with (*a*) an aqueous extract of marrow and (*b*) the precipitate obtained from such an extract by addition of

---

[1] A difficulty experienced in obtaining flocculation of the material at this stage was overcome by addition of potassium acetate.

[2] Calculated from the specific rotation, assuming fructose and glucose to be the principal components. The I values of these sugar fractions were vitiated by the presence of I-reducing substances derived from the crude enzyme preparation.

Table II. *Interconversion of aldo- and keto-hexosephosphates by preparations of bone phosphatase and marrow.*

* Phosphatase preparations. C, precipitate obtained by addition of alcohol and ether to aqueous extract of rabbit bones. C_2, C twice purified by extraction with water and reprecipitation with alcohol in presence of sodium sulphate.

† Marrow preparations. *a*, aqueous extract of bone marrow; marrow from the long bones of young rabbits was shaken with 3 times its weight of water, left 3 hours at 0° and centrifuged; 0·04 ml. ≡ 10 mg. fresh marrow. *b*, precipitate obtained by addition of alcohol and ether to unfiltered aqueous extract of bone marrow; 1 mg. was obtained from 11·6 mg. fresh marrow.

The amounts of these preparations used are given as mg. or ml. per mg. P of the substrate.

The figures for aldose and aldo-derivatives are based on the I values (less the amount due to the enzyme preparations) and are given as percentages of the total calculated hexose (not the H.J. value) in the substrate. The fructose esters reduce I to a small extent and are, therefore, shown as apparently containing 2–5 % aldosephosphate; fructose (Kerfoot) gives an I value of about 0·8 %. The specimen of glucose-6-phosphate used contained a small proportion of other esters, chiefly mannosephosphate.

The concentrations of the substrates varied between 0·015 *M* and 0·04 *M* in the different experiments.

‡ In Exp. 13, tests on fructose-6-phosphate + marrow were also done after 40 minutes and gave nearly the same percentages of aldo-derivatives as were found after 4 hours.

alcohol and ether. The results are shown in Table II. It was found (Exps. 10, 11) that either of the marrow preparations, when added to the purified phosphatase C_2 restored the power to produce aldo-compounds from fructosediphosphate. Addition of the marrow extract to the cruder phosphatase C led to a slight increase in the percentage of aldo-compounds formed on hydrolysis of the diphosphate; but larger quantities of marrow extract, added to either crude or purified phosphatase, did not raise the proportion of aldo-compounds beyond certain limits, namely, about 25 % of the total hexose when hydrolysis had reached 32 % and about 36 % when 60–70 % of the phosphate had been set free. Other experiments, not quoted in Table II, showed that the marrow preparation, like the crude phosphatase, lost its power to effect this change when left for some hours in aqueous alcohol. Exp. 11 also showed that the addition to phosphatase C_2 of 1/20 its weight of phosphatase C was sufficient to increase the proportion of aldo-compounds from 5 to 21 %, while 10 times the quantity of C alone produced 29 %. It was concluded that the same agent was present in both marrow and bone extracts but the results did not warrant the assumption that its presence in the latter was due solely to the marrow left in the bone.

In order to learn more about the properties of this agent its action on other phosphoric esters and on fructose + inorganic phosphate was investigated. By the use of the marrow preparation *b*, whose phosphatase activity was very low, and the highly purified phosphatase C_2, the action of the two enzymes could be readily distinguished.

Fructose-6-phosphate was converted into aldo-esters to the extent of 55–63 % by marrow preparations alone at p_H 8·4, 7·7 and 6·4, very little hydrolysis taking place (Exps. 11, 12, 13). The amount of conversion was, in some cases, maximum within 40 minutes. When both phosphatase and marrow were allowed to act on this ester, 98 % hydrolysis occurred in 40 hours, but the percentage of aldose was the same as that produced by marrow alone.

Fructose-1-phosphate, on the other hand, did not yield any aldo-compounds with marrow alone (5 % hydrolysis) or with marrow + phosphatase (100 % hydrolysis), nor did the marrow preparation produce any aldose from a mixture of fructose + inorganic phosphate in periods up to 40 hours. The action of marrow on glucose-6-phosphate caused the aldose content to fall to 63 %, the same proportion as that produced from fructose-6-phosphate under similar conditions.

It should be stated that the amounts of aldosephosphates present in the equilibrium mixtures may be somewhat higher than the maximum values recorded, for two reasons; (*a*) owing to the relatively large I-reducing power of the enzyme preparations the total reduction exceeded in some cases the limit recommended for this method [Macleod and Robison, 1929]; (*b*) the aldo-esters probably included some mannose-6-phosphate which gives an abnormally low I value.

The results of these preliminary experiments suggest that the active agent present in bone and marrow is a phosphohexokinase having the power to convert the hexose-6-phosphates into an equilibrium mixture of aldo- and keto-esters. It has no action on fructose-1-phosphate and, most probably, none on intact fructose-1:6-diphosphate. When the diphosphate is hydrolysed by bone phosphatase, fructose-1-phosphate and fructose-6-phosphate are formed in approximately equal proportions, so that if the kinase is also present the percentage of aldo-compounds in the products may rise to about half that given by fructose-6-phosphate under optimum conditions. The actual figure will depend on the relative activities of the phosphatase and kinase, that is, on how much of the fructose-6-phosphate is hydrolysed before conversion. The kinase does not effect the conversion of free sugar.

This phosphohexokinase is probably identical with the enzyme discovered by Lohmann [1933] in extracts of muscle, kidney, liver, brain and dried yeast. Lohmann showed that these extracts converted the Neuberg ester into a true equilibrium mixture which resembled, in its rates of hydrolysis by HCl and in its aldose content, the Embden and Robison esters of muscle and yeast fermentations. The conversion was extremely rapid; at 20° equilibrium was reached in a few seconds with dialysed muscle extract and in about 5 or 10 minutes with the other tissue extracts. In our own experiments only a few tests were made after short periods, but these showed that fructose-6-phosphate was converted into the equilibrium mixture in about 40 minutes at 23° and p_H 7·7 by 3 mg. of marrow *b* ($\equiv$ 35 mg. fresh marrow) per mg. ester P. The proportion of animal tissue extract used by Lohmann corresponded with about 600 mg. fresh tissue per mg. ester P. It would seem, therefore, that the activity of the marrow is at least as great as that of brain, kidney and liver tissues.

Lohmann showed that a similar equilibrium was also reached in a few seconds when muscle extract was allowed to act on the aldosephosphate mixture resulting from partial hydrolysis of the Embden ester by acids. The same result was obtained in Exp. 13 of the present series, starting with glucose-6-phosphate. Other experiments [Patwardhan and Robison, 1935] have shown that mannose-6-phosphate behaves in the same way when acted on by yeast extract. There can therefore be little doubt that each of these hexose-6-phosphates is converted by phosphohexokinase into an equilibrium mixture in which all three esters are present. Each has been isolated from the hexosemonophosphate of fermentation which, however, contains other esters whose precise nature is still unknown. It would be interesting to discover whether the kinase has any effect on these also or plays any part in their formation. It has been suggested [Robison and Rosenheim, 1934] that the calcifying mechanism of bone may consist of a complex enzyme system analogous to those in yeast and muscle. The presence of phosphohexokinase in association with the phosphatase of hypertrophic cartilage and osteoid tissue may have some significance in this connection and its location in the bone is therefore being further investigated.

The isolation of fructose-1-phosphate.

The high laevorotation of the mixed hexosemonophosphates obtained with purified phosphatase suggested that these would provide the most suitable material for the preparation of pure fructose-1-phosphate; but further consideration led to a different conclusion. The proportion of fructose-1-phosphate in these products was probably not greater than in those of lower specific rotation and high aldose content, and whereas aldosephosphates could be quantitatively removed by oxidation, a method for the elimination of fructose-6-phosphate had still to be found. It was therefore decided to use crude bone extract for the partial hydrolysis of fructosediphosphate on a larger scale. Two such hydrolyses (Table I, Exps. 6 and 7) were carried out and yielded 7·5 g. and 8·4 g. respectively of barium hexosemonophosphates, equivalent to about 15 % of the total P of the diphosphate. From their analytical values it was judged that these products, like that of Exp. 5, contained approximately 30 % of aldosemonophosphates and 50 % of fructose-1-phosphate[1]. The residues from Exps. 1–7 contained considerable amounts of unchanged fructosediphosphate, which was separated from the inorganic phosphate by repeated precipitation of the acid barium salt; this was converted into sodium salt and partially hydrolysed with crude bone extract, whereby a further quantity (6·7 g.) of hexosemonophosphate of slightly lower aldose content was obtained.

Removal of aldosemonophosphates. 14 g. of the barium hexosemonophosphates were dissolved in 240 ml. of water and treated, at room temperature, with 1·5 ml. bromine; 70 ml. of a cold saturated solution of baryta (0·47 *N*) were added in 10 ml. portions at intervals during 20 minutes, with constant shaking; these quantities represented a 200 % excess of bromine and 50 % excess of baryta over the calculated amounts required for the oxidation of the aldosephosphate. After a further 5 minutes the solution was acidified with 12 ml. *N* HCl and the excess of bromine was removed by aeration for one hour. The p_H, which was then 4·2, was raised to 8·0 by addition of baryta and the precipitated barium phosphohexonate was filtered off; the fructosephosphates were recovered from the filtrate by precipitation with alcohol and were freed from phosphohexonate by repeated solution in small quantities of water and fractional precipitation with alcohol. The fraction finally precipitated between 18 and 66 % alcohol weighed 7·2 g. and had P 7·81 % and $[\alpha]_{5461} - 27°$. 6·7 g. of hexosemonophosphate obtained from recovered diphosphate were similarly treated and yielded 3·1 g. barium salt having P 7·63 % and $[\alpha]_{5461} - 23°$. The product obtained by Macleod and Robison [1933] had $[\alpha]_{5461} - 25·8°$.

---

[1] The figures are best satisfied by assuming the presence of both glucose and mannose esters, but the exact composition cannot be calculated without more information on this point.

Separation of the fructosemonophosphates. An attempt was first made to separate the two fructosemonophosphates by fractional precipitation of the barium salts ($[\alpha]_{5461} - 27°$) from aqueous solutions by alcohol. Three fractions were obtained having $[\alpha]_{5461} - 28·7°$, $-27·1°$, $-24·2°$ respectively. The first, which amounted to 60 % of the total salt, contained the highest proportion of fructose-1-phosphate; but the degree of separation was small and it was thought well to try other methods before continuing this fractionation.

The next attempt was based on the possibility that in alkaline solutions fructose-6-phosphate might be converted into aldosephosphate (which could be oxidised with bromine) while fructose-1-phosphate remained unchanged. A number of tests were carried out with the mixed monophosphate (I value 3·5 %) obtained from Exp. 1 *a*; the results are briefly summarised below:

(*a*) In aqueous solution at p_H 8·4 and 28° no increase in the I value occurred in 11 days.

(*b*) In 0·01 *N* NaOH at 28° the I value slowly increased, reaching 6·6 % in 6 hours; but the H.J. value fell, in the same period, from 35 to 32 %; after 46 hours the I value had risen to 11 % and the H.J. value had fallen to 23 %, while 10 % of the total phosphate had been set free.

(*c*) In 0·05 *N* NaOH at 28° similar but more rapid changes occurred; in 1 hour the I value rose to 6·2 % and the H.J. value fell to 32 %; in 46 hours the H.J. value fell to 16 %, and 26 % of the phosphate was set free.

These results indicated that in 0·01 *N* and 0·05 *N* NaOH at 28° the fructose esters had undergone changes more profound than the simple conversion of ketose into aldose. In a final experiment 0·78 g. of the mixed monophosphates of low aldose content was treated with bromine in presence of a large excess of baryta (0·2 *N*) and the reaction was allowed to proceed for 100 minutes at room temperature. The amount of barium fructosephosphate recovered was only 0·12 g. and its specific rotation, −20°, was not very much higher than that of the original mixture. Destruction of both fructose esters had clearly taken place; the method was therefore abandoned as useless.

Recourse was now had to the fractional crystallisation of the brucine salts. It had been feared that this method might involve serious loss of the fructose-1-phosphate through hydrolysis during crystallisation or in the frequent interconversion of brucine and barium salts for analysis and further fractionation. Fortunately the brucine salts proved reasonably stable in aqueous and alcoholic solutions, while it was found possible to follow the course of their separation by measuring their specific rotations in aqueous solution; the loss in weight at 100° (Pregl micro-dryer) and P content of the salt were determined in each case. From time to time portions were converted into the barium salts and analysed; the amounts of hydrolysis occurring in 25 and 60 minutes in *N* HCl at 100° were also determined on a few mg. of the barium salts and furnished an indication of their purity.

The solution of the brucine salts in 80 % aqueous alcohol was prepared, as previously described [Robison and King, 1931], from 8·6 g. barium salts; it was cooled to −15° and, after crystallisation had begun, was left for a further 12 hours at 0°; weight of crystalline salt 21 g., representing 80 % of the total P. It was recrystallised three times by dissolving it in a small volume of 40 % alcohol at 30° and adding absolute alcohol to give 90 % concentration; weight after third recrystallisation 10·7 g. A small portion was converted into the barium salt for analysis; it had P 7·7 %, H.J. val. 28 %, I val. 1·5 %, $[\alpha]_{5461}-28°$; hydrolysis 88 % in 60 minutes. It was thus evident that very little separation had been achieved. The brucine salt was next dissolved in 35 ml. of 40 % alcohol and allowed to crystallise at 0°; four fractions, amounting to half the total salt, were removed and found to have an increased laevorotation, while the barium salt from one fraction had $[\alpha]_{5461}-31°$. Still better results were obtained by recrystallisation from water, in which the brucine salt was much less soluble than in dilute aqueous alcohol. Solution was effected at 40° and crystallisation allowed to proceed at room temperature. Successive fractions of the brucine salt had specific rotations ranging from −47 to −34°. All the fractions obtained in previous operations were therefore crystallised from water, and fractions of high rotatory power were combined and recrystallised. In this way the specific rotation of the brucine salt was gradually raised to −52°, that of the corresponding barium salt to −39° and the hydrolysis, in *N* HCl at 100°, to 98 % in 25 minutes and 100 % in 60 minutes.

The barium salt was purified by repeated solution in 10 parts of water and precipitation by alcohol. Traces of a sparingly soluble substance persisted and the salt was therefore again purified by fractional precipitation with alcohol; the main fraction obtained between 20 % and 70 % alcohol was filtered off, washed with absolute alcohol and dried in an evacuated desiccator. The analytical values for this salt are shown in Table III; the rates of hydrolysis of the free acid in 0·01 *M* aqueous solution (autolysis) and of the potassium salt in 0·1 *N* and *N* HCl at 100° are given in Table IV. It is seen that the value of *k* increases with the c_H of the solution; in this respect the behaviour of the ester agrees with that of fructosediphosphate and differs from the very abnormal behaviour of the

The values of *k* are calculated from the equation for a unimolecular reaction

$$k=\frac{1}{t_2-t_1}\log\frac{a-x_1}{a-x_2}.$$

For the hydrolysis in *N* HCl the values in columns (*a*) and (*b*) are those determined in two separate experiments. The values in columns (*c*) and (*d*) are calculated, (*c*) for 100 % of an ester having $k=70\times 10^{-3}$ and (*d*) for a mixture containing 98 % of an ester having $k=75\times 10^{-3}$ and 2 % of an ester having $k=4{\cdot}2\times 10^{-3}$. On the whole the observed values agree better with those in column (*c*) than with those in column (*d*)[1].

aldose-6-phosphates. The fall in the value of *k* during autolysis is probably due to the fall in c_H as phosphoric acid is set free.

The specific rotation of the barium salt is a little higher than the value previously calculated from the properties of the mixed fructosemonophosphates (−39° against −35°), while the value of *k* for hydrolysis in *N* HCl is a little lower (0·070 against 0·075). With such high rates of hydrolysis the possible errors of the micromethods employed may appreciably affect the calculated values of *k*, and the presence of 1 %, or even of 2 %, fructose-6-phosphate in our final product cannot be definitely ruled out. In Table IV the percentages of hydrolysis calculated for 100 % of an ester with $k=0{\cdot}070$ and of 98 % of an ester with $k=0{\cdot}075$ are shown side by side with the observed values. Another explanation is, however, suggested by the results noted in a later paragraph, which show that when hexosediphosphate is hydrolysed with *N* acid the fructosemonophosphate produced at first is dextrorotatory, but soon becomes laevorotatory as hydrolysis proceeds. The final value of *k* observed in this hydrolysis cannot, therefore, represent the value for the ester first produced, presumably fructose-6-phosphate, while the latter compound may conceivably be more dextrorotatory than has heretofore been supposed. The assumptions made for the second component of the fructosemonophosphate mixture were therefore not strictly correct. Further discussion of this interesting point will be postponed until the completion of experiments now in progress.

Reaction of fructose-1-phosphate with phenylhydrazine. 1·2 ml. of a solution containing 13 mg. of the free ester were treated with 0·2 ml. phenylhydrazine and 0·2 ml. glacial acetic acid. A portion of this solution left at 0° for 48 hours deposited no crystalline phenylhydrazone. The remainder was heated in a boiling water-bath for 20 minutes, cooled to 0° and filtered after some hours; weight of dry osazone, 13 mg. The mother-liquor, which gave no weighable precipitate on heating for a further 45 minutes, contained 1·36 mg. P, almost entirely as inorganic phosphate. The crude osazone contained only a trace (0·1 %) of P and, after recrystallisation, melted at the same temperature as glucosazone, alone and when mixed with the latter; the yield of glucosazone was equivalent to about 90 % of the original ester. Since only a very small percentage of this ester would have been hydrolysed in 20 minutes at the p_H of the solution, the liberation of phosphoric acid must be attributed to the oxidising action of the phenylhydrazine on the terminal group, to which the phosphoric acid is therefore most probably attached.

---

[1] The sealed ampoules containing the acid solutions were immersed in a covered bath of vigorously boiling water. Variations in the temperature of the bath due to changes in barometric pressure might account for some of the observed differences in these rates. Hydrolyses (*a*) and (*b*) were carried out at 99·7° ($p=752$ mm.); a subsequent hydrolysis of the same ester, at 100·7° ($p=779$ mm.) gave *k*, 0·080.

Products of partial hydrolysis of fructosediphosphate by N H_2SO_4.

It had occasionally been noted that preparations of the Neuberg ester obtained in this laboratory by hydrolysis of fructosediphosphate with mineral acids at 100° were slightly laevorotatory; the possibility that this might be due to the presence of fructose-1-phosphate was investigated. A solution of the free diphosphoric ester in N H_2SO_4 was heated at 100° for 5 minutes and the barium hexosemonophosphate isolated in the usual way; the residual diphosphate was again heated in N H_2SO_4 for a further 25 minutes and the monophosphate again separated from the products. Both barium salts were purified by solution in water and reprecipitation by alcohol: their analyses are given in Table III. Unexpectedly, it was the second fraction, obtained after 30 minutes' heating, that proved to be laevorotatory (−5·1°), while the specific rotation of the 5-minute fraction (+2·6°) was close to that usually found for fructose-6-phosphate. Precipitation of the 30-minute product from aqueous solution by 20 % alcohol gave a fraction having $[\alpha]_{5461} - 9·9°$. These dextro- and laevorotatory salts were each hydrolysed to approximately the same extent by N HCl at 100° in 25 minutes and 60 minutes. The laevorotatory substance cannot, therefore, have been fructose-1-phosphate. The presence of a derivative of fructopyranose, containing the phosphoric acid group in position 3, 4 or 5, might indicate either that the fructosediphosphate is not, after all, homogeneous or that migration of the phosphoric acid group from position 6 occurs under the conditions of hydrolysis. If the latter explanation be correct it might also account for other puzzling results noted in the past, *e.g.* the failure to obtain pure glucose-6-phosphate, in more than small proportion, from trehalosemonophosphate after long-continued hydrolysis in N H_2SO_4. It would also mean that the final rates of hydrolysis of the hexosephosphoric esters in N HCl at 100° may not be those of the ester supposedly present. Further work on this question is in progress and will shortly be reported.

SUMMARY.

1. In continuation of the experiments of Macleod and Robison [1933] the hydrolysis of fructose-1:6-diphosphate by preparations of bone phosphatase has been further investigated. It has been shown that the products of hydrolysis by specially purified phosphatase are fructose-1-phosphate and fructose-6-phosphate in approximately equal proportions; aldo-derivatives are not formed.

2. The production of aldo-derivatives which was previously observed is due to the presence of a phosphohexokinase in crude bone extracts and in phosphatase

preparations obtained from these by addition of alcohol and ether. During further purification of the phosphatase this kinase is destroyed.

3. The phosphohexokinase is present also in marrow extracts and can be precipitated from these extracts by alcohol and ether; it is inactivated if the precipitate is allowed to remain for some hours in aqueous alcohol.

4. This phosphohexokinase is probably identical with the enzyme found by Lohmann in extracts of muscle, kidney, liver, brain and yeast. It converts fructose-6-phosphate and glucose-6-phosphate into equilibrium mixtures of aldo- and keto-esters. It has no apparent action on fructose-1-phosphate and none on fructose-1:6-diphosphate unless phosphatase is also present and first removes the phosphate group from position 1. It does not effect the conversion of free fructose into aldose.

5. Fructose-1-phosphate has been isolated in apparently pure condition from the products of hydrolysis of the diphosphate by fractional crystallisation of the brucine fructosemonophosphates from water.

The properties of the ester have been studied. The value of $[\alpha]_{5461}$ for the barium salt is $-39{\cdot}0°$, slightly higher than that calculated by Macleod and Robison [1933]; $[\alpha]_{5461}$ of the free ester is $-64{\cdot}2°$.

The rates of hydrolysis of the free ester in 0·01 M aqueous solution and in 0·1 N and N HCl at 100° have been determined. The values of k are for autolysis $0{\cdot}62 \times 10^{-3}$, for 0·1 N HCl 9×10^{-3}, for N HCl 70×10^{-3}.

6. When heated with phenylhydrazine in acetic acid solution for 20 minutes at 100° the ester is converted almost quantitatively into glucosazone. This confirms the previous conclusion that the phosphate group occupies position 1 in the fructose molecule. The ester is probably 1-phosphofructopyranose.

7. Other laevorotatory fructosemonophosphates have been obtained as the result of heating fructosediphosphoric ester with N H_2SO_4 at 100°. Experiments are in progress to discover the nature of these esters and to explain their formation.

CXVII. THE OXIDATIVE DISAPPEARANCE OF LACTIC ACID FROM BRAIN AND THE PASTEUR REACTION.

BY KENDAL CARTWRIGHT DIXON[1].

From the Biochemical Laboratory, Cambridge.

(*Received March 1st, 1935.*)

MEASUREMENTS of the rate of oxidative lactic acid disappearance have been made by Holmes and Ashford [1930] and Ashford and Holmes [1931] in chopped brain, by Meiklejohn [1933] in minced tissue and by Meyerhof and Lohmann in brain slices [1926, 1]. Ashford and Dixon [1935] made some measurements of oxidative lactic acid disappearance and pointed out the small rate of this disappearance in relation to the rate of anaerobic lactic acid production. It seemed desirable to confirm this low value for rate of lactate disappearance in view of the doubt it throws on the generally accepted mechanism of the Pasteur reaction, namely, that oxygen removes the lactic acid which is continually formed as under anaerobic conditions. Further, it was necessary to establish if in reality more lactic acid disappears than can be accounted for by the oxygen uptake, as Ashford and Holmes [1931] have maintained.

In general the lactic acid oxidised is calculated (as Meyerhof did first for muscle) from the extra oxygen uptake caused by the addition of lactate. The justification for this method has been questioned in Ashford and Holmes's paper on the ground that sparing of the oxidation of intracellular substances may result from lactate addition and thus the oxygen uptake is really greater than that calculated. Ashford and Holmes concluded that sparing had not taken place.

Quastel and Wheatley [1932] however showed that lactate spared the oxidation of succinate. They also showed that the excess oxygen uptake caused by small addition of lactate to brain respiring without substrate would account for most of the lactate added if measured over a prolonged period of time. It seems evident however (as indeed they admit) that this only shows that complete oxidation may occur finally. Resynthesis in the Meyerhof sense might well have occurred at first, the resynthesised carbohydrate being later oxidised. Without continuous measurements of lactate disappearance this question could not be answered.

As the rate of respiration without substrate falls off markedly with time and that with added lactate only falls slightly, the difference between these values increases with time (this is seen from O_2 uptake curves in phosphate buffer [Holmes and Ashford, 1930; Ashford and Holmes, 1931] and is demonstrated below for bicarbonate buffer). It thus appeared that data as to the fate of the disappearing lactate could be obtained by studying the lactate disappearance and corresponding O_2 uptake over a period of several hours. If the accepted method of calculating lactate oxidation is correct (that is, that the difference between the lactate and no substrate respiratory values gives the lactate oxidation), then since this difference increases with time, the rate of disappearance of lactate should also increase. If on the other hand the oxidation of lactate suppresses the autorespiration, then the lactate will go on disappearing at the same rate. If this latter is really the case the lactate oxidised should be calculated not from the difference or excess O_2 uptake but from the total oxygen uptake.

---

[1] Harold Fry Student, King's College.

METHODS.

All experiments were performed with slices of rabbit's brain cortex suspended in bicarbonate Ringer at 37°. Measurements of oxygen uptake and CO_2 production were made by the indirect (two vessel) method of Warburg. Sodium lactate made by neutralising *dl*-lactic acid with NaOH (with heating during the process to ensure hydrolysis of the lactide) was used so as to give a final concentration of 0·2 % lactic acid. Warburg measures aerobic lactic acid production by subtracting the O_2 uptake (Q_{O_2}) from the total CO_2 production in bicarbonate (Q_{SCO_2}). This method assumes a respiratory quotient of 1; if this is the case then that part of the total CO_2 production over and above an amount equal to the oxygen uptake is due to the formation of lactic acid and consequent decomposition of bicarbonate. Conversely, when lactic acid is disappearing the total CO_2 production is less than the oxygen uptake by an amount equal to that bound by the liberated cation of the lactate. This method has been described by Meyerhof and Lohmann [1926, 2]. The disappearance of lactate was thus measured by the value $Q_{O_2} - Q_{SCO_2}$[1] which gives the CO_2 absorbed owing to lactic acid disappearance and resulting liberation of base. This assumes R.Q. of 1 for the oxidation of lactic acid[2]. (The R.Q. for the autorespiration of brain slices is 1 [Dickens and Greville, 1933].) The values observed are essentially of the same order as those obtained chemically by Ashford and Holmes. The advantage of this method is that it readily gives the rates of lactic acid disappearance during the whole course of the experiment.

EXPERIMENTAL RESULTS AND DISCUSSION.

Table I shows rates of lactate disappearance ($-Q_L^{O_2}$), O_2 uptake (Q_{O_2}) and also total CO_2 production observed (Q_{SCO_2}) both with and without substrate. In

Table I.

[1] $Q_{O_2} = \mu l$ O_2 uptake per mg. dry weight per hour. $Q_{SCO_2} = \mu l$ observed CO_2 output per mg. dry weight per hour. $-Q_{O_2}$, the rate of disappearance of lactic acid, is equal to $Q_{O_2} - Q_{SCO_2}$.

[2] If the R.Q. were less than unity, the disappearance of lactic acid would be still less; this would not alter the conclusions reached in this paper.

one experiment the anaerobic glycolysis from glucose was simultaneously measured and values of $Q_{\mathrm{L}}^{\mathrm{N}_2}$ are given.

It is first seen that the low values for lactate disappearance are amply confirmed, an average value of $-Q_{\mathrm{L}}^{\mathrm{O}_2}$ of 2·1 being obtained.

Secondly, although considerable fall in rate of autorespiration is shown with time, only a slight fall of lactate respiration rate is experienced. This is very strong evidence that lactate addition largely suppresses the autorespiration.

In the third place although the difference between the oxygen uptake with and without lactic acid increases with time, the rate of lactate disappearance maintains either a fairly constant level or even falls slightly, but does not rise as would be the case if the resynthesis theory were correct (see above).

We may conclude then that subtracting the O_2 uptake without substrate from that obtained with added lactate is not a correct method of obtaining a value for the lactic acid oxidised, and that this can be obtained with much more justification from the total oxygen uptake. The existence of resynthesis or unaccounted lactic acid disappearance in brain thus becomes very doubtful. It seems safe to assume that the lactic acid is completely oxidised. The average of the values in Table I ($Q_{\mathrm{O}_2}=7{\cdot}0$ and $-Q_{\mathrm{L}}^{\mathrm{O}_2}=2{\cdot}1$) is quite in harmony with this view.

Ashford and Holmes [1931] described experiments with washed chopped brain and also with chopped brain from animals killed in insulin convulsions. Under these conditions they obtained in some cases more lactate disappearing than could even be accounted for by total oxygen uptake. An experiment has been performed using brain cortex slices from a starved rabbit killed when in hypoglycaemic convulsions caused by an injection of 15 units of insulin 2½ hours previously. The results are shown in Table II.

Table II.

		Lactate			No substrate	
Date	Remarks	Q_{O_2}	Q_{sCO_2}	$-Q_{\mathrm{L}}^{\mathrm{O}_2}$	Q_{O_2}	Q_{sCO_2}
21. ii. 35	2nd half hour	7·8	5·3	2·5	4·55	3·7
	2nd hour	6·8	4·6	2·2	(1·7)	(−0·6)
	3rd hour	5·85	3·2	2·65	1·9	2·0
	4th hour	6·8	4·6	2·2	1·1	0·6
	5th and 6th hour	6·35	4·1	2·25	1·0	1·3
	7th hour	6·3	4·3	2·0	0·5	0·5

In this experiment the average Q_{O_2} in lactate (a mean of the values in the table) is 6·65, while the average lactate disappearance is given by $-Q_{\mathrm{L}}^{\mathrm{O}_2}=2{\cdot}3$. This result is nearer the theoretical 3 molecules of oxygen used for every lactic acid molecule oxidised than the values obtained with the normal brain slices. The small excess of the theoretical value of $Q_{\mathrm{O}_2}=6{\cdot}9$ over the observed $Q_{\mathrm{O}_2}=6{\cdot}65$ is almost certainly due to experimental error. In fact the agreement with the theoretical value is better than in the normal brain, where the Q_{O_2} of 7·0 instead of a calculated value of 6·3 was observed. It may well be that a very slight respiration of other substrate occurs in the normal brain and that this is removed by insulin with its attendant hypoglycaemia. The experiment shown in Table II shows the same general course of metabolism as in experiments recorded in Table I, that is, fairly steady disappearance of lactate, while rise in the difference between respiration in lactate and respiration without substrate occurs with increase in time. In this case then also the lactate oxidised should be calculated from the total oxygen uptake and not from the difference between the respiration in lactate and the autorespiration.

It seems clear that the hitherto much favoured theory of mechanism of the Pasteur reaction now requires, at any rate for brain, considerable modification. The rate of lactate disappearance in oxygen is no more than a quarter that obtained for lactic acid production in nitrogen (as is seen in Table I). This precludes the possibility that lactic acid is formed in oxygen as in anaerobic conditions and then removed. It might be said that the metabolism without substrate is still producing lactic acid and this is being re-oxidised to such an extent as to impede the disappearance of added lactate. This view, however, is rendered very unlikely for the following reasons. Firstly, it has been shown by Holmes and Holmes [1925; 1927], Ashford and Holmes [1931] and Holmes and Sherif [1932] that the anaerobic lactate formation without glucose is very small. Secondly, the metabolism without substrate seems to be largely suppressed in the presence of lactate. And, thirdly, the addition of potassium chloride does not cause aerobic glycolysis to appear in brain slices without substrate; this points to the absence of lactic acid formation and lactic acid-forming substance under these conditions.

The use of potassium chloride as an indicator for the presence of lactic acid-forming substances should here be briefly described. It has been shown [Ashford and Dixon, 1935] that addition of this substance causes appearance of marked aerobic glycolysis from glucose as well as increased oxygen uptake. It has since been shown that with fructose only increased oxygen uptake is observed and no aerobic lactic acid formation occurs. This was to be expected since Loebel [1925] and others since have shown that fructose gives hardly any anaerobic glycolysis. Lactate also gives increased oxygen uptake with potassium chloride. If, therefore, in the metabolism without substrate some lactic acid-forming substance were being used we should expect that the addition of potassium chloride would here cause aerobic lactic acid formation as with glucose. The following experiments with added potassium chloride in $M/10$ concentration negative this possibility: it is seen that without substrate there is no aerobic glycolysis, whereas with glucose and mannose which readily glycolyse under anaerobic conditions there is marked aerobic glycolysis.

Table III.

19. ii. 35	$Q_{\mathrm{L}}^{\mathrm{O}_2}$*	0	10·7	—	11·0	—	0

* Rough direct method of Warburg [see Ashford and Dixon, 1935].

We may conclude then that in oxygen lactic acid is not formed at the same rate as in nitrogen and then reoxidised. Firstly, lactic acid does not disappear fast enough in oxygen for this to be the case. Secondly, if all the lactic acid formed in nitrogen were oxidised completely in oxygen the Q_{O_2} would be of the order of three times the $Q_{\mathrm{L}}^{\mathrm{N}_2}$—it is in fact equal to about half the $Q_{\mathrm{L}}^{\mathrm{N}_2}$. For this reason one would have to assume resynthesis of lactic acid or some other form of disappearance unaccounted for by oxygen uptake, to explain a high rate of disappearance. However, the experiments described here disprove the idea of resynthesis, since the lactic acid disappearing is completely oxidised, at any rate at the concentrations employed (0·2 %). It seemed possible that unaccounted disappearance might occur at higher concentrations (0·5 %) employed by Ashford and Holmes. However, an experiment performed using 0·5 % lactic acid has shown no unaccounted disappearance of lactic acid, as is seen in Table IV.

Table IV.

		Lactate (0·5 % lactic acid)			No substrate		Glucose
Date	Remarks	Q_{O_2}	Q_{SCO_2}	$-Q_L^{O_2}$	Q_{O_2}	Q_{SCO_2}	$Q_L^{N_2}$
13. iii. 35	1st hour	8·3	5·6	2·7	4·9	3.8	19·9
	2nd hour	7·4	4·8	2·6	3·5	2·8	17·5
	3rd hour	7·1	4·5	2·6	1·6	0 8	20·4
	4th hour	6·5	4·1	2·4	1·3	1·0	15·8
	5th hour	6·8	4·9	1·9	0·7	0·5	15·8
	Average	7·2	—	2·4	—	—	—

One must assume that in oxygen lactic acid is either not formed at all from glucose, or, if formed, is produced at a rate slow enough to be removed by complete oxidation. It thus appears that oxygen exerts its sparing effect on glycolysis at some point in the system prior to the formation of lactic acid.

SUMMARY.

1. Low values for rate of disappearance of lactate relative to rate of lactic acid formation in brain slices are confirmed, values averaging $-Q_L^{O_2}=2\cdot 1$ for lactate disappearance being obtained.

2. The rate of lactate disappearance is shown to remain fairly constant over prolonged periods of time. Only slight fall in respiration rate in lactate is observed, up to 35 % over 6 hours. Marked fall in respiration without substrate up to 90 % is simultaneously observed.

3. The bearing of these results on the question of the fate of lactic acid disappearing and on the site of action of oxygen in the Pasteur reaction is discussed. It is concluded that the lactic acid oxidised should be calculated from the total oxygen uptake and that complete oxidation occurs.

4. The use of potassium chloride for detection of possible lactic acid-forming substance under aerobic conditions is indicated.

I wish to thank Dr E. G. Holmes and Dr H. A. Krebs for their valuable advice and criticism.

CXVIII. THE RELATION OF SODIUM TO CHLORINE IN THE MILK OF SHORTHORN AND GUERNSEY COWS.

BY TUDOR STANLEY GEORGE JONES
AND WILLIAM LEWIS DAVIES.

From the National Institute for Research in Dairying, Shinfield.

(*Received March 2nd, 1935.*)

THE determination of the distribution of the cations in milk has, until recent years, been rendered difficult by the lack of a rapid and convenient method for the determination of sodium. The description by Barber and Kolthoff [1928] of an accurate gravimetric method by which micro-quantities can be determined by a macro-technique was followed by the description of a colorimetric method by McCance and Shipp [1931]. Earlier methods for the determination of sodium in milk have been described by Blanchetière [1923] and Barthe and Dufilho [1926; 1928, 1]. The method for the determination of sodium described in this paper consists of the application of the gravimetric method of Barber and Kolthoff to milk. Owing to the uncertainty of the temperature at which sodium is volatilised as chloride and the prolonged time necessary for complete ashing at the maximum allowable temperature, it was decided to adopt the method of wet ashing with nitric acid.

Few values for the sodium content of cow's milk have appeared in the literature and these are usually given as mean values together with the ranges in which they occur. Little attempt has been made to correlate the sodium and chloride values except to state that the chloride in milk is more than equivalent to the sodium and that the excess is probably combined with calcium. Indeed it has been stated [Barthe and Dufilho, 1927] that the sodium content of the milk of healthy cows is never greater than 50 mg. per 100 ml. and that the Na : Cl ratio is never higher than 0·339. The idea however is presented that the sodium content of cow's milk increases as the period of lactation advances [Barthe and Dufilho, 1928, 2].

The milk of 20 cows of the Shorthorn and Guernsey breeds has been examined in an attempt to correlate the sodium and chloride contents of their milk and their stages of lactation. The results of duplicate, and in some cases triplicate, determinations are given in Table I together with the length of time during which the cows had been in lactation. The values for sodium and chloride have ranged from 39·2 to 139·2 and 70 to 193 mg. per 100 ml. respectively, with mean values of 76·8 and 113·4 mg. per 100 ml. respectively. The calculation of the correlation coefficient for the collected data has resulted in the high value of 0·91 and the straight line representing this correlation, calculated by the method of least squares, is represented by the equation

$$Cl = 1{\cdot}24\,Na + 18{\cdot}09$$

where Cl and Na are expressed in mg. per 100 ml. This is the straight line drawn in the graph (Fig. 1). This correlation is given independently of the breed of the cow, no significant difference having been found between the milks of the two breeds investigated.

When expressed in milli-equivalents, the relation takes the form

$$\mathrm{Cl} = 0{\cdot}805\,\mathrm{Na} + 0{\cdot}51$$

from which it is evident that chloride is always in excess. This holds for values of Cl from 70 to 193 mg. per 100 ml., the higher value being well into the region of abnormality preceding "drying off". It is not certain that the equation holds for values of chloride below 70 mg. per 100 ml. (or sodium below 39·2 mg. per 100 ml.) since samples of cow's milk of lower chloride content are rarely encountered. The Na: Cl ratio is evidently not a fixed quantity for milk, but is a function of the value of either element, so the statement of Barthe and Dufilho [1927] is incorrect. Indeed, in no cases were values as low as 0·339 found for this ratio in the milk of the cows of our herd, which is to be regarded as typical of English herds of their breeds. The value given for the mean of the

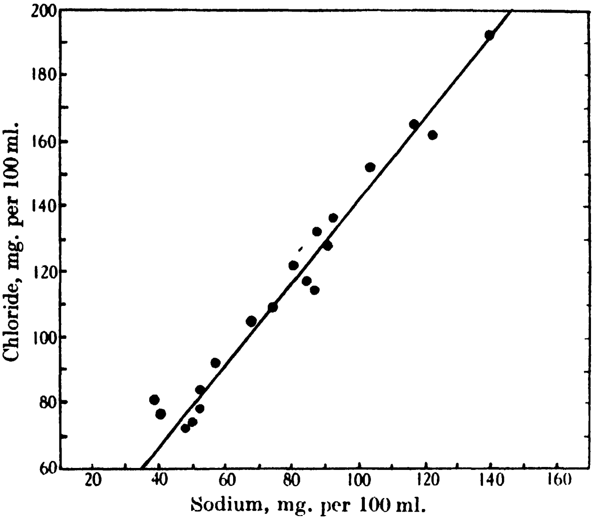

Fig. 1. Relation of sodium to chloride. $\mathrm{Cl} = 1{\cdot}24\,\mathrm{Na} + 18{\cdot}09$; $r = 0{\cdot}91$.

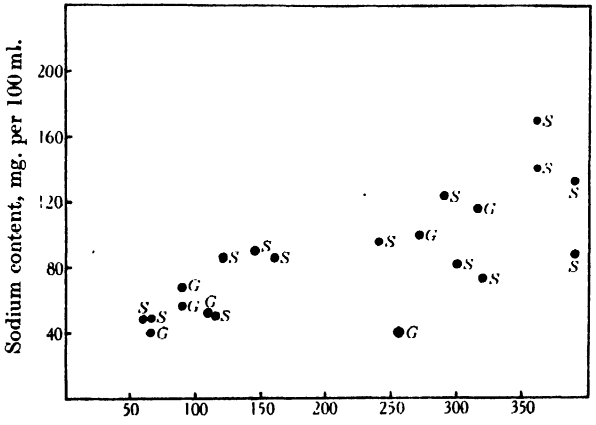

Fig. 2. Sodium content and duration of lactation.

chloride contents of the milks examined is somewhat higher than the value found for over a thousand samples [Davies, 1935] which was 100 mg. per 100 ml. The latter corresponds to a sodium value of 66·0 mg. per 100 ml. which can be regarded as the mean sodium content for cow's milk.

As is well known, the chloride content of milk increases with advance in the period of lactation. Consequently, the value for the sodium content of milk must increase. Fig. 2 shows the scatter diagram for sodium against the period of lactation in days. Again it is evident that there is no significant difference between Shorthorn and Guernsey types. There appears to be a general upward trend but the number of determinations is not large enough for statistical treatment.

METHODS.

The milk samples used were taken from individual cows either at the a.m. or p.m. milking and represent the whole of the milk at that particular milking (fore milk being rejected).

Chloride was determined by the method of Davies [1932]. Sodium was determined by the triple acetate gravimetric method as follows:

Reagents. (1) Concentrated nitric acid (sp. gr. 1·4).

(2) Alcoholic zinc acetate with zinc hydroxide. This is prepared from sodium-free zinc sulphate according to the method of McCance and Shipp [1931].

(3) Zinc uranyl acetate solution: (*a*) 10 g. of uranyl acetate (A.R.) are dissolved in 50 ml. of boiling water containing 2 ml. of glacial acetic acid; (*b*) 30 g. of zinc acetate are dissolved in 50 ml. of boiling water containing 1 ml. of glacial acetic acid. (*a*) and (*b*) are mixed while boiling, re-boiled for a few minutes, cooled, allowed to stand overnight and filtered. This solution is always kept saturated at working temperature with sodium zinc uranyl acetate, prepared by mixing some of the reagent with an alcoholic solution of sodium chloride, and filtered before use.

(4) 95 % alcohol saturated with the triple acetate. The alcohol is kept in contact with the triple acetate at working temperature and filtered before use.

Procedure. 25 ml. (or if the milk is known to contain less than 80 mg. Na per 100 ml., 50 ml.) of milk are measured into a 150 ml. silica flask, 10 ml. of concentrated nitric acid are added, and the mixture is heated on a sand-bath. When the solution has been almost reduced to dryness the mass chars and the carbon ignites and burns in the nitric fumes. By the cautious addition of nitric acid it is possible to obtain a white ash in a few minutes. This ash is dissolved in a small amount of dilute nitric acid and transferred with the aid of 10 ml. of water to a 25 ml. graduated flask. For removal of phosphate 15 ml. of the zinc acetate-zinc hydroxide reagent are added, mixed with the solution and allowed to stand 24 hours. The solution is made up to the mark and filtered. 2 ml. portions of the filtrate are measured into 10 ml. of the zinc uranyl acetate reagent contained in a 10 G 4 Jena filter of 15 ml. capacity which is stoppered at the bottom in the manner described by Peters and Van Slyke [1932]. After vigorous stirring by means of a short, thin rod, the latter is washed down by two successive portions of 1 ml. of the reagent and the filter is covered and set aside for 1 hour. After removal of the stopper, the fluid contents are sucked through by means of the pump and the precipitate is washed five times with 2 ml. portions of alcohol saturated with the triple acetate and twice with 5 ml. portions of ether. The outside of the filter is then wiped dry, the filter is placed in a desiccator for 1 hour and weighed, an ordinary analytical balance being sufficiently accurate. The precipitate weighs 66·9 times its content of sodium, so that using 25 ml. of milk, and 2 ml. of filtrate, the mg. Na per 100 ml. milk are

$$\frac{100 \times \text{mass of precipitate (mg.)}}{2 \times 66{\cdot}9}.$$

The agreement between triplicates is usually well within 1 % and often identical values are obtained.

Excess of potassium interferes with the determination, but this element does not occur in milk to such an extent that special precautions have to be taken as is the case with certain urines, feeding stuffs *etc.*

SUMMARY.

1. A detailed account of the determination of sodium in cow's milk is given.

2. In the milk of 20 cows the average values of Cl and Na were 113·4 and 76·8 mg. per 100 ml. respectively.

3. The relation between chloride and sodium in milk of Shorthorn and Guernsey cows is given by the equation

$$\text{Cl} = 1{\cdot}24\ \text{Na} + 18{\cdot}09$$

where Cl and Na are expressed in mg. per 100 ml.

OBITUARY NOTICE.

JOHN ALEXANDER MILROY.

(1871–1934.)

JOHN ALEXANDER MILROY, one of the Original Members of the Biochemical Society, died at Belfast after a brief illness on September 19, 1934, having just passed his sixty-third birthday. Born in Wigtownshire, he received his school and university education in Edinburgh, obtaining in 1893 the degree of M.A., in 1896 that of M.B. and in 1902 that of M.D. While still a medical undergraduate he spent a winter in Salkowski's laboratory in Berlin, and at a later date he was for a time a student under Emil Fischer. After graduation he acted as Demonstrator of Physiology first in Owens College, Manchester, and then in Yorkshire College, Leeds. In 1902 he accompanied his elder brother, Prof. T. H. Milroy, to Queen's University, Belfast, where the latter had just been appointed to the Chair of Physiology. At Belfast he held at first the post of Lecturer in Physiology, but in 1909 was appointed Lecturer, and in 1922 Reader, in Biochemistry. In 1924 he was promoted to the newly-founded J. C. White Professorship of Biochemistry. It had been his intention to terminate his tenure of the Chair after one more year of service, and to retire from active academic work at the same time as his brother in 1935. An association, which had endured already for thirty-two years, would thus have found an appropriate and felicitous conclusion.

In 1902 Milroy submitted to the University of Edinburgh a thesis for which he was awarded the degree of M.D. with the added distinction of a gold medal. The title of this thesis—"A contribution to the knowledge of the products of the reduction of haematin"—indicates his early interest in a field, to which in succeeding years he made a variety of important contributions. He had already, as a matter of fact, presented to the Physiological Society (*J. Physiol.*, 1901) a preliminary account of the matters dealt with in his thesis, and in 1904 he communicated through the same channel a paper on "Products of the distillation of haematin with zinc dust" and another on "Reduced acid haematin and some of its derivatives." In 1909 he described a remarkably stable derivative of haemochromogen, in which iron had been largely replaced by nickel, and also reported a careful measurement of the specific CO-capacity of reduced acid haematin (*J. Physiol.*, 1909). The last paper of this series (*Biochem. J.*, 1918) describes the preparation, the absorption spectra and the properties of a number of metallic compounds of haematoporphyrin, some of them previously unknown. Notable among these was the stannous compound, which was found to be remarkably stable and to show a spectrum of singular intensity. Upon this observation Milroy based a new test for blood pigment, exceeding in delicacy any other known test of specific character.

The group of papers just cited embodies in itself a substantial contribution to Biochemistry. Milroy's other publications show that he took a lively and productive interest in many widely different topics. They include papers on albumosuria (*J. Path.*, 1901), on the staining of protein crystals (*Proc. Scot. Microscop. Soc.*, 1902), on the estimation of urea (*Biochem. J.*, 1913), blood sugar (*Biochem. J.*, 1925) and blood fat (*Biochem. J.*, 1928), and on sublimation *in vacuo* as a method of separating certain chemical constituents of the body (with S. Andrews, *J. Physiol.*, 1930). Latterly he had turned his attention to the pentose compounds of the animal organism; and in his last paper, planned as the first of a series, he dealt (again in collaboration with S. Andrews) with the micro-determination of free and combined pentoses (*Biochem. J.*, 1933).

John Milroy was joint author with his brother Thomas of a well-known text-book on Practical Physiological Chemistry, first published in 1904. A revision and extension of this book, leading to the issue in 1921 of a third greatly enlarged edition, was to a preponderating extent the individual work of the younger brother. The task was one which he performed in the spirit rather of the investigator than of the compiler; and the book incorporates much that must be credited to him as original work. The improvement of practical instruction in his Department was indeed an object in the pursuit of which Milroy spared himself no pains. The thoroughness of his methods was appreciated even by junior students, still more by the many graduates, both in Science and Medicine, who attended his advanced course.

Those fortunate enough to have known John Milroy are aware that his gifts of intellect were not more conspicuous than the charm of his personality and the mingled strength and sweetness of his character. The vivid smile that lit his face in conversation reflected a mind and a disposition at once eager and ingenuous. His modesty, his sociability, his kindly courtesy endeared him to all, young or old, with whom he came in contact. The interests of others always claimed his attention more readily than his own, and to any colleague who called upon him for information or advice he offered his time and his knowledge with prodigal liberality. Happy in his daily work, happy in his many friendships, he was happiest of all in the family life which he shared with his two brothers and two sisters—all, like himself, unmarried. All those—and they are many—who have been admitted to that closely-knit but hospitable household will understand, and share, the sorrow of its surviving members.

A. HUNTER.

CXIX. THE RÔLE OF THE PLACENTA IN THE FAT METABOLISM OF THE RABBIT FOETUS.

BY ELDON MATHEWS BOYD.

From the Department of Pharmacology, Queen's University, Kingston, Ontario, Canada.

(*Received January 8th, 1935.*)

IN recent years, the author has been interested in the study of fat metabolism during the reproductive cycle. The results of previous investigations leading to the present contribution may be briefly indicated. The preliminary step consisted in the elaboration of a method whereby all known lipoids could be simultaneously estimated in micro-amounts, in the same extract and using the same analytical principle—isolation followed by oxidation [Boyd, 1933, 1]. This differential micro-analysis was then applied to a study of lipoids in the blood of pregnant women in whom it was shown [Boyd, 1934, 1] that the concentration of lipoids is increased in plasma but not in the red blood cells and that the increase in plasma is different in regard to time and extent for each lipoid. The white blood cells were noted to contain smaller amounts of fatty substances in pregnant [Boyd, 1934, 2] than in non-pregnant [Boyd, 1933, 2] women but after parturition there occurred a remarkable increase of several hundredfold in the phospholipin, free cholesterol and neutral fat of these cells. Experiments which have not been published to date confirmed the observations of Baumann and Holly [1926] and others that in rabbits the blood lipoids are decreased rather than increased during pregnancy. In the ovary of pregnant and pseudopregnant rabbits, certain changes were encountered in lipoid composition which were interpreted as signifying that the physiological activity of this organ in this species increases up to the mid-point of pregnancy and retrogresses during the latter half [Boyd, 1935, 1].

Two possible effects of the lipaemia of pregnancy in women have so far been investigated. It has been shown that normal lactation following the termination of pregnancy is accompanied by a decline in the value of all plasma lipoids but that if lactation is prevented by drying up the breasts the lipaemia persists or may be augmented [Boyd, 1935, 2]. This was interpreted as signifying that the lipaemia assists in the production of milk fat or that the prevention of lactation causes some further maladjustment in fat metabolism. The second effect investigated was the possibility that the lipaemia may act in the nature of an increased pressure head forcing lipoids into the umbilical circulation through the placenta and on to the foetus where they are utilised in the building up of the developing organs. In this connection, it was found that the human placenta at full term pregnancy adds considerable amounts of lipoids to umbilical blood from which they are absorbed by the growing offspring [Boyd and Wilson, 1935]. The average large, well-nourished infant was recorded to absorb in the neighbourhood of 50 g. of lipoids per day from umbilical blood, 40 g. of these being phospholipin and the remainder equally divided between free cholesterol and cholesterol esters; neutral fat was occasionally absorbed and occasionally given up by the foetus.

From these results it was concluded that the placenta plays an important part in the transfer of lipoids from the mother to the foetus *in utero*. Two possible explanations may be offered regarding the manner in which this exchange takes place. First, lipoids in the maternal blood-stream may simply be passed across the placental membrane to the umbilical blood. In referring to this process, the term permeability has been purposely avoided since the manner in which lipoids are transferred across animal membranes is at present obscure; it may be through the intermediate formation of semi-soluble phospholipin although even this is disputed. Secondly, the placenta may act in the nature of a secreting gland, taking up lipoids from the maternal blood-stream and passing them on, with or without structural modification, to the foetal circulation. The absence of glandular tissue from the placenta in no way militates against this conception, since apparently all tissues of the body are capable of taking up and discharging lipoids of the blood. If the tissues of the placenta are actively engaged in the production or elaboration of lipoids for the foetus, then it appears that any alteration in the lipoid composition of the foetus at the various stages of pregnancy may be accompanied by corresponding changes in the lipoid composition of the placenta. The present investigation was concerned with the development of this postulate.

Rabbits were used in this investigation because the placenta in this species is functionally similar to that in man, *i.e.* it is of the haemo-chorial type, and hence results obtained with this animal may be more readily applied to and compared with our previous findings in the human placenta [Boyd and Wilson, 1935]. The procedure adopted was to select female rabbits at different periods during pregnancy, open the abdomen and uterus, take out a foetus with its corresponding placenta and then measure the lipoid content of each. When a sufficient number of such experiments had been done, it was possible to plot the lipoid composition of the foetus against the lipoid composition of the placenta at the various stages of pregnancy, noting whether or not there were any indications of variations in the fat metabolism of the placenta during gestation.

EXPERIMENTAL PROCEDURE.

Foetuses and placentas were obtained from the uteri of gravid rabbits at various days during pregnancy from the 14th day to the 32nd day or term. No determinations were made earlier than the 14th day because the foetus before this date is too small for a complete lipoid micro-analysis. The structures were kept in pairs so that the lipoid composition of the foetus could be compared with that of the placenta to which it had been attached while in the uterus. After removal from the uterus, the foetus and placenta were separately weighed and ground up to a fine mud in a mortar using rough quarry sand which had been de-carbonated with hydrochloric acid, washed with water and extracted with alcohol and was of a uniform size between 18 and 20 mesh. The mixture of sand and tissues was transferred quantitatively to a flask and shaken with at least 50 volumes (*v/w*) of a mixture of alcohol and ether, 3 : 1, both redistilled and the ether peroxide-free. The mortar was washed out several times with small amounts of this solvent and the tissue-sand, which tended to cake when the proteins were precipitated, broken up with a clean spatula. The contents of the flask were then brought to boiling on a steam-bath for a few minutes, thus completing the extraction of lipoids. After cooling to room temperature, the extracted fatty substances were filtered off through alcohol-extracted filter-paper into a volumetric flask, the residue was washed with repeated portions of alcohol-ether, and the combined filtrate made up to volume. Foetuses weighing over 10 g. were cut into fine pieces and continuously extracted with 10 to 15 volumes of alcohol-ether, for 10 to 15 hours in Bloor percolator-extractors. Both of these methods were found to give complete extraction and the choice was purely for convenience in adjusting the final volume of the extracts, the first method requiring large amounts of solvent and a short extraction time and the Bloor method using smaller amounts of solvent but a longer extraction time.

In each extract the lipoids determined experimentally were total fatty acids, total cholesterol, free cholesterol and phospholipins, using the Bloor oxidative micro-technique as modified by Boyd [1933, 1]. From these values determined experimentally were calculated the concentrations of the various lipoids present. Thus phospholipin and free cholesterol were obtained directly, ester cholesterol calculated by subtracting the value of free cholesterol from total cholesterol, and neutral fat by subtracting from the total fatty acids the fatty acids of phospholipin and cholesterol ester. These residual fatty acids, which were taken to represent neutral fat fatty acids and calculated to comprise 95 % of the neutral fat fraction, are probably present in the tissues mostly in the form of glycerol esters but may have other combinations and some may be present as free fatty acid. In view of this probability and of the absence of definite knowledge concerning their nature, they have been referred to collectively as neutral fat.

EXPERIMENTAL RESULTS.

The concentrations of the four main groups of lipoids, namely phospholipins, free cholesterol, ester cholesterol and neutral fat, in the rabbit foetus and placenta during the latter two-thirds of pregnancy are depicted respectively in Figs. 1, 2, 3 and 4. Curves for total lipoid, total fatty acid, total cholesterol and the other lipoids have not been given because they are not essential to the interpretation of the data and because they may be calculated approximately from the information given. The ordinates and abscissae in all figures are in the same units. The ordinate represents mg. of lipoid per 100 g. tissue, wet weight. The abscissa represents the weight of the foetus in g. In order to demonstrate clearly the variations in the smaller foetuses, the progression of the abscissa was made geometric rather than arithmetic. This should be remembered when interpreting the slope of the curves. The weight of the foetuses has been used for the abscissa rather than the day of gestation because the lipoid composition was found to vary with the weight of the foetus rather than with the duration of pregnancy. This was particularly apparent when three or four foetuses were analysed from a single uterus, especially in the earlier stages of gestation. To obtain the approximate duration of pregnancy in each curve, the following figures may be given as guides: at 14 days, average weight of foetus about 0·25 g.; at 17 days, 1·0 g.; at 24 days, 12 g.; at 31 days, 40 g.

A. *Phospholipins.*

The concentration of phospholipins in the foetus (Fig. 1) increased in the earliest embryos studied and in every embryo throughout pregnancy whenever the weight of the foetus increased, the most rapid increase being around the 14th day of gestation. As the weight of the foetus rose from 0·2 to 0·4 g., the phospholipin content rose from 122 to 513 mg. per 100 g. From then until the termination of pregnancy, phospholipin continued to rise in value but at a much smaller rate. At the termination of pregnancy, phospholipin composed on the average 1 % of the weight of the foetus.

While the phospholipin content of the foetus was steadily increasing, the phospholipin content of the placenta was found to exhibit two phases. As the foetus increased in weight from 0·2 to 2 g., the concentration of phospholipin in the placenta fell from over 1500 mg. per 100 g. to about 1000 mg. per 100 g. From then on to term, phospholipin rose to and remained at a plateau level of around 1500 mg. per 100 g., with considerable variation both high and low in different placentas. The appearance of this double phase became obvious only after examining a number of placentas, particularly those in the earlier stages of gestation. It is not shown in the results of previous investigators on other types of placentas; most of this previous work reports only one or two stages, but Watanabe [1923] obtained a "step down" type of curve for the human placenta, that is a high plateau in the first trimester, a drop to a lower plateau in the second trimester and then the lowest level of all in the last trimester. The only previous report on the placenta of the rabbit gives 600 mg. per 100 g. as the value for phospholipin on the 29th day of gestation [Baumann and Holly, 1926].

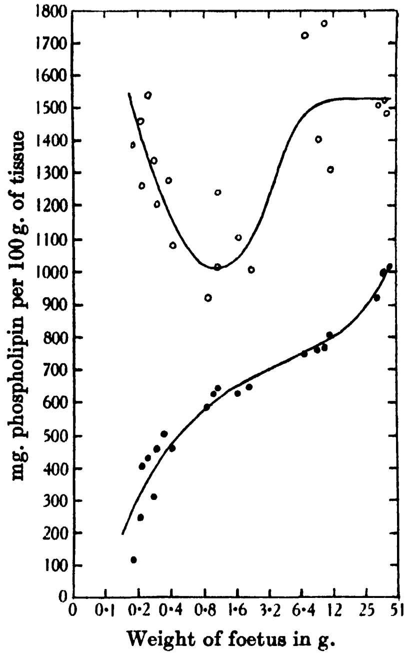

Fig. 1.

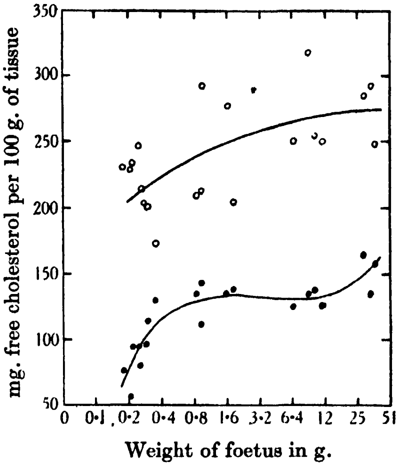

Fig. 2.

Fig. 1. Changes in the percentage of phospholipin in the foetus and in the placenta of the rabbit during intra-uterine growth. o—o placenta; •—• foetus.

Fig. 2. Changes in the percentage of free cholesterol in the foetus and in the placenta of the rabbit during intra-uterine growth. o—o placenta; •—• foetus.

The results suggest that the initial fall in the level of placental phospholipin is due to removal of phospholipin either to certain maternal organs such as the mammary glands, which were found by Baumann and Holly [1926] to have an infiltration of phospholipin during pregnancy, or to the foetus in which there is a very rapid increase in phospholipin as shown above. Since the weight of the placenta increases during pregnancy more rapidly than the concentration of phospholipin falls, there is actually a slight increase in the total amount of phospholipin segregated in this organ. Hence the increase in the phospholipin of the foetus cannot be due to a simple transfer of a certain number of mg. of phospholipin from the placenta. The phospholipin content of a tissue is a dynamic value, being increased by absorption of lipoid from the blood and decreased by oxidation, hydrolysis, and removal by the blood. Hence the placenta of early pregnancy, or rather the early part of the second half of pregnancy, may be giving up to the foetus or to some other organ more phospholipin than it actually requires to satisfy its own needs.

B. *Free cholesterol.*

Changes in the concentration of free cholesterol (Fig. 2) in the foetus during pregnancy closely paralleled the changes in phospholipin. This was not unexpected since the two lipoids appear to be closely related in vital economy, the one being antagonistic to the other in many physiological reactions, for example, haemolysis of the red blood cells. In the foetus, free cholesterol rose from a value of 58 mg. per 100 g. in a 0·2 g. embryo to 167 mg. per 100 g. in a 34 g. embryo almost at term. Again the increase in the foetus was more marked in the earlier cases studied.

The placenta exhibited considerable variation in regard to its free cholesterol with a tendency toward increasing amounts of the lipoid as gestation proceeded. The curve as represented in Fig. 2 was considered best adapted to the various points. The relationship to phospholipin may be shown more clearly if the first eight points for free cholesterol in the placenta are united by a straight line progressing downward followed by a rise in the latter part of pregnancy as in the case of phospholipin. In such a case, most of the discussion which was applied to phospholipin may also be applied to free cholesterol. Be this as it may, the results clearly indicate that cholesterol metabolism of the placenta varies according to the duration of pregnancy.

C. *Ester cholesterol.*

This lipoid underwent a remarkable change in the rabbit placenta during pregnancy. As shown in Fig. 3, it rose from a value of 139 mg. per 100 g. on the 14th day of gestation to almost 500 mg. per 100 g. between the 16th and 22nd days of pregnancy. After that, the concentration of placental ester cholesterol fell and at the end of pregnancy the value was similar to that found in the 14-day animals. During this time, small and comparatively insignificant amounts of ester cholesterol were present in the foetus, the values varying between 0 and 98 mg. per 100 g. but showing no definite trends.

Variations in the concentration of placental ester cholesterol are in many respects the opposite of those for phospholipin and free cholesterol, particularly phospholipin. Thus, while the values for phospholipin fell in the placenta between 0·2 and 10 g. foetuses, the ester cholesterol rose. Ester cholesterol in tissues is bound with fatty acids and the results suggest that the decrease in phospholipin may have been due to a liberation of fatty acids which were then combined with cholesterol to produce cholesterol esters. The concentration of total cholesterol also increased in this period, so that there must have been a considerable infiltration or synthesis of cholesterol.

It is worthy of note that the placenta of the rabbit was found to contain more cholesterol esters than are usually found in tissues. On the average, about one half of the total cholesterol was present as ester; in adult tissues, ester cholesterol rarely comprises more than 10 % of the total cholesterol. Since cholesterol esters appear to act as transporters of fatty acids [Bloor, 1924;

Schaible, 1932; Ling, 1931], there may be some significance in the high cholesterol ester content of the placenta in relation to the postulated transport of fatty acids to the foetus.

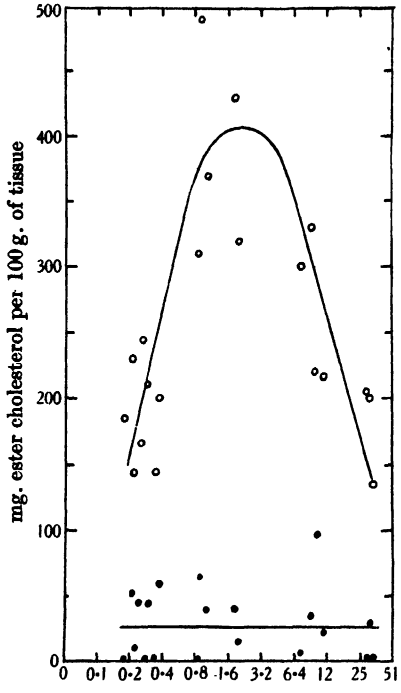

Fig. 3.

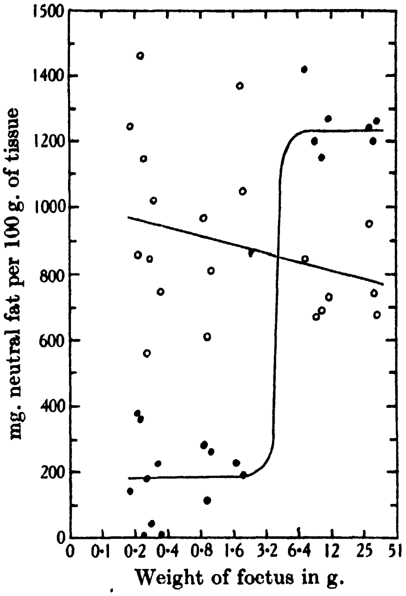

Fig. 4.

Fig. 3. Changes in the percentage of ester cholesterol in the foetus and in the placenta of the rabbit during intra-uterine growth. o—o placenta; •—• foetus.

Fig. 4. Changes in the percentage of neutral fat in the foetus and in the placenta of the rabbit during intra-uterine growth. o—o placenta; •—• foetus.

D. *Neutral fat.*

Comparatively little is known about the physiology of neutral fat apart from the fact that it is the chief storage form of fat in the body. Analyses for neutral fat in the rabbit foetuses, Fig. 4, confirmed the well-known clinical observation that premature and abortive embryos have a thin, emaciated appearance in contrast to the plump, well-rounded out appearance of full-term foetuses. These latter embryos owe their appearance to the presence of subcutaneous fat which is mostly neutral fat. In the foetuses of rabbits studied, neutral fat increased over 600 % between the 14th and last days of pregnancy, the rise taking place about the 20th day.

The neutral fat of the placenta varied within a wide range of values, especially in the earlier cases studied wherein figures were obtained between 560 and 1470 mg. per 100 g. Although the differences between placentas were also wide at subsequent periods of pregnancy, in general the values tended to fall somewhat. The total loss of neutral fat to the placenta was less than the total gain in neutral fat of the foetus.

DISCUSSION.

The present investigation offers certain further information concerning the relationship between the lipoid composition of the foetus and the activity of the placenta. It has been shown that the embryo of the rabbit acquires increased concentrations of phospholipin and free cholesterol as it grows in the uterus. There was no relation found between growth and the cholesterol ester content of the foetus, but about 10 days before the end of intra-uterine development the neutral or glyceride fat of the foetus increased sixfold. At birth the foetus of the rabbit contained a much higher percentage of all lipoids except cholesterol esters than in the early stages of growth within the mother.

The rates of increase in the concentrations of phospholipin and free cholesterol of the foetus were greatest up to about the 16th day or middle of pregnancy. Then ensued slower rates of increase until the last week of gestation when again the percentage of these lipoids rapidly increased. Phospholipin and free cholesterol, especially phospholipin, have been shown in recent years to increase in concentration in a tissue or organ whenever that tissue or organ becomes physiologically active [Bloor and Snider, 1934; Boyd, 1935, 1]. If it may be assumed that the rate of increase in physiological activity varies as the rate of increase in phospholipin, then the embryo of the rabbit may be said to exhibit two stages of marked activity, the first up to the 16th day and the second in the last week of intra-uterine life. The activity of the embryo in the first half of pregnancy is probably referable chiefly to growth. In the last week of gestation, however, the growth rate is falling off and it seems from the data obtained that activity of the embryo at this time is due to increased activity of fat metabolism, resulting in the deposition of large amounts of neutral or storage fat.

This stimulus to foetal fat metabolism in the last days of intra-uterine development may be shown to be accompanied simultaneously by an increase in the physiological activity of the placenta. As previously stated, physiological activity is characterised by increasing percentages of phospholipin and free cholesterol. On the other hand, degeneration, retrogression or inactivity results in a decrease in phospholipin and an increase in cholesterol esters [Bloor and Snider, 1934; Boyd, 1935, 1]. Up to about the middle of pregnancy, the placenta has been shown to exhibit a decreased concentration of phospholipin and an increased concentration of cholesterol esters. This indicates that the placenta declines in activity during the first half of gestation.

Lipoid analyses reveal that about the middle of gestation, the placenta begins to take on increased function, *i.e.* the percentage of cholesterol ester falls while that of phospholipin and free cholesterol rises. At the same time, fat metabolism in the foetus becomes augmented as evidenced by the laying down of great quantities of storage fat and increased concentrations of phospholipin and free cholesterol.

It would appear that these two phenomena may be related. From the data given in Figs. 1 to 4, the foetus of 16 days may be calculated to contain a total of about 6 mg. of phospholipin, 1 mg. of free cholesterol, 4 mg. of ester cholesterol and 2 mg. of neutral fat. The foetus at term may be similarly shown to contain 500 mg. of phospholipin, 75 mg. of free cholesterol, 75 mg. of ester cholesterol and 600 mg. of neutral fat. Thus it is only in the latter part of pregnancy that appreciable amounts of lipoids are segregated in the foetus. Previous studies [Boyd and Wilson, 1935] suggested that in the haemo-chorial type of placentation, the major portion of foetal lipoids is passed through the placenta. Present studies indicate that the bulk of foetal lipoids, excluding a possible portion which may be synthesised from carbohydrate, must pass through the placenta in the latter part of pregnancy. If this passage were simply one of physical transfer across the placental membranes, it is difficult to see why there should be any change in the lipoid metabolism of the placenta, especially a change which indicates increased physiological activity. Rather do the results suggest that the actual tissue substance of the placenta plays an important rôle in the transfer of lipoids from the mother to the growing offspring.

While in this series of investigations attention has been directed chiefly to the placenta as the medium through which lipoids are transferred from the mother to the embryo, it is possible that other mechanisms may exist. In animals possessing an epithelio-chorial or syndesmo-chorial type of placenta, with several layers of cells separating the maternal and foetal blood streams, *e.g.* pigs, horses and ruminants, it is difficult for the foetus to obtain sufficient nourishment directly from the maternal blood *via* the placenta and return to it waste products of metabolism. In such animals, accessory mechanisms such as "uterine milk" are provided for the nourishment of the foetus and accessory organs like the allantois for the disposal of waste products. The decidua and amniotic fluid constitute another possible mechanism for foetal nourishment.

Little is known about the relations of these several possible mechanisms to foetal fat metabolism except in the case of amniotic fluid. This fluid was found to contain but traces of fatty acids in human beings [Konstantinovitch, 1906] but appreciable amounts in the cow [Eckles, 1916]. Traces of cholesterol have been reported in human amniotic fluid [Chauffard *et al.*, 1911]. A sample of pure amniotic fluid, obtained by the author from a human ovum about two months old, gave the following lipoid analysis: neutral fat, 0; free cholesterol, 4 mg. per 100 g.; ester cholesterol, 27 mg. per 100 g.; phospholipin, 67 mg. per 100 g. It is of interest that the lipoids concerned with fat transport, *i.e.* phospholipin and cholesterol ester, were present in greatest amounts. A possible manner by which lipoids may be absorbed from amniotic fluid by the foetus can be deduced from the work of Keiffer [1926]. He found that "vernix caseosa," which is a cheesy deposit from amniotic fluid on the skin of the mammalian embryo and contains some 10 % fat, will be absorbed, if left on the skin, within eight hours of birth. These various facts suggest that lipoids may be added to amniotic fluid through the decidua and amnion, deposited on the skin of the embryo and from there absorbed by the foetus. Further work is required to substantiate this postulate.

SUMMARY.

The lipoid composition of the foetus and of the placenta was determined in the rabbit at various stages during intra-uterine development with a view to demonstrating any relation between the fat metabolism of placental tissue and fat metabolism of the foetus.

It was found that the lipoid composition both of the foetus and of the placenta varied according to the duration of growth of the foetus. In the foetus, the concentrations of phospholipin and free cholesterol increased rapidly up to the middle of gestation, then more slowly until the last week or ten days when again the rate increased. During the last ten days there was a marked increase of 600 % in the neutral or storage fat content of the foetus. The embryo contained variable but similar amounts of cholesterol ester at all stages of growth within the uterus.

Up to the mid-point of pregnancy, the placenta exhibited a fall in the concentration of phospholipin and an increased percentage of cholesterol esters.

In the latter half of gestation, the reverse changes occurred, *i.e.* the value of phospholipin rose while the value of cholesterol esters fell. Throughout pregnancy there was a slight increase in placental free cholesterol and a slight increase in placental neutral fat.

On the basis of current theory regarding the relation between lipoid composition and physiological activity, these changes were interpreted as follows. Growth maintains a high degree of physiological activity in the foetus until about the middle of pregnancy. In the last few days of gestation, the foetus again becomes active owing to an increased turnover of fat metabolism resulting in the laying down of large amounts of storage fat in the embryo. The deposition of this fat occurs along with an increased concentration of phospholipin and free cholesterol and is associated with increased activity on the part of the placenta. Such placental activity appears inconsistent with the conception that lipoids are passed through the placenta merely as through an animal membrane and suggests that the actual tissue substance of the placenta is actively engaged in transferring at least a part of the lipoids from the mother to the embryo in the latter part of gestation.

Other possible pathways for the exchange of lipoids between the mother and the foetus were discussed, particularly the decidua and amniotic fluid.

The author takes pleasure in acknowledging that he obtained the idea that the placenta may be more than a permeable membrane in relation to the acquisition of lipoids by the foetus from reading the stimulating description of this subject by Dr Joseph Needham in his book, *Chemical embryology.*

This investigation was begun while the author was associated with the Department of Obstetrics and Gynaecology, The University of Rochester, School of Medicine and Dentistry, Rochester, New York. The author desires to thank Dr A. W. Makepeace of that department for providing much of the experimental material.

CXX. STUDIES ON VACUUM EVAPORATION AND DISTILLATION.

By HANS NORBERT NAUMANN.

From the Devonport Pathological Laboratories, Seamen's Hospital, Greenwich.

(*Received February 5th, 1935.*)

In many chemical processes, especially in connection with modern biochemical problems, the rapid evaporation of large amounts of dilute solutions which contain heat-labile substances is necessary. For this purpose vacuum apparatus such as those of Anschütz, Hausmann and others are not efficient enough.

In recent publications the author [1929; 1930, 1, 2; 1931, 1, 2] has described efficient vacuum apparatus for rapid evaporation at low temperature. These vacuum distillation plants[1], working with water-jet pumps and giving yields of 2–10 litres of aqueous distillate per hour at temperatures of 15–20° (see Figs. 1 and 2) have the following principles in common:

(1) A highly efficient cooling system. The good condensation so produced makes for low steam pressure and boiling-point in the evaporating vessel (Fig. 1 *a*, Fig. 2 *a*).

(2) A large diameter of the tube system connecting the evaporation flask and the pump. This decreases the friction, speed and pressure of the steam flow to the lowest possible amount (Fig. 1 *b*, Fig. 2 *b*).

(3) An automatic arrangement so that the solution to be evaporated or distilled is drawn up continuously (Fig. 1 *c*, Fig. 2 *c*) and the distillate is automatically removed (Fig. 1 *d*, Fig. 2 *d*).

(4) A resistant capillary of rustless steel which can be regulated and cleaned by means of a stilette wire (Fig. 1 *e*, Fig. 2 *e*). This prevents any delay in boiling.

The apparatus now described has the further improvement, that in addition to both functions mentioned, the pump water is used also for cooling the condenser. For this purpose there is a direct connection of the outflow pipe with the condenser (Fig. 1 *f*, Fig. 2 *f*). This gives good results and, owing to the syphon action of the condenser, there is no reduction in the efficiency of the pump, if a sufficient water pressure is available. The mechanical work of the pump is not increased, and therefore the additional load of the pump is confined to the greater frictional resistance of the walls in the condenser system. When the pump is stopped the water of the condenser jacket runs into the pump and out into the vessel which may have been connected to receive the distillate. Before stopping the pump therefore either this vessel is removed or a check valve (Fig. 2 *g*) can be fitted to prevent the water reflux. The special water-jet pump working continuously and automatically has therefore three functions: (1) it evacuates the apparatus; (2) it drains off the condensate; (3) it cools the system[2].

---

[1] All types of apparatus can be obtained from Messrs H. Cornbleet, 34, East Street, London, S.E. 17.

[2] Fischer [1931] considers the omission of oil pumps a disadvantage in my apparatus; but this is not in accord with my own observations as explained above. He admits, however, that the removal of the steam by oil pumps is difficult and uneconomical, and that in most cases a condenser cannot be dispensed with. Oil pumps in my opinion therefore should be confined to the domain of high vacuum distillation.

Efforts have been made in the past few years to utilise these advantages of the water-jet pump for industrial purposes as for example by Peterson and the Nederlandsche Installatie Maatschappij Therma [1925] in a British Patent for vacuum evaporation of hot inorganic salt solutions of, *e.g.*, $MgSO_4$, Na_2SO_4 *etc.* There is a similarity in the construction principle, with the exception that the condenser is erected before the pump. This arrangement however seems not to be so good because the pre-heated pump water has a higher vapour pressure which prevents an optimum vacuum.

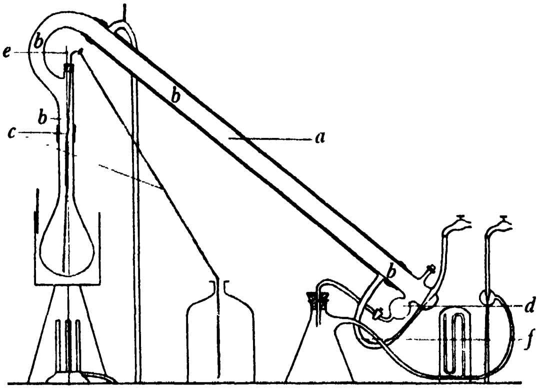

Fig. 1. Standard model of a vacuum evaporator and still for an efficiency of about 2 litres per hour at 20°.

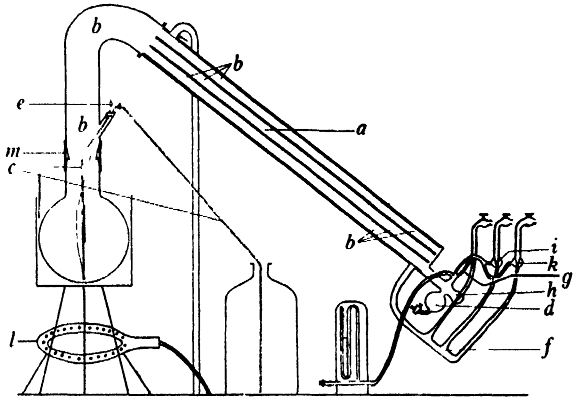

Fig. 2. Vacuum evaporator with seven-tube condenser and a continuous automatic efficiency of 5–8 litres pér hour at 20°.

The triple function of the water-jet pump is greatly extended by using a larger apparatus with seven-tube condenser (Fig. 2).

This apparatus consists of a special pump (Fig. 2 *h*) and two ordinary pumps (*i*, *k*) as auxiliary pumps, the outflow pipes of which are joined to a single tube connected to the condenser (*f*). When the evaporation is begun all three pumps are working together for the purpose of more rapid evacuation. When a suitable vacuum has been attained, the auxiliary pumps (*i*, *k*) are stopped and the evacuated system is blocked by a check valve (*g*), so that water reflux is prevented. The apparatus is then worked with this single special pump, which, notwithstanding its small size, is sufficient for fulfilling the three functions: maintaining the vacuum, draining off the condensate and cooling. The apparatus has an efficiency of 5 litres water per hour at 20°.

The economical working of the larger model is important in technical work, when it is desired to increase the evaporation efficiency to more than 5 litres per hour.

The condensation of 5 kg. of steam per hour with the use of only 300 litres of cooling water supplied by one water-jet pump is possible on account of the great surplus of the cooling surface; actually the maximum efficiency of the condenser is considerably higher. Experiments with a single copper tube condenser (Fig. 1 *a*) have shown that the condensation of 4–5 kg. of steam per hour is possible with 300 litres of cooling water. Since the larger condenser (Fig. 2 *a*) consists of seven copper tubes of the same diameter and length with a sectional cooling water surface approximately 19 times greater, an efficiency of about 30 litres per hour can be expected by using 2000 litres of cooling water. Under ordinary laboratory conditions this can hardly be effected owing to lack of sufficiently powerful heating, approximately 18,000 Cals. per hour being necessary for evaporating 30 litres water at 20°. By heat supplied directly by means of a large ring burner with 24 flames (Fig. 2 *l*) to a tinned iron boiler of 30 litres capacity, efficiencies of about 10 litres per hour have been attained.

Smaller improvements can be attained by tinning the inner surface of the condenser[1] or by using chromium-nickel-steel resistant to acid vapours and also by a conical intermediate piece connecting the evaporation vessel and the metal connecting tube (Fig. 2 *m*) as suggested independently by Hansen [1933]. As regards the boiling capillary made of rustless steel, it is to be noted that the alloy (V2*a* Krupp-Stahl) was corroded not only by hydrochloric acid, but also by more concentrated cold sulphuric acid. It has also been ascertained that a capillary tube can often be dispensed with when working with continuous inflow, since the inflowing solution contains sufficient absorbed air to prevent delay in boiling. After all the solution is in the vessel, the inflow tube can itself serve as a boiling capillary (Fig. 1 *c*, Fig. 2 *c*). But the correct regulation of the apparatus, especially at the moment when all the solution has run into the flask, demands considerable practice in order to prevent the sputtering of the solution consequent on the violent entrance of air. A boiling capillary is therefore preferable even on a continuously working apparatus.

SUMMARY.

The special water-jet pump for continuous automatic working previously described by the author has been improved, so that three functions, evacuating, cooling and removal of the condensate, are fulfilled by this one special pump.

A large apparatus has also been devised fitted with a seven-tube condenser and three pumps, in which, when a full vacuum has been obtained, a single special pump suffices for maintenance of the vacuum, cooling and draining off the condensate at an efficiency of 5 litres per hour at 20°.

The efficiency of this larger apparatus can be increased to 10 litres water per hour at 20° by using a vessel of 30 litres capacity which is heated directly. Efficiencies up to 30 litres per hour may be attained if sufficient increase of heat in proportion to the condenser capacity can be applied to the boiling vessel.

I wish to record my best thanks to Dr Arthur Davies, Director of the Devonport Pathological Laboratories of the Seamen's Hospital, Greenwich, for his help and interest in my work, to the Seamen's Hospital Society for their assistance and hospitality to me and my assistant, Miss Larissa Frenkel, whose cooperation has been of value, and to the Academic Assistance Council for a personal grant.

---

[1] In one case the apparatus was silvered, which was scarcely more expensive but possibly more resistant than the tinning process.

CXXI. THE PERFUSION OF THE ADRENAL GLAND WITH REFERENCE TO THE MECHANISM OF ADRENALINE STABILISATION.

By ROBERT DONALD HOSKIN HEARD
and ARNOLD DeMERRITT WELCH.

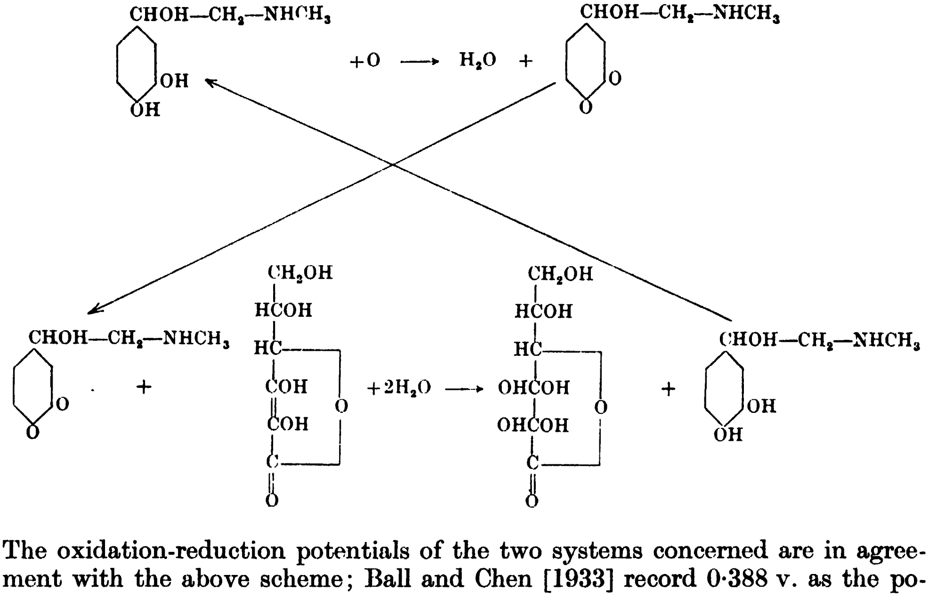
*From the Departments of Biochemistry and Pharmacology,
the University of Toronto.*

(*Received February 7th, 1935.*)

An investigation of the physiological properties of the Ringer-Locke perfusate of the adrenal gland by Schkawera and Kusnetzow [1923] revealed the presence of a sympathomimetic substance which is remarkably resistant to oxidation but in all other respects behaves as adrenaline; they concluded that a stable "adrenaline-like" substance, possibly a precursor of the hormone, is secreted on perfusion. More recently evidence was adduced [Heard and Raper, 1933] which suggested that this stable "adrenaline-like" substance of Schkawera and Kusnetzow is in reality a stabilised adrenaline. It was found that perfusion of 3:4-dihydroxyphenylalanine and its *N*-methyl derivative renders these substrates resistant to oxidation by tyrosinase, and that adrenaline, when added to the Ringer-Locke perfusate, retains its pressor activity on remaining in the alkaline medium for several days. Conceivably stabilisation of adrenaline may be effected directly by chemical combination, or by the presence of amino-acids which delay its rate of oxidation [Wiltshire, 1931], or by means of a continuous interplay of chemical reactions constituting an oxidation-reduction system. The principal purpose of the present communication is to describe results showing that the latter supposition is correct, and that, in all probability, ascorbic acid is the agent responsible for the stabilisation.

On oxidation of the perfusate by molecular oxygen at physiological hydrogen ion concentration and temperature, it was shown that pressor activity does not diminish at a steady rate as with solutions of pure adrenaline or those in which oxidation is delayed by the presence of amino-acids [Welch, 1934], but is maintained at its original level for a considerable period of time before physiological activity decreases. During this maintenance period when pressor activity remains constant, the reducing power of the perfusate, as determined by titration with 2:6-dichlorophenolindophenol, diminishes gradually and reaches zero when irreversible oxidation of adrenaline manifests itself by diminution in physiological activity and appearance of the well-known red coloration. The above observations, together with results of respirometric experiments in which it was found that the oxygen uptake curve given by the perfusate is similar to that shown by adrenaline in the presence of a reducing substance such as ascorbic acid or glutathione, indicate that stabilisation is effected by means of an oxidation-reduction system. That ascorbic acid is the agent responsible for the fixation of adrenaline may be inferred from the behaviour of the perfusate with 2:6-dichlorophenolindophenol. Harris and Ray [1933] have found that ascorbic acid is the only known naturally occurring reducing substance, with the possible exception of cysteine, which reduces this dye under the conditions employed by them. They have applied the method to the estimation of the ascorbic acid content of the adrenal gland with results in excellent agreement with those obtained by biological vitamin C assay. Consequently, with this organ, expression of the indophenol titration value in terms of ascorbic acid is seemingly justifiable; however, it should be emphasised that this does not necessarily apply to other tissue [*cf.* Young and Mitolo, 1934].

It may be assumed from the investigations of Raper and collaborators [Raper, 1932] and from potentiometric measurements recorded by Ball and Chen [1933] that the first stage in the oxidation of adrenaline involves dehydrogenation to the corresponding 3:4-quinone. The latter then rapidly undergoes further irreversible oxidation; conceivably, the quinone, at least in part, undergoes intramolecular change with the formation of an indole derivative. However, in the presence of a reducing substance of sufficiently low potential, the 3:4-quinone is reduced to adrenaline before ring formation takes place. Such a reduction of quinone was demonstrated by Szent-Györgyi [1928] with hexuronic acid and by Welch [1934] with cysteine and glutathione. The recent elucidation of the chemical structure of ascorbic acid and its primary oxidation product by Herbert *et al.* [1933] makes it possible to represent the reactions involved in the coupled system ascorbic acid-adrenaline as follows:



The oxidation-reduction potentials of the two systems concerned are in agreement with the above scheme; Ball and Chen [1933] record 0·388 v. as the potential of the adrenaline system at p_H 7 and 30° which is well above that of ascorbic acid ($E'_0 = -0{\cdot}045$ v. at p_H 7 and 30° [Green, 1933]). The coupled system has been investigated respirometrically and oxygen uptake curves obtained which are similar to those shown by the perfusates of the adrenal gland, where stabilisation of adrenaline is effected by ascorbic acid as long as a small amount of the latter persists in the reduced form. Thereafter the intramolecular change which the 3:4-quinone undergoes is somewhat delayed by the presence of amino-acids. The mechanism by which this is accomplished has been previously investigated [Welch, 1934], when it was demonstrated that the 3:4-quinone, in part, oxidatively deaminates amino-acids and is itself reduced thereby.

The fundamental rôle which ascorbic acid plays in normal metabolism has not yet been elucidated. Certainly the relatively large amounts present in both the cortex and medulla of the adrenal gland cannot be regarded as a reserve supply of vitamin C. This quantity is insufficient to supply the vitamin requirements of the body for more than a few hours. Furthermore Harris and Ray [1933] have shown that the ascorbic acid content of the gland diminishes only gradually during the whole course of scurvy, and that, at death from avitaminosis, it is not unusual to find small amounts still present in that organ. This is in marked contrast to the behaviour of the reserve supply of vitamin A held in the liver which is entirely depleted before ill-effects are observed. Inasmuch as the physiological properties of ascorbic acid appear to depend essentially upon its high reducing power and the reversible nature of its oxidation, it has been supposed that the presence of the vitamin in the adrenal gland is involved in a system which maintains adrenaline or adrenaline-like substances in a reduced state. The behaviour of the Ringer-Locke perfusate of the gland may be adduced as experimental evidence in support of this assumption. Of the reducing substances known to occur within the gland apparently ascorbic acid only is secreted on perfusion. The latter is always accompanied by adrenaline and with no perfusate was one encountered without the other. This suggests that ascorbic acid, although it represents but one component of a complex oxidation-reduction system functioning within the gland, is that reducing substance directly concerned with the maintenance of the 3:4-quinone of adrenaline in the reduced state and the inhibition of pigment formation. Its oxidation-reduction potential, which is more positive than that of glutathione and other reducing substances present in the adrenal gland, is in agreement with the above hypothesis. The effect of the vitamin on pathological pigmentation is also of interest in this connection. Szent-Györgyi [1932] states that its administration has no effect on normal pigmentation but causes the disappearance of the pathological pigmentation which accompanies adrenal insufficiency (Addison's disease). There is not secreted on perfusion a reducing substance more negative than ascorbic acid which would effect reduction of the primary oxidation product of the latter. However, there is present in the perfusate an agent which minimises the rate of autoxidation of ascorbic acid and thus tends to maintain the vitamin in the reduced form. Protection of ascorbic acid in this manner is brought about by many tissues; this has also been observed recently by other investigators [Quastel and Wheatley, 1934; De Caro and Giani, 1934; Mawson, 1934].

EXPERIMENTAL.

Perfusion of the adrenal gland.

A technique slightly modified from that previously described [Heard and Raper, 1933] and that employed by Schkawera and Kusnetzow [1923] was adopted in perfusion of this organ. The glands of an ox, together with a large piece of surrounding fatty tissue which encased 6 or 8 inches of both aorta and vena cava, were obtained from the abattoir immediately after slaughtering of the animal and conveyed to the laboratory in a Dewar flask. The inferior vena cava was opened longitudinally revealing location of the two glands, the left applied to the renal vein at its junction with the vena cava and the right directly applied to the latter immediately superior to the right renal vein. In some cases but one large vein drained each gland, whilst in others as many as five smaller vessels were found. The aorta was then sectioned in the same manner and the arterial vascularisation examined. Usually the three large lumens of the coeliac and superior mesenteric arteries and one renal artery were exposed, although occasionally there was found a common coeliac and superior mesenteric vessel which subdivided immediately on leaving the aorta. The vascularisation of the adrenal of the ox is described by Schkawera and Kusnetzow who state that two main vessels irrigate each gland; the posterior vessel arises from the aorta or renal artery whilst the anterior may branch directly from the aorta in the vicinity of the diaphragmatic artery or from any of the main aortic vessels in that region. In our experience vascularisation of the two glands is less markedly differentiated; usually two main vessels predominantly irrigating one gland could be located in the region described by Schkawera and Kusnetzow, but invariably a certain amount of cross-circulation to the second gland was encountered. In most cases adequate perfusion was obtained through an adrenal artery leading directly from the aorta; when this could not be effected, a cannula was placed in either the coeliac, superior mesenteric or renal artery, the peripheral end of which was ligatured. In order to collect perfused fluid, a section of vena cava was disengaged from surrounding tissue and tied about a large glass tube of sufficient diameter to enclose the lumens of all adrenal veins. The preparation was then placed on a heated pad maintained at 38° and oxygenated Ringer-Locke solution, warmed to this temperature, perfused at a pressure of 70–120 mm. of mercury by means of a Dale-Schuster pump. The vessel receiving the perfusate was contained in an ice-salt mixture and air was displaced by a steady stream of nitrogen.

Adrenaline and ascorbic acid contents of the perfusate.

In all experiments estimation of pressor activity was made by intravenous injection into a pithed cat; when acetylcholine was present in the fluid, the animal was previously desensitised with atropine.

Titration with 2:6-dichlorophenolindophenol using a technique slightly modified from that described by Birch *et al.* [1933] was adopted as a measure of reducing power. In order to accommodate the small amount of ascorbic acid present in the perfusate, the concentration of the dye employed was reduced to approximately 0·001 M, a procedure which increases the probable error of the determination to 5–10 %. The dye was standardised immediately before use against a commercial sample of vitamin C (B.D.H.), the reduced ascorbic acid content of which had previously been determined by titration with iodine. Indophenol titrations were carried out at p_H 2·5, which was attained either by adjustment with glacial acetic acid or by addition of an equal volume of phthalate-hydrochloric acid buffer ($M/5$) at this reaction.

The adrenaline contents of the perfusates from 15 preparations were found to vary from 10 to 0·5 mg./100 ml., which is in agreement with the values obtained by Schkawera and Kusnetzow (5–1 mg./100 ml.). This deviation may be attributed to the fact that the extent of perfusion is by no means the same in every case; on injecting methylene blue at completion of an experiment and sectioning the gland, it was seen that in some cases irrigation of as much as 70 % of the tissue was effected, in others only 20 %.

In three perfusions the effects of acetylcholine and eserine on adrenaline secretion were investigated. When added to the perfusing fluid in concentrations up to 1 in 10,000, the former gave rise to no enhanced pressor activity; however, eserine (1 in 500,000) resulted in a slight increase (40 %), and both eserine (1 in 500,000) and acetylcholine (1 in 1,000,000) significantly increased adrenaline output by 150 %. These observations are in agreement with those obtained by Feldberg *et al.* [1934] and support the hypothesis that acetylcholine is the humoral transmitter of splanchnic impulses to the adrenal medulla, so that the preganglionic sympathetic fibres are cholinergic.

In order to gain insight into the mechanism by which adrenaline present in the perfusate is stabilised and rendered resistant to oxidation, an Erlenmeyer flask of 200 ml. capacity containing perfused Ringer-Locke solution (50 ml.), was attached to the shaking arm of a water-bath maintained at 38° and constantly agitated to facilitate oxygenation. Samples were assayed and titrated at regular intervals until pressor activity had disappeared. Data from experiments performed in this manner with perfusates from several different preparations are embodied in Table I. In no case did diminution in pressor activity commence immediately; there was always found a period of some 3 to 21 hours during which time reducing power gradually diminished, whilst physiological activity remained constant (see Fig. 1). Also no development of red coloration took place until after this initial maintenance period had elapsed. This is in marked contrast to the behaviour of solutions of pure adrenaline treated in the same manner, when development of a red coloration and diminution in pressor activity commenced immediately. Adrenaline, when added to the perfusate in

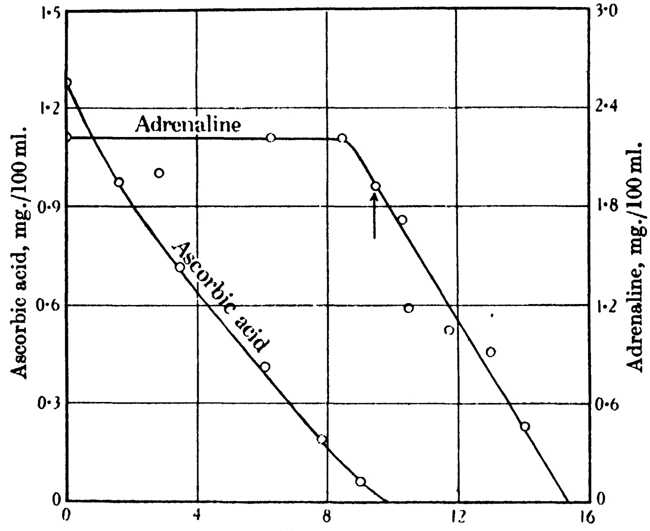


Fig. 1. Perfusate 9. Temperature 38°. Arrow indicates time when red coloration becomes apparent.

Table I.

Perfusion No.	Adrenaline content of perfusate mg./100 ml.	Maintenance period when pressor activity remains constant hours	Ascorbic acid content of perfusate mg./100 ml.	Time when indophenol titre reaches zero hours	Adrenaline content after addition of adrenaline to perfusate mg./100 ml.	Maintenance period when pressor activity remains constant hours
2	1·28	4·5	—	—	3·10	0
3	1·00	8·4	—	—	3·00	3·5
6	1·30	10·2	0·906	10·2	4·55	4·5
8	0·67	5·5	0·242	6·0	—	—
9	2·23	9·0	1·277	9·5	—	—
12	1·67	21·0	0·832	21·3	—	—
13	0·64	3·0	0·134	3·5	—	—

concentration sufficient to double or treble that originally present (see Table I) was stabilised in the same manner, although in these cases (perfusions 2, 3 and 6) the duration of the maintenance period was considerably lessened.

The above results indicate clearly that stabilisation is effected by means of an oxidation-reduction system rather than by chemical combination or amino-acids. Addition of adrenaline to the perfusate increases the concentration ratio of adrenaline to ascorbic acid so that the period during which the 3:4-quinone of the former is maintained in the reduced form (adrenaline) is considerably diminished. When the ascorbic acid is completely oxidised, irreversible oxidation of adrenaline, manifested by the appearance of a red coloration and diminution in pressor activity, commences. The rate of oxidation is now dependent upon the amino-acid content of the perfusate, and was found to vary from 0·05 to 1·06 mg. per hour. In the presence of large quantities of amino-acids, the course of adrenaline oxidation is somewhat altered; under these conditions the red coloration is replaced by a yellowish tinge.

Values ranging from 0·134 to 1·277 mg./100 ml. ascorbic acid were obtained with the various perfusates. Apparently no correlation exists between the relative amounts of ascorbic acid and adrenaline secreted on perfusion. The maximum observed ratio, in terms of molar equivalents of adrenaline to ascorbic acid, was 4·9, the minimum, 1·41; however, with 9 perfusates out of 16 examined, a value between 2 and 3 was found. In no case was the sulphydryl group detectable by the nitroprusside test either before or after reduction of the perfusate with tin and hydrochloric acid.

Respirometer experiments.

The Barcroft differential respirometer was employed in these experiments.

The stabilisation of adrenaline by an oxidation-reduction system. The coupled systems adrenaline-ascorbic acid and adrenaline-glutathione were investigated. At physiological hydrogen ion concentration and temperature, both adrenaline and ascorbic acid rapidly undergo autoxidation; in order to obtain total oxygen consumption, phosphate buffer solution at p_H 7·36 (2·25 ml. of $M/5$) was placed in the side-arm of the Barcroft vessel and, after equilibration in the water-bath at 38°, spilled into solutions of *l*-adrenaline hydrogen tartrate and ascorbic acid contained in the main body of the flask. The required amounts of solutions of ascorbic acid containing 0·88 mg. (1/200 millimol.) per 0·25 ml. and of adrenaline hydrogen tartrate containing 0·916 mg. (1/200 millimol.) of free adrenaline per 0·25 ml. were added to the main body of the reaction vessel to give the proportions indicated in Fig. 2; where necessary distilled water was added to a total volume of 3 ml. In all cases the compensator vessel contained 3 ml. of buffer solution only. In order to absorb carbon dioxide, a small pledget of cotton-wool was placed within the ground glass joint of the respirometer and moistened with potassium hydroxide solution (0·2 ml. of 12 %). In the same manner oxidation of adrenaline in the presence of the quantities of glutathione indicated in Fig. 3, was investigated. However, in these experiments it was necessary to modify the technique slightly in order to accommodate sufficient glutathione to give an optimum uptake of oxygen and yet preserve a favourable proportion of adrenaline. Only 1 ml. of $M/5$ buffer was used and maintenance of reaction at p_H 7·36 was ensured by addition to this buffer (contained in the side-arm of the flask) of potassium hydroxide solution (0·31 N) in quantity sufficient to neutralise the amount of adrenaline hydrogen tartrate employed. The amount of alkali required was determined previously by titration to p_H 7·4 (bromo-thymol blue). On spilling the contents of the side-arm into the flask after equilibration, the side-arm was washed out several times with the contents of the flask in order to ensure adequate mixing.

Curve *B*. Glutathione (1/40 millimol.)-adrenaline (1/40 millimol.).
Curve *C*. Glutathione (1/40 millimol.)-adrenaline (1/166 millimol.).

One-half atom of oxygen per molecule of glutathione = 140 μl. Arrow indicates time when red coloration becomes apparent.

The oxygen uptake curves obtained are those characteristic of a reversible oxidation-reduction system. With glutathione (Fig. 3) differentiation of the component curves expressing rate of oxidation of reductant and oxidant respectively is clearly defined; approximately one-half atom of oxygen per molecule of glutathione (theoretical 140 μl.) is absorbed before the lag phase is encountered and irreversible adrenaline oxidation commences with the appearance of a red coloration. However, with ascorbic acid (Fig. 2) demarcation is less evident, which may be attributed to the fact that the reversible primary oxidation product of ascorbic acid is capable of undergoing further oxidation rapidly [Herbert *et al.*, 1933], whereas oxidised glutathione is relatively stable under experimental conditions. The total oxygen uptake of ascorbic acid alone (curve *D*, Fig. 2) is approximately 3 atoms of oxygen per molecule of ascorbic acid (theoretical 168 μl.), whilst irreversible oxidation of adrenaline takes place before this quantity of oxygen is utilised. A control experiment in which a solution of ascorbic acid (0·033 %) in phosphate buffer at p_H 7·4 (15 ml. of $M/5$) was shaken in the same bath with the Barcroft apparatus showed that the reducing power, as determined by titration with 2:6-dichlorophenolindophenol, reached zero when approximately 2·4 atoms of oxygen per mol. of ascorbic acid had been absorbed, which is in fair agreement with the time at which irreversible oxidation of adrenaline begins.

Behaviour of the perfusate. When examined respirometrically, all perfusates gave oxygen uptake curves characteristic of an oxidation-reduction system. However, in this instance ample evidence was obtained which suggests that the system is complicated by uncontrollable factors and is not strictly comparable with a reaction mixture containing ascorbic acid and adrenaline only. Of 9 perfusates investigated in this manner, 6 showed immediate utilisation of oxygen whilst a lapse of several hours was encountered with the remainder before an appreciable quantity of oxygen was consumed. The curve shown in

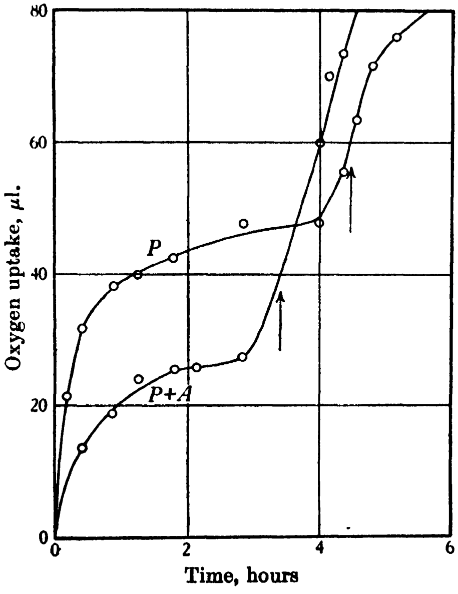

Fig. 4.

Curve *P*. Perfusate 6 (10·0 ml.): 1·30 mg./100 ml. adrenaline-0·91 mg./100 ml. ascorbic acid.
Curve *P*+*A*. Perfusate 6 (9·86 ml.) + adrenaline (0·143 ml. of 1 in 1000): 2·70 mg./100 ml. adrenaline-0·9 mg./100 ml. ascorbic acid.

Temperature 38°. Arrow indicates time when red coloration becomes apparent.

Fig. 4 illustrates the behaviour of a perfusate from the former group. The example cited is typical, and any deviation from this type of curve was manifested by lesser demarcation of the components expressing rates of oxidation of ascorbic acid and adrenaline, which in some cases was detectable only by development of a red coloration signifying irreversible oxidation of the latter; as demonstrated above, this may be explained by the relative proportions of ascorbic acid and adrenaline present. Again it is evident that addition of a further quantity of adrenaline to that originally contained in the perfusate (curve $P+A$) accelerates the rate of oxidation of ascorbic acid and diminishes the period during which adrenaline is maintained in the reduced form. It is also apparent that the rates of oxidation obtained respirometrically and by indophenol titration are not commensurate. For example, with perfusate 6 irreversible oxidation of adrenaline begins in the Barcroft vessel within 4·5 hours (Fig. 4), whilst approximately 10 hours elapse before diminution in physiological activity becomes noticeable (see Table I). At least two factors contribute to this irregularity; first, comparison of the rate of oxidation of a small volume of perfusate in the respirometer with that of a larger volume contained in an Erlenmeyer flask is not justifiable where conditions of surface area *etc.*, are radically altered, and second, removal of carbon dioxide from the atmosphere surrounding feebly buffered Ringer-Locke solution in the Barcroft vessel renders the reaction considerably more alkaline. Several unsuccessful attempts were made to establish conditions such that oxidation would proceed at the same rate in each case. The presence of phosphate buffer renders the end-point of the titration with the dye extremely indefinite, and in the respirometer, the difference between rates of oxidation with and without CO_2 absorption is not sufficiently great to account for the observed discrepancy.

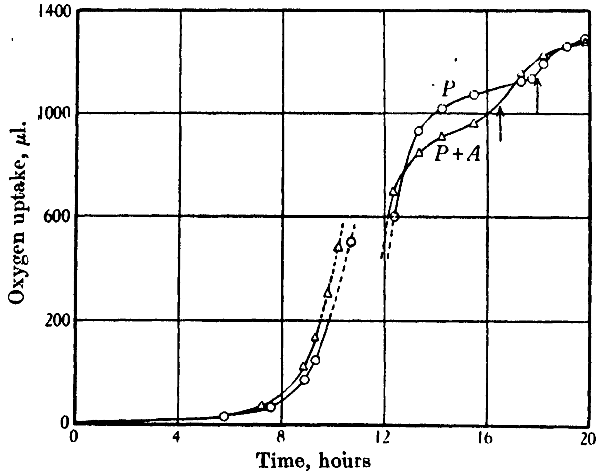

Fig. 5.

Curve P. Perfusate $2X$ (3·0 ml.): 8·06 mg./100 ml. adrenaline.
Curve $P+A$. Perfusate $2X$ (2·8 ml.) + adrenaline (0·2 ml. of 1 in 1000): 14·17 mg./100 ml. adrenaline.

Temperature 28°. Arrow indicates time when red coloration becomes apparent.

The oxygen uptake curve shown in Fig. 5 is representative of the second group of three perfusates which displayed a lag phase and illustrates the behaviour of one of the earlier perfusates obtained by cross-circulation to the second gland. In this instance perfusion for 4 hours yielded 6 ml. only; hence it was not possible to follow the rate of oxidation of ascorbic acid by indophenol titration or that of adrenaline physiologically, and thereafter a perfusate of such high potency was not encountered.

The lapse of several hours before an appreciable amount of oxygen is utilised indicates the presence of a substance or mechanism which delays oxidation of ascorbic acid. In this connection, the effects of other tissues on the inhibition of ascorbic acid oxidation have been examined respirometrically and the widespread occurrence of an inhibitor throughout the animal body noted. At p_H 7·36 and 38°, the Q_{O_2} of ascorbic acid (defined as μl. of oxygen consumed per mg. per hour) is approximately 100, whilst in the presence of a trichloroacetic acid (2·5 %) extract of liver (corresponding to 0·1 g. of wet tissue) this value is reduced to 4·5. Similarly the rate of diminution of reducing power, as determined by titration with 2:6-dichlorophenolindophenol and under the conditions defined above, is equivalent to 0·95 mg. per hour with ascorbic acid alone and 0·05 in the presence of the same quantity of liver extract.

With the various perfusates examined respirometrically, it has been found that the amount of oxygen consumed before irreversible oxidation of adrenaline begins is not proportional to the ascorbic acid content of those perfusates. This value (Figs. 4 and 5) is many times greater than the theoretical 2–3 atoms of oxygen per molecule of ascorbic acid obtained with a reaction mixture containing ascorbic acid and adrenaline only (Fig. 2). This aspect of the problem is being further investigated; preliminary experiments have shown that the primary oxidation product of ascorbic acid is capable of oxidising certain other substances such as pyruvate and amino-acids, so that the total oxygen uptake under these conditions is considerably enhanced.

SUMMARY.

1. An investigation of the chemical and physiological properties of the Ringer-Locke perfusate of the adrenal gland has confirmed secretion of a stable sympathomimetic substance.

2. The pressor activity of the perfusate may be attributed to its adrenaline content. Adrenaline, when added to perfused fluid, is likewise stabilised and rendered resistant to oxidation.

3. Stabilisation is effected by means of an oxidation-reduction system. Judging from reduction of 2:6-dichlorophenolindophenol, ascorbic acid is the agent responsible for the maintenance of the 3:4-quinone of adrenaline in the reduced state and the inhibition of pigment formation. As long as a small amount of ascorbic acid remains present in the reduced form, diminution in pressor activity does not take place; thereafter oxidation of adrenaline is somewhat delayed by the presence of amino-acids.

4. The oxygen uptake curve given by the perfusate is characteristic of an oxidation-reduction system and is similar to those obtained with the coupled systems ascorbic acid-adrenaline and glutathione-adrenaline which have been investigated respirometrically.

5. On perfusion, there is not secreted any reducing substance more negative than ascorbic acid; however, the perfusate does contain an agent which minimises the rate of autoxidation of ascorbic acid and thus tends to maintain the latter in the reduced state. Protection of ascorbic acid in this manner is effected by cell-free extracts of several tissues.

Our thanks are due to the Banting Research Foundation for defrayment of expenses in part and to Prof. V. E. Henderson for facilities provided and advice; one of us (R. D. H. H.) is indebted to the Foundation for a personal grant and to Prof. H. S. Raper for helpful suggestions.

CXXII. THE ACTION OF IODOETHYL ALCOHOL ON THIOL COMPOUNDS AND ON PROTEINS.

By DAVID ROCKWELL GODDARD[1]
and MAXWELL PHILIP SCHUBERT.

From the laboratories of The Rockefeller Institute for Medical Research, New York.

(*Received February 15th, 1935.*)

Mowat and Stewart [1934] have made a study of the inhibitory action of iodoethyl alcohol on the rate of disappearance of glucose from shed blood. Iodoethyl alcohol appears to be only about half as efficient as iodoacetic acid in inhibiting the glycolysis. The further observation is made that although iodoacetic acid reacts with glutathione, iodoethyl alcohol appears not to do so at all. The conclusion is drawn that although iodoacetic acid may inhibit glycolysis by interaction with thiol groups of the enzyme, the mechanism of inhibition by iodoethyl alcohol must be different.

It is the purpose of the present work to show that iodoethyl alcohol does react with thiol groups in the same way as iodoacetic acid [Dickens, 1933; Michaelis and Schubert, 1934]. In the first place the compound

$HO.CH_2.CH_2.S.CH_2.CHNH_2.COOH$, *S*-($\beta$-hydroxyethyl)cysteine,

has been isolated in crystalline form and identified by analysis and properties. It was prepared by the action at room temperature of iodoethyl alcohol on cysteine in aqueous solution at a p_H in the bicarbonate-carbonic acid range.

To show that iodoethyl alcohol also reacts with glutathione it was thought sufficient not to isolate the compound as in the case of cysteine but merely to measure the decrease with time in iodine titre of a solution containing glutathione

Table I.

Each experiment is made with 50 ml. of *M* phosphate buffer with enough added KOH solution to neutralise added cysteine hydrochloride, glutathione or iodoacetic acid. Either 0·4 g. cysteine hydrochloride or 0·7 g. glutathione is dissolved in this buffer and if an iodo-compound is to be added, 0·5 g. of either iodoacetic acid or iodoethyl alcohol. At the time intervals mentioned 10 ml. samples are withdrawn and dropped into 5 ml. of 25 % acetic acid. The samples are titrated with 0·0406 *M* alcoholic iodine, the number of ml. of this solution being recorded in the table. After the last sample has been withdrawn the p_H is measured with a glass electrode.

ml. iodine solution used.

[1] National Research Fellow in the Biological Sciences.

and iodoethyl alcohol at p_H 7·5. This rate of decrease is of about the same order as with cysteine in which case the compound itself had been isolated. The data are given in Table I. It is at once evident that although iodoethyl alcohol reacts with the thiol group of cysteine and glutathione it does so at a rate very much slower than iodoacetic acid. Some similar experiments were made with iodoacetamide and showed that this substance reacts as quickly with either cysteine or glutathione as does iodoacetic acid, but since the figures have no value except to show roughly the speed of the reaction they are not included here.

15 g. $NaHCO_3$ are placed in an Erlenmeyer flask through which a steady stream of nitrogen is passed. Through a dropping funnel is added a solution of 6·4 g. cysteine hydrochloride in 15 ml. water, and then 7·2 ml. iodoethyl alcohol are washed in with 15 ml. more water. The mixture is allowed to stand 12 hours. The solution is then acidified with HCl and neutralised to Congo red paper with NaOH. It is now evaporated to dryness *in vacuo* and the residue extracted with 75 to 100 ml. of 85 % alcohol. The mixture is filtered and to the filtrate about 500 ml. acetone are added. A white crystalline precipitate forms. This may be recrystallised several times more by precipitation from 60 to 80 % alcohol with acetone. The product is dried *in vacuo*. Found C, 36·61; H, 6·32; N, 8·27; S, 19·13 %. $C_5H_{11}O_3NS$ requires: C, 36·36; H, 6·72; N, 8·49; S, 19·39 %.

That the iodoethyl alcohol has reacted with the SH group and not the NH_2 group of the cysteine is evident from the negative nitroprusside test.

Behaviour with proteins. Mirsky and Anson [1935] have shown that iodoacetic acid reacts completely with the thiol groups of certain proteins. The data listed in Table II show that iodoethyl alcohol and iodoacetamide react similarly with a thiol-protein, but that the iodoethyl alcohol does not react as rapidly as does iodoacetic acid or iodoacetamide.

The protein used for the experiments is a protein prepared from wool by reduction with alkaline thiolacetate [Goddard and Michaelis, 1934]. This protein contains about 12 % cystine, and may easily be reduced. 1·75 g. of dry protein and 50 ml. of molar phosphate buffer (p_H 7·4), containing 1 milliequivalent of neutralised thiolacetic acid, are added to each of 4 flasks through which a steady stream of N_2 is passed. Two hours are allowed for reduction of the proteins. (The proteins are not completely dissolved, but solid proteins are reduced by thiolacetate, and react with iodo-compounds.) To three of the flasks 50 ml. of *M* phosphate buffer (p_H 7·4) containing 2 milliequivalents of either iodoethyl alcohol, iodoacetamide or neutralised iodoacetic acid, are added. The fourth flask serves as a control. After 2 hours the p_H is determined with a glass electrode, and the proteins are then brought to the turning point of methyl red with acetic acid. The proteins are then dialysed for 3 days against running water. Samples of these proteins are prepared for analysis by precipitation with trichloroacetic acid, washed with acetone and acid acetone and dried in a vacuum desiccator [see Mirsky and Anson, 1935]. The cystine analyses are made by the method of Folin and Marenzi [1929], after oxidising the acid hydrolysate with 3 % H_2O_2. Moisture content is determined by drying to constant weight at 105°. A similar experiment was carried out at higher p_H using sodium veronal as buffer.

The reduction of the proteins by thiolacetic acid is not complete, as is shown by the analyses for residual cystine given in Table II. When the reduction is carried out at a higher p_H the reduction is more complete as is shown by the lower residual cystine values. The reaction of the iodo-compounds with the thiol groups was complete in all preparations except that with iodoethyl alcohol at p_H 7·4, this preparation alone gave a positive nitroprusside test on the protein dialysed free from thiolacetic acid.

Table II.

Figs. % based on dry weight of the proteins.
Proteins dried at 105° to constant weight.

Protein	Cystine	Sulphur	Nitrogen
A. Wool protein (control)	12·1, 12·3	3·21	15·9
B. Prepared from A by iodoacetate at			
p_H 7·4–6·99	2·06	3·31	15·7
p_H 9·5–8·6	1·42	—	—
C. Prepared from A by iodoacetamide at			
p_H 7·4–7·33	2·25	3·25	14·8
p_H 9·5–8·8	1·7	—	—
D. Prepared from A by iodoethyl alcohol at			
p_H 7·4–7·1	6·25	3·29	14·5
p_H 9·5–9·0	1·27	—	—

DISCUSSION.

It thus appears that iodoethyl alcohol reacts with the thiol groups of cysteine and glutathione or of proteins derived from wool just as does iodoacetic acid, only the reaction is much slower. With the wool proteins this slowness is less apparent, since even at p_H about 7, half of the SH of the protein has reacted in 2 hours. With cysteine or glutathione on the other hand in 2 hours less than 25 % of the SH group has reacted. Mowat and Stewart, in testing the action of iodoethyl alcohol on glutathione, allowed only 1 hour, while in testing the action on glycolysis the reaction covered 5 to 7 hours. This coupled with the fact mentioned above that iodoethyl alcohol, in the case studied, reacts faster with protein SH than with glutathione may easily account for the apparent findings of Mowat and Stewart. Therefore we do not believe that the existing evidence requires that a new assumption be made that the mechanism of inhibition by iodoethyl alcohol is different from that by iodoacetic acid.

SUMMARY.

It has been shown that iodoethyl alcohol reacts with SH groups of cysteine, glutathione and proteins derived from wool. There is no need to assume different mechanisms of inhibition of glycolysis by iodoacetic acid and by iodoethyl alcohol.

CXXIII. A NEW METHOD FOR THE DETERMINATION OF FRUCTOSE IN BLOOD.

By LESLIE DOUGLAS SCOTT.

From the Department of Biochemistry, Charing Cross Hospital, Institute of Pathology.

(*Received March 6th, 1935.*)

A considerable experience in the routine practice of the fructose tolerance test has amply demonstrated the inadequacy and unsatisfactory nature of the test in determining liver insufficiency when the response is measured by the changes in the level of the total reducing sugar of the blood, resulting from the ingestion of fructose. The defects of the test in its present form will be fully discussed in a subsequent paper from this laboratory and need not be elaborated here except to say that they led to the recognition that it was eminently desirable to attempt to determine the actual fructose in the blood following the ingestion of this sugar in place of the ordinary values for the total reducing sugar content. The methods most generally adopted for the purpose of estimating the true fructose content of the blood are those based on the Van Creveld principle using the colour developed in the reaction with dimethylamine [Radt, 1928], whilst an entirely different principle, biological in character, has recently been used by Harding *et al.* [1933].

An alternative colorimetric method emerged from a previous study of the interaction of bile salts and fructose. It was first suggested by Dr J. Patterson that an attempt should be made to adapt the bile salt reaction described by Scott [1934] in order to apply it for the determination of fructose in blood, that is, instead of an excess of fructose being utilised for the estimation of minute amounts of bile salts, the latter might, it was thought, be employed in a similar manner to react with minute quantities of fructose. On trial it was found that a similar reddish purple colour still resulted as in the original reaction, so that it was subjected to a detailed study and has been made the basis of the method for fructose determination which is outlined below.

Reagents and apparatus:

(1) 10 % zinc sulphate solution.

(2) 0·5N sodium hydroxide.

(3) 1 % (by volume) acetic acid.

(4) 1 % stock fructose (Merck or B.D.H. glucose-free) in a saturated solution of benzoic acid.

(5) Absolute alcohol.

(6) 2·25 % alcoholic sodium tauroglycocholate (B.D.H.).

(7) Concentrated hydrochloric acid (B.D.H. "Analar").

(8) Filter-papers: No. 41, 9 cm., and No. 50, 7 cm. (Whatman).

(9) Monax boiling-tubes, 25 × 150 mm.

METHOD.

Into a boiling-tube (25 × 150 mm.), graduated at 40 ml., place 5 ml. of whole blood. Then add about 30 ml. of water, followed by 5 ml. of 10 % $ZnSO_4$ and 5 ml. of 0·5N NaOH. Mix well after the addition of each. Dilute both to the 40 ml. mark and again mix thoroughly. Place in the water-bath at 80–85° for

5 minutes, noting that the water in the bath completely covers the volume of the blood mixture in the tube. At the end of 5 minutes cool very thoroughly in running water and mix well. Filter through a No. 41, 9 cm. paper, stirring gently the remaining gelatinous precipitate on the filter-paper to free the last few ml. of filtrate. Transfer 20 ml. of clear filtrate to one of the monax boiling-tubes, add 3 drops (0·15 ml.) of 1 % acetic acid and a few silica chips to prevent bumping in the subsequent evaporation and carefully boil down to about 1·5 ml. When the fluid decreases in volume avoid excessive heat so as not to char the solution. Prepare the standard by adding to a similar monax tube 2·5 ml. 0·01 % fructose solution (by dilution of the 1 % stock fructose). Carefully boil off the excess water until the volume is about 1·5 ml. To the standard and unknown add 3 ml. 2·25 % alcoholic sodium tauroglycocholate. After the addition of an extra 7–10 ml. absolute alcohol and a few more silica chips to each tube, evaporate to complete dryness on the boiling water-bath. If bumping should occur in the blood filtrate tube owing to the precipitate which forms on the addition of the alcoholic bile salts, gently rotate the tube until all the alcohol has been evaporated. After the last drops of alcohol have disappeared allow the tubes to remain in the water-bath an extra minute or two to ensure the complete removal of the last traces of alcohol, which should be accomplished without causing the precipitate to adhere too firmly to the bottom and sides of the boiling-tube. When cool add 10 ml. concentrated HCl to both tubes, and after mixing well, securely stopper the tubes. Place in the water-bath or a beaker of water at 40° for half an hour with occasional agitation to ensure an even emulsion and production of colour. A reddish purple colour, proportional to the amount of fructose present, slowly develops, reaching a maximum intensity in 30 minutes. Remove the tubes from the bath and cool very thoroughly in running water. Filter the coloured solutions through No. 50, 7 cm. papers, refiltering the first 2 or 3 ml. as these are usually slightly cloudy. Compare in the colorimeter in the usual way. Calculation:

$$\frac{\text{Standard}}{\text{Unknown}} \times \text{Strength of standard (0·25 mg.)} \times \frac{100}{2·5} = \text{mg. fructose per 100 ml. blood.}$$

Table I. *Showing the quantitative recovery of various quantities of fructose added to normal whole blood.*

Standard employed	Amount of fructose added per 100 ml. normal blood	Amount of fructose recovered mg. per 100 ml.
1 ml. (1 mg.) of 1 in 10 dilution of 1 % fructose	50	50
	25	27
2·5 ml. (0·25 mg.) of 1 in 100 dilution of 1 % fructose	15	15
	10	10
	5	6
Using as standard 20 ml. (equiv. 2·5 ml. blood) of normal blood-filtrate to which had been added the requisite amount of fructose (see above)	50	48
	25	24
	15	14
	10	10
	5	5

When for various reasons it is impossible to obtain venous samples, the test can be carried out on 2 ml. whole blood obtained by finger puncture with only slight modification of the original technique. The essential difference can be summarised as follows:

Into a test-tube, graduated at 20 ml., place 10 ml. water, 2 ml. blood and corresponding amounts of precipitating reagents. After diluting to 20 ml. with water place in the water-bath at 80° for 5 minutes. Cool and filter through a No. 41, 9 cm. paper. Measure 10 ml. filtrate into a monax tube, add 2 drops of 1 % acetic acid and boil down to about 1 ml. After the addition of 1 ml. alcoholic bile salts *plus* 7–10 ml. alcohol, evaporate to dryness on the boiling water-bath. The standard is prepared by taking 1 ml. of a 1 in 100 dilution of 1 % fructose *plus* 1 ml. bile salt solution and 7–10 ml. alcohol. Take to dryness on water-bath. 5 ml. concentrated HCl are added to each tube, after which the tubes are heated at 40° for 30 minutes. Cool and filter through No. 50, 7 cm. papers. Compare the colours in a micro-colorimeter or by small graduated test-tubes suitable for dilution colorimetry. Calculation:

$$\frac{S}{U} \times 10 = \text{mg. fructose/100 ml. blood.}$$

Quantitative figures again show a complete recovery of added fructose.

Comparison of the capillary blood with venous samples shows that the actual fructose content is a shade higher in the former than in the latter, the difference being about 2 mg. per 100 ml. (Table II). The fructose curve thus shows the same tendency, though not nearly so marked, as does the total reducing sugar curve, in rising to a slightly higher level in the capillary than in the venous blood. Different standards of normality must therefore be accepted for the different types of blood used. In the single normal case studied in detail where the fructose contents of venous and capillary blood show close correspondence, the blood sugar levels in the two display much greater divergence.

Table II. *Showing the difference between the venous and capillary fructose in a normal subject; also a case of liver disease complicated by diabetes after the ingestion of 50 g. pure fructose.*

	Venous		Capillary	
Case	Actual estimated fructose mg./100 ml.	Total reduction (MacLean's method) mg./100 ml.	Actual estimated fructose mg./100 ml.	Total reduction (MacLean's method) mg./100 ml.
Normal subject:				
Before fructose	0	102	0	105
1 hour after	8	102	9	121
2 hours after	5	97	3	92
Subacute yellow atrophy and diabetes:				
Before fructose	0	184	—	—
1 hour after	16	232	—	—
2 hours after	13	221	—	—
After 2 months when the jaundice had entirely disappeared:				
Before fructose	0	176	—	—
1 hour after	12	240	—	—
2 hours after	7	217	—	—

Note. For the sake of convenience it might be mentioned that the average normal response in terms of actual fructose is 10 mg. and 5 mg. per 100 ml. blood in the 1 and 2-hour samples after fructose respectively.

A case of liver disease complicated by diabetes has been included in Table II for the purpose of illustrating the influence of diabetes on the actual fructose curve. The disturbance from the normal due to diabetes appears to be of the order of 2 mg. per 100 ml. in the 1 and 2-hour samples of venous blood after the administration of 50 g. pure fructose.

Table III shows a comparison of the fructose content of the blood following the ingestion of 50 g. Merck's pure fructose in normal subjects with that of

Table III.

patients suffering from certain forms of liver disease. The alteration in the total reducing sugar as estimated by MacLean's method is also included for purposes of comparison.

A full survey of the results obtained by this method and their relation to the carbohydrate metabolism and liver function will, it is hoped, be ready for publication shortly.

If the amounts of fructose shown here as appearing in normal blood after the ingestion of 50 g. fructose be compared with the corresponding values found by the biological method of Harding *et al.*, they are seen to be of about the same order (actual figures are not given there but have to be arrived at by inspection of the recorded chart). On the whole the biological values are a little smaller and show the disappearance of fructose from the blood at an earlier stage than does the colorimetric method. On the other hand almost exact agreement has been obtained between the present method and a modification of the original Radt diphenylamine method [Patterson, unpublished results].

SUMMARY.

1. A new method is described for the estimation of fructose in blood based on the reaction between bile salts and fructose. The delicacy of the reaction is such that fructose contents of the order of 5–20 mg. per 100 ml. can be estimated with an error of approximately ± 1 mg. Using the method comparisons have been made between venous and capillary blood and also between normal and diabetic blood following the ingestion of fructose.

2. Preliminary results also show that a more satisfactory fructose tolerance test for liver function can be made on the basis of specific fructose estimations, than by taking account of the total blood sugar values.

I wish to thank Dr J. Patterson for his encouragement and advice throughout the course of this work, and also Dr R. A. Hickling, Physician to Charing Cross Hospital for his kindness in allowing access to his wards for the liver cases.

CXXIV. THE EFFECT OF γ-RAY IRRADIATION UPON THE GROWTH AND NITROGENOUS METABOLISM OF THE PROTOZOON, *BODO CAUDATUS*.

By NORMAN RISBOROUGH LAWRIE[1]
AND MURIEL ROBERTSON.

From the Bonnett Memorial Laboratory, Addenbrooke's Hospital, Cambridge, and the Lister Institute, London.

(*Received March 30th, 1935.*)

DATA concerning the retardation of the multiplication of growing cultures of *Bodo caudatus* when exposed to γ-radiation were recorded in a previous communication by one of us [Robertson, 1932]. The biological reactions to this radiation, the nature of this inhibiting effect and a consideration of the sensitive period in the life of the cell and of its behaviour upon removal from the radium, form the subject of a detailed study which will be recorded elsewhere [Robertson, 1935]. The reader is referred to this paper for particulars of the technique used for the culture, counting and measurement of the organism.

The purpose of the present communication is to record certain effects of γ-radiation upon the nitrogenous metabolism of *Bodo caudatus* and to correlate these effects with the morphological changes which were simultaneously produced. It has been shown in a previous communication [Lawrie, 1935] that the chief end-product of nitrogenous metabolism of a culture of *Bodo caudatus* fed upon a suspension of bacteria in an inorganic medium is ammonia. The method of estimation of ammonia by deproteinisation and nesslerisation there described has been used in the present work. The rate of production of ammonia has been taken as an index of the rate of nitrogen metabolism in the cultures.

There is little previous work which bears directly upon our experiments, because previous studies of the biological and biochemical effects of irradiation have usually been concerned with the effects following the irradiation rather than with those contemporaneous with the irradiation.

Crabtree [1932] irradiated Jensen Rat Sarcoma from radium so screened that the tissues received mainly, but not quite exclusively, γ-rays. She found that exposures of at least ten hours were required to produce a regular response. With periods of irradiation of ten hours, respiration, but not aerobic glycolysis, was depressed. When eighteen hours' exposure was employed both respiration and aerobic glycolysis were depressed. A similar result was obtained with normal animal tissues. Krontowski [1933], using a similar source of radiation, found that an exposure sufficient to produce delayed death of his tissue cultures was insufficient to impair glycolysis. Krontowski was, however, studying effects subsequent to irradiation. Holmes [1933] studied the effect of γ-radiation upon the metabolism of embryonic kidney tissue. An exposure of 14 hours was allowed and the culture fluid analysed after two days' development of the culture. Thus the effects here measured were effects subsequent to irradiation combined with the effects contemporaneous with the irradiation. This treatment resulted in a 50–60 % inhibition of carbohydrate breakdown but had no effect upon protein breakdown. With smaller doses results suggestive of stimulation of carbohydrate breakdown were obtained.

---

[1] Beit Memorial Research Fellow.

EXPERIMENTAL.

Every irradiated culture was studied simultaneously with normal control cultures taken from the same freshly inoculated material as the irradiated culture and differing from it only in as much as they were at no time exposed to γ-radiation. Thus a typical experiment carried out to observe the effect of irradiation from the 8th to the 11th hour would involve the following observations. After eight hours' growth one Petri dish would be taken for counting and estimation of ammonia content. A second Petri dish would be placed on radium at this time. At eleven hours this culture on radium and also a second normal control culture would be taken for counting and analysis. Thus the gain in numbers and ammonia content could be found for (*a*) a normal culture developing from the 8th to the 11th hour and (*b*) for an exactly similar culture undergoing irradiation during this period. The assumption, which other experiments have proved to be justified, is made, that the culture set to develop on radium is, at the 8th hour, very nearly identical with the other normal cultures.

The γ-radiation was applied from the following source. The radium element was enclosed in a soldered silver plaque. It amounted to 400 mg. divided over an area of 38·5 cm.^{2} and was contained in cells of 0·1 mm. thickness of platinum further screened with 1·0 mm. of silver. The plaque may be considered as representing a concentration of 10·38 mg. per cm.^{2}, and the distance of the bodos from the radium was 0·5 to 0·75 cm.

DISCUSSION OF RESULTS.

Our results are summarised in Table I.

The unit of area employed in measuring the cells is 0·25 micron^2.

In the first column of the table the periods during which irradiations were carried out and the age of the culture when these irradiations were applied are tabulated. The irradiated bodos were invariably larger than the bodos in the corresponding normal control cultures. In the third column, the effects of the irradiations upon the total number of cells in the cultures are given. In each case the figures express the number of bodos in the irradiated culture per 100 bodos in the normal culture. In the fourth column, the figures for the increase in the number of bodos in the normal and irradiated cultures during the period of irradiation are presented in the same way. The morphological changes produced by the irradiation are summarised in the fifth column. A classification of the periods of irradiation on a rather broader basis than that used in the first column is given in the sixth column, and the influence of these irradiations upon the rate of ammonia production is tabulated in the seventh column. The method by which these figures, termed here the "ammonia ratio," were obtained is as follows. The ammonia produced during any given period was measured in both irradiated and control cultures. This quantity of ammonia was divided by the number of bodos present in the culture at the end of the period. This ratio represents the nitrogenous metabolism, calculated on a "per bodo" basis, associated with the development of the culture from an initial state, common to both irradiated culture and control, to the final state found in the culture at the end of the period of observation. Finally, this ratio, calculated for the irradiated

culture, is expressed as a percentage increase above, or decrease below, the same ratio calculated for the normal control culture. It is these percentages which appear in column VII.

It is seen that γ-irradiation can produce very different effects upon the nitrogenous metabolism according to the duration of the exposure and its morphological effects. Thus, progressively increasing periods of irradiation give first an inhibition in the rate of ammonia production per bodo, then a marked increase and finally a less marked increase. The inhibition of ammonia production coincides with the least marked effects upon the size and rate of division of the cells. The greatest stimulation of ammonia production, on the other hand, coincides roughly with the most marked effects upon the size and rate of division of the cells. Finally, an effect upon the ammonia production of an intermediate degree—*i.e.* a moderate stimulation—coincides with a well-marked effect upon the size of the cells, appearing in the absence of any marked effect upon their rate of division. This last morphological effect was well illustrated in the graph showing the growth rates of normal and irradiated cultures published in 1932 [Robertson, 1932]. The resumption of the normal rate of division and fall in the "ammonia ratio" coincided with the development of the second generation of cells produced in the presence of the radium. It would seem that the capacity for the resumption of growth at this normal rate in irradiated cultures is connected with, or conditioned by, the physiological and morphological changes taking place during the period of the greatest stimulation of ammonia production, which is also the period of the evolution of the first generation of cells exposed to the γ-rays.

It is important to note that the same type of effect is produced upon the total ammonia production of the cultures by the different durations of irradiation described above as is produced upon the ammonia production per bodo. Thus the increased value of the "ammonia ratio" in the longer irradiations is not merely an expression of the fact that there are fewer and larger bodos in the irradiated cultures.

We have no means of deciding from our data as to whether the effects upon ammonia production are secondary to the morphological effects, or *vice versa*, or whether all these effects are directly produced by the γ-radiation.

The qualitative contrast between the effects of very small and of large doses of γ-radiation is, of course, in accordance with the biological effects of many toxic agents.

SUMMARY.

Cultures of the protozoon *Bodo caudatus* have been exposed to γ-radiation. The effects of varying the duration of this exposure upon the cell size, rate of multiplication and the rate of ammonia production in the culture are described.

We are indebted to the Radium Committee of the Medical Research Council for kindly supplying the radium used in this research.

CXXV. NOTE ON THE SPONTANEOUS DECOMPOSITION OF LECITHIN.

By CHRISTOPHER WILLIAMS PRICE.
47, Blackmores Grove, Teddington, Middlesex.

(*Received March 21st, 1935.*)

The most recent work on the decomposition of lecithin is due to Fischgold and Chain [1934], who have obtained evidence that lecithin, even in the absence of air, undergoes a spontaneous change. This change was found to be due to separation of free fatty acid from the lecithin molecule.

C. W. Price and Lewis [1933, 1] noted a change in the electrophoretic properties of lecithin as it became aged even though the material was kept in the dark and in an atmosphere of dry nitrogen. In the p_H region in which the lecithin dispersion was negatively charged, it was found that there was a rapid increase in electrophoretic mobility with the age of the lecithin used for the dispersion. After a period of about 3 weeks the lecithin reached some state of equilibrium, its electrophoretic properties remaining constant (at a given p_H) for at least 5 months.

Fig. 1 shows the effect of age on the mobility of lecithin at p_H 5·02 and Fig. 2 compares the mobility-p_H curve of lecithin in its stable condition (*A*), with that of lecithin aged for 8 days only (*B*). Owing to the continuous change in the behaviour of the substance, the latter curve is approximate only. However, the points were plotted in such an order that, as nearly as possible, the curve is representative of lecithin aged for the above period.

The lecithin was prepared from egg-yolk by the method of Levene and Rolf [1927] and the measurements were carried out by the macro-electrophoretic method described by C. W. Price and Lewis [1933, 1].

From the curves it is evident that there is a very large change in the electrophoretic properties of lecithin with age, including a shift in the isoelectric point towards the acid region.

The isoelectric point of lecithin in the "aged" or equilibrium condition has been found by C. W. Price and Lewis to be at p_H 2·7. This corresponds fairly closely to the values obtained by other methods employed by workers in this field. Thus Fugii [1924] observed the isoelectric point of lecithin to be at p_H 2·7, H. I. Price and Lewis [1929] at p_H 2·6 and Remezov [1930] at p_H 2·0–2·8. It might be concluded therefore, that the material used by these authors was similar to the "aged" material used by us. Recently Chain and Kemp [1934] have reported the isoelectric point of freshly prepared lecithin as p_H 6·7; a value more nearly approximating to that calculated, namely p_H 7·5[1].

---

[1] This value was estimated from the values of the dissociation constants of choline and of glycerophosphoric acid (and similar phosphoric acid derivatives) and is a correction of the value (p_H 5·06) estimated in the same way by C. W. Price and Lewis but based on an erroneous value of K_b for choline. This correction is acknowledged; the error being consequent upon the assumption that the reproducibility of K_b, calculated from the p_H of an extreme range of concentrations of choline chloride, was sufficient evidence to show the absence of traces of free acid or free base. This error was likewise observed by Jukes [1934].

Fig. 2.

As previously stated, Fischgold and Chain have shown that the spontaneous change undergone by lecithin in the absence of air, is due to the separation of free fatty acid. From a knowledge of this Chain and Kemp [1934] consider, and in the writer's view quite properly, that the low value of the isoelectric p_H obtained by earlier workers is due to the presence of this material. The reason for this peculiar effect of free fatty acid in a buffered solution is, however, not considered. Clearly, the presence of free fatty acid as such, can influence the electrophoresis of the dispersion only if it is adsorbed at the surfaces of the lecithin micelle. Consequently this becomes, simply, a special case of ion adsorption, *viz.* the adsorption of fatty acid anions (or molecules subsequently ionising). This is in accordance with the view expressed by C. W. Price and Lewis [1933, 1, 2] that the charge on "aged" lecithin is a composite factor, involving an adsorption charge in addition to the ionisation charge. The source of the adsorption charge is the free fatty acid anions rather than simple OH^- ions as tentatively suggested. The reality of an adsorption charge was demonstrated by C. W. Price and Lewis [1933, 2] from determinations of the isoelectric point of the lecithin in dispersions of increasing ionic strength. It was shown that a very large shift in the isoelectric p_H from p_H 2·7 to 5·1 was consequent upon the addition of small concentrations (*e.g.* 0·03 *M*) of $BaCl_2$. Further increase in the ionic strength of the solution merely resulted in the mobility-p_H curve revolving around this point, as would be expected if, at p_H 5·1, the adsorption charge was completely nullified. The fact that the isoelectric point did not shift above p_H 5·1 to a value nearer to that calculated would seem to indicate the presence of some very small quantity (about 10^{-2} mol. %[1]) of further ionising groups in the molecule formed by the inevitable slight oxidation of the lecithin. This is probably also the explanation of the discrepancy between the calculated isoelectric point and that observed by Chain and Kemp (p_H 6·7) for freshly extracted lecithin, rather than the presence of a very small quantity of free fatty acid suggested, since no shift was observed in the isoelectric point on varying the ionic strength of the dispersion. This criterion was used by Chain and Kemp to show the absence of an adsorption charge on the fresh material.

The susceptibility of lecithin for acquiring an adsorption charge can be seen from the fact that at fairly high concentrations of $BaCl_2$ (*e.g.* 0·15 *M*) it becomes charged positively at all p_H values[2].

It should be stressed that in the experiments of the writers only "aged" lecithin was used. It is quite probable that lecithin *in situ* resembles this equilibrium material more closely than that freshly extracted. Thus Fischgold and Chain [1934] point out that by precipitation of the lecithin with cadmium chloride (a process used in its purification) it is possible to remove the free fatty acid.

Since the physiological function of certain phosphatides is usually associated, at least in part, with their great dispersing properties, the fact that freshly extracted lecithin emulsifies only with difficulty (a phenomenon also observed by Fischgold and Chain) gives some support to the above view.

Again, the opacity of a lecithin dispersion decreases very markedly with the age of the lecithin used, until the equilibrium position is reached. This would be expected if the material becomes more hydrophilic on ageing, the refractive index of the material approaching more closely to that of water. The increase in hydrophilic nature might well be associated with the increased charge (of a negative sign) due to the presence of fatty acid adsorbed on the lecithin micelle. The process of purification would seem, therefore, to decrease, at least temporarily, the dispersing qualities of the lecithin by removing the free fatty acid and also as a consequence of this, to render it less hydrophilic.

---

[1] The ionisation is assumed to be from carboxyl groups formed by oxidation of unsaturated glycerides with a p_K value of 5.

[2] This phenomenon was observed for the fresh material by Chain and Kemp [1934] and for the "aged" material by C. W. Price and Lewis [1933, 2].

SUMMARY.

The spontaneous change taking place in lecithin, in the absence of air, has been shown to be associated with a change in its electrophoretic properties (resulting in an increased charge of negative sign) and a decrease in the isoelectric p_H.

It is considered that lecithin aged to constant electrophoretic mobility in the absence of air, more closely resembles the state of the material *in situ* than does the freshly extracted substance, since free fatty acid present is removed in the process of purification.

CXXVI. A NOTE ON THE NITROGEN OF THE POLYSACCHARIDE COMPLEX FROM *CHONDRUS CRISPUS*.

BY MARGARET RUTH BUTLER.

From the Department of Biology, Dalhousie University, Halifax, Nova Scotia.

(*Received March 16th, 1935.*)

DURING the investigation of some biochemical properties of the polysaccharide extract of the alga, *Chondrus crispus*, varying quantities of nitrogen were found in different samples. The amount of nitrogen present in the extracts as prepared by a standard method [Butler, 1934] was found to differ from one collection of plants to another. In all samples prepared from the same collection of plants, however, it was constant. This indicated that the variations of nitrogen in the extracts depended on variations in the samples from which they were prepared. The total nitrogen was, therefore, determined in a number of collections and in the standard extracts from these same collections. The results (Table I) show that the differences occurring from one collection of plants to another are great; also that in general the nitrogen content of the extract varies as that of the collection from which it is made.

Table I. *Percentage of nitrogen in plants and extracts.*

Sample	% nitrogen in plants (dry weight)	% nitrogen in extract (dry weight)
S	0·74	0·26
N	1·75	0·39
H*	4·05	2·75
C	0·99	0·24
B	0·93	0·29

* It is interesting that Sample H, which shows the greatest deviation from the average nitrogen content, is the only one collected during the winter. Though this is but an incidental observation, it has suggested further investigations, now being carried on regarding seasonal variations.

In an attempt to purify the polysaccharide extract by reprecipitation, the effect on its nitrogen content was noted. As shown in Table II, the change effected was negligible.

Table II. *Percentage of nitrogen in re-precipitated extracts.*

Sample	% nitrogen in extract (dry weight)	% nitrogen in re-precipitated extract (dry weight)
T	0·85	0·86
P	1·21	1·10
D	1·43	1·18
S	0·26	0·30
F	3·55	2·25
M	0·81	0·62
B	0·28	0·29
C	0·24	0·24
C*	0·27	0·27

* 3 times precipitated.

In order to obtain some idea of how the nitrogen is distributed in the plant, it has been determined, as % of dry weight, in various extracts and residues (Table III).

Table III. *Percentage of nitrogen in fractions of* Chondrus.

Sample	% nitrogen in dry weight
Whole plant	0·93
Aqueous extract (not precipitated)	0·64
Residue from aqueous extract	2·06
Crude precipitate	0·28
Alcohol-soluble fraction of aqueous extract	1·13
Purified precipitate (Standard Extract)	0·29
Residue of plants freed from all water-soluble constituents	3·85
Alcoholic extract	0·71
Residue from alcoholic extract	0·82

The highest percentage of nitrogen per dry weight is found in the residue from plants washed under running water for a week or ten days. This is doubtless due to the great decrease in carbohydrate which makes this fraction itself small. Thus, while the percentage of nitrogen per dry weight is high, expressed as % of total nitrogen it would be very small. Because of the colloidal and highly viscous nature of the extract, the difficulties involved in manipulation are great. For this reason it is impossible to make a truly quantitative fractionation of the plants, but an approximation is given in Table IV.

Table IV. *Fractionation of plants.*

Fraction	% whole plant
Aqueous extract	65–67
Residue from above	33–35
Alcohol precipitate of aqueous extract	50–54
Alcohol-soluble aqueous extract	13–15

In Table V is given the percentage distribution of nitrogen as calculated by combining Tables III and IV.

Table V. *Percentage distribution of nitrogen in plant fractions.*

Fraction	% total nitrogen
Whole plant	100
Aqueous extract	37
Residue from above	63
Alcohol precipitate of aqueous extract	13
Alcohol-soluble aqueous extract	15

B	Borden, P.E.I.	August
F	Details of collection missing. Extract made without any washes of absolute alcohol	—
M	Mixture of extracts from different samples dissolved together and precipitated	—

DISCUSSION.

If the nitrogen were simply an impurity one would expect that it might be removed, or at least appreciably reduced, by repeated precipitations. There is, however, no indication of such reduction. On the other hand, there is no evidence that the nitrogen content can be brought to a constant figure for all samples, as might be expected if it were chemically united with the polysaccharide complex (Table II).

No doubt there is protein material in the plants, but in the extract from only one sample, *viz.* H, could a positive biuret test be obtained. The protein nature of the nitrogen in the polysaccharide extracts, therefore, seems doubtful. Furthermore, no nitrogen was detected by the Van Slyke amino-nitrogen method.

Haas [1921] and Russell-Wells [1922] reported positive protein tests for their extracts of *Chondrus*. More recently, Haas and Hill [1933] have reported a sample of *Chondrus* with a total nitrogen content of 2·33 %, as giving a negative biuret test.

Russell-Wells [1922] found that nearly half of the 0·56 % of nitrogen in the extract she used occurred in an ammonium radical. In the present investigation none was identified as such.

From a consideration of these results no suggestion can be offered as to the form in which the nitrogen present exists. It is possible, however, that the nitrogen which accompanies the carbohydrate complex through repeated precipitations does so because it is adsorbed on the colloidal particles.

SUMMARY.

The percentage of nitrogen in the polysaccharide complex extracted from *Chondrus crispus* by a standard method is found to depend on the amount of nitrogen originally present in the plants.

The percentage of nitrogen in this complex is not reduced by repeated precipitations.

The amount of nitrogen associated with this carbohydrate material is calculated to be approximately 13 % of the total nitrogen in the plants.

The nature of this nitrogen is still undetermined.

CXXVII. THE CATALYTIC OXIDATION OF ASCORBIC ACID.

By ALEXANDER EDWARDS KELLIE
AND SYLVESTER SOLOMON ZILVA[1].

From the Division of Nutrition, Lister Institute, London.

(*Received March 23rd, 1935.*)

As long ago as 1922, Hess [1922] demonstrated the possibility of destruction of vitamin C through the catalytic action of metals. He showed in this connection that when milk was pasteurised in glass containers it was antiscorbutically more active than when it was submitted to this treatment in copper vessels. Recently, Euler *et al.* [1933] found that pure ascorbic acid took up oxygen more readily in the presence of certain metals. The experiments described in this communication, which were the outcome of an observation on the instability of ascorbic acid in distilled water, yield further information on this subject.

The rate of oxidation of ascorbic acid dissolved in water of different degrees of purity.

In these experiments the spontaneous oxidation of ascorbic acid in tap water, ordinary laboratory distilled water obtained from a tin-lined copper still, water redistilled from glass apparatus and water distilled from and received in quartz apparatus was investigated. 15 mg. of *l*-ascorbic acid were dissolved in 40 ml. of each sample of water contained in conical flasks of 100 ml. capacity. In the case of the quartz-distilled water round-bottomed flasks of 50 ml. capacity were used. The reaction in each case was adjusted to p_H 7·4 by addition of the requisite quantity of sodium hydroxide and the flasks were kept at 37°. At the end of 20 hours the reaction in each case fell to about p_H 6·7. 5 ml. of the solutions were withdrawn at various intervals and the ascorbic acid was determined by titration with indophenol. The results are given in Table I, from which it will be seen that the rate of disappearance of ascorbic acid in tap water and in laboratory distilled water was fairly quick but that the oxidation in glass-distilled and quartz-distilled water was very much slower. It should be mentioned, however, that unless the distillation of the water in glass was carried out three times and the product used immediately the low rate of oxidation was not observed. On the other hand, when oxygen was bubbled for one hour through

Table I.

[1] Member of the Scientific Staff, Medical Research Council.

this water the rate of oxidation of the vitamin was not significantly accelerated. These results suggested that the increase in the rate of oxidation of ascorbic acid in tap water or in ordinary distilled water was due to the presence of traces of metal. Subsequent experiments proved this view to be true.

The catalytic action of traces of metals present in ordinary distilled water on the oxidation of ascorbic acid.

The first step taken in order to ascertain whether the higher rate of oxidation of ascorbic acid in tap water and ordinary distilled water was due to the catalytic effect of substances dissolved in the water, was to establish whether the addition of such substances to glass-distilled water would accelerate the oxidation of ascorbic acid. For this purpose the incinerated and untreated residues left on evaporation of ordinary distilled water were employed. These were obtained in the following way. Ten litres of ordinary distilled water were evaporated to about 100 ml. The liquid was then divided into two equal quantities, which were evaporated to dryness on a water-bath; one of the residues was then incinerated. In each case the residue was taken up in 100 ml. of glass-distilled water and the oxidation of ascorbic acid dissolved in these two samples was determined by the procedure mentioned above. These results which are given in Table II show that both residues accelerated the oxidation.

Table II.

mg. of ascorbic acid per 100 ml. of water.

Hours	Glass-distilled	Glass-distilled + untreated residue	Glass-distilled + incinerated residue
0	37·9	36·7	35·1
¼	36·8	28·6	24·2
1½	34·9	19·8	13·7
3	33·3	8·8	6·3
20	26·5	0·0	0·0

In view of the fact that the inorganic residue increased the rate of oxidation in glass-distilled water an experiment was performed in which cyanide was added to the ordinary distilled water. The results (Table III) showed that the rate of disappearance of the ascorbic acid fell to about the same level as in glass-distilled water thus suggesting that at least some of the inorganic constituents contained in the normal sample were catalysing the oxidation. This water was therefore submitted to an examination for iron and copper, since it has been shown by Euler *et al.* [1933] that traces of these metals, especially of the latter, were capable of catalysing the absorption of oxygen by ascorbic acid in a Barcroft apparatus. The presence of such traces could well be expected in

Table III.

distilled water obtained from a laboratory still. The detection of iron was carried out with analytically pure potassium thiocyanate according to Sakuma [1923]. The reaction was found to be positive in water concentrated 200 times, the concentration of the iron being, however, too low for quantitative determination. After precipitating the iron with ammonium hydroxide the copper was determined colorimetrically with sodium diethyldithiocarbamate and was found to be present in a concentration of 0·001 mg. per 100 ml. of water.

It was then possible to demonstrate that when these metals were added to quartz-distilled water the oxidation of ascorbic acid proceeded at an increased rate (Table IV). This was particularly marked in the case of the added copper which is in consonance with the results of Euler *et al.* [1933]. It may be mentioned that when quantities of copper were added to bring up the concentration to that found in the ordinary distilled water, the rate of oxidation was also raised but was less than that observed in the above experiment.

Table IV.

mg. of ascorbic acid per 100 ml. of water.

Hours	Quartz-distilled	Quartz-distilled + 0·01 mg. Fe/40 ml.	Quartz-distilled + 0·01 mg. Cu/40 ml.
0	37·0	34·5	34·1
1	35·2	31·8	24·2
2	33·0	29·6	21·2
3	30·9	28·2	15·2
4	29·4	25·8	8·0
20	25·7	10·3	0·0

The next experiment was instituted with the object of establishing whether by treating ordinary distilled water by the usual procedures employed in the removal of the bulk of dissolved oxygen the rate of oxidation of the vitamin could be significantly modified. The results obtained (Table V) showed that with the quantities of ascorbic acid used, this was not the case. Furthermore, as already mentioned, when the catalysts are absent, the water (fresh glass-distilled)

Table V.

mg. of ascorbic acid per 100 ml. of water.

Hours	Ordinary distilled	Ordinary distilled. Air removed by boiling	Ordinary distilled. Air removed by evacuation	Ordinary distilled. Air replaced by passing nitrogen
0	34·9	34·7	33·0	34·4

may be saturated by previously passing through it a current of air or oxygen without significantly accelerating the disappearance of the dissolved ascorbic acid (Table VI).

The inhibiting effect of animal tissues and other substances on the oxidation of ascorbic acid in ordinary distilled water.

It has recently been observed [Quastel and Wheatley, 1934; De Caro and Giani, 1934; Mawson, 1934] that when animal tissues or their extracts were added to a solution of ascorbic acid the oxidation of the vitamin was greatly inhibited. In other words the action of the tissue is similar to that of cyanide in this connection. Similar observations had already been made in this laboratory independently, but as a detailed investigation on this subject has already been published by De Caro representative experiments only will be reported here for the purpose of continuity.

The technique employed in these experiments was as follows. One g. of tissue (guinea-pig) was thoroughly ground with 10 parts by weight of ordinary distilled water. After centrifuging, the supernatant liquid was added to 30 ml. of an aqueous solution containing 15 mg. of ascorbic acid thus bringing up the total volume to 40 ml. The incubation and determination of the ascorbic acid were carried out as above. The results of such an experiment are given in Table VII from which the stabilising action of tissue extracts becomes evident. Extracts from the large and the small intestine were found by us also to be effective. Like De Caro, we found that extracts from the tissues of scorbutic animals exercised the same effects as those from tissues of normal guinea-pigs.

Table VII.

mg. ascorbic acid per 100 ml. of water.

Hours	Liver	Kidney	Muscle	Spleen	Plasma	Ordinary distilled water

That the inhibiting action of animal tissues and their extracts was due to their influence on the catalytic action of metals present in solution was proved by the following experiments in which graded amounts of iron and copper were added to solutions containing ascorbic acid and liver tissue extracts prepared as above. The oxidised ascorbic acid was determined in the usual way. The results (Table VIII) showed that although copper is more effective as a catalyst

Table VIII.

20	33·2	31·2	24·7	12·6	4·6	32·4	32·1	24·9	6·0	1·4

than iron in this process, the inhibiting action of the tissue extract is very much more marked in the former case. It should be mentioned here that ordinary distilled water which contains copper and iron was used in these experiments and consequently the actual amount of catalyst put out of action was rather higher than that suggested by the figures in Table VIII.

De Caro observed further the interesting fact that Ringer's solution and the salts of which it is made up had also a stabilising effect on ascorbic acid. We have repeated this part of his work since the appearance of his paper and have been able to confirm his results. The protective action of the salts will be seen from the results given in Table IX. It was of interest to ascertain whether this protective action was, as in the case of animal tissues, due to the suppression of the catalytic action of metals. The rate of oxidation was therefore studied in the presence and in the absence of NaCl in quartz-distilled water to which copper was added. The results obtained were clear cut and as will be seen from Table X the oxidation catalysed by Cu was very much slower when NaCl was present. It may be noted that the addition of N/10 NaCl did not reduce the velocity of the reaction to that of the control solutions of ascorbic acid which did not contain any copper.

Table IX.

Hours	mg. of ascorbic acid per 100 ml. of water. N/10 KCl	N/10 NaCl	N/10 $CaCl_2$	Ringer solution	Ordinary distilled water

1	38·1	35·8	31·8	28·6
2	37·4	33·9	28·6	21·2
3	35·4	32·8	26·1	15·6
4	33·5	32·3	22·8	7·7

The influence of blood on the catalytic oxidation of ascorbic acid.

Particular attention has been given to this point owing to the fact that it is claimed that in the blood vitamin C is present as dehydroascorbic acid [Emmerie *et al.*, 1933]. The effects of plasma, intact and haemolysed red corpuscles and leucocytes were therefore investigated. It was mentioned above (Table VII) that plasma had an inhibiting action on the catalytic oxidation of ascorbic acid. In the case of the red corpuscles an equivalent of 1 ml. and in that of the leucocytes an approximate equivalent of 10 ml. of blood was added to the same quantity of ascorbic acid and under the same conditions as mentioned above. In both cases the cells were washed three times with an isotonic solution of sodium citrate. It will be seen from Table XI that whilst the erythrocytes offered very marked protection, the leucocytes had no perceptible influence on the rate of oxidation of the ascorbic acid.

Table XI.

mg. of ascorbic acid per 100 ml. of water.

Hours	Intact red corpuscles	Leucocytes	Citrate control	Laked red corpuscles	Ordinary distilled
0	34·2	33·9	34·7	30·7	32·3
1	33·0	28·2	28·9	30·4	23·0
2	31·9	21·9	22·1	30·2	16·7
3	31·2	16·3	17·2	27·4	7·9
4	30·5	11·1	11·6	20·7	3·3

Laked red corpuscles were also found to be capable of protecting ascorbic acid from oxidation but in this case an initial disappearance of the vitamin was noted. It was possible to show that the quantity of ascorbic acid which disappeared was proportional to the amount of haemolysed blood added and further that when the red corpuscles were previously treated with CO the destructive action of the haemolysed erythrocytes was hardly appreciable (Table XII).

Table XII.

mg. of ascorbic acid per 20 ml. of solution determined immediately after addition.

	Control	1 ml.	2 ml.	4 ml.
Intact red corpuscles	7·0	7·1	7·5	7·8
Laked red corpuscles	6·7	5·8	4·9	3·0
Laked red corpuscles treated with carbon monoxide	6·8	6·8	7·0	7·5

It would therefore appear that on haemolysing a substance, most probably oxyhaemoglobin, is set free which is capable of interacting with ascorbic acid.

The product formed by the catalytic oxidation of ascorbic acid.

In the above experiments the disappearance of the ascorbic acid was followed up by titration with indophenol. This procedure did not therefore offer any evidence concerning the character of the oxidation product formed. In the experiments to be described an attempt was made to determine the amount of dehydroascorbic acid present at various intervals, namely after 4, 20, 24 and 28 hours' incubation. The dehydroascorbic acid was determined by titrating an aliquot portion of the solution with indophenol before and after treatment with hydrogen sulphide. The results revealed that after 4 hours' incubation in the cases of both the ordinary distilled water and the quartz-distilled water with added copper a significant part of the vitamin was still present as dehydroascorbic acid although the major part of the ascorbic acid was irreversibly oxidised. There was no dehydroascorbic acid present either in the solution to which cyanide was added or in the quartz-distilled water (Table XIII). After

Table XIII.

mg. of ascorbic acid per 100 ml. of water.

Hours	Quartz-distilled	Quartz-distilled + 0·01 mg. Cu/40 ml.	Cyanide	Ordinary distilled
0	38·6	35·4	34·2	36·1
1	38·1	28·6	32·8	28·1
2	37·4	21·2	31·9	14·7

4 hours after treatment with H_2S	34·9	15·4	30·5	7·5

Table XIV.

mg. of ascorbic acid per 100 ml. of water.

Hours	Quartz-distilled	Quartz-distilled + 0·01 mg. Cu/40 ml.	Cyanide	Ordinary distilled
0	38·8	36·0	36·7	37·0
4	35·3	8·6	33·3	2·8
20	30·2	0·0	26·7	0·0
20 hours, after treatment with H_2S	30·7	3·7	27·2	3·5
24	29·5	0·0	25·8	0·0
24 hours, after treatment with H_2S	30·0	1·8	26·1	2·1

20 and 24 hours (Table XIV) the quantity of dehydroascorbic acid present in the two above experiments was decidedly less and it was further found that after 28 hours it was only just appreciable in both cases. It would appear therefore that the dehydrogenation of ascorbic acid takes place first and is then followed by irreversible oxidation. This view is further strengthened by the fact that after a short time (about 10 minutes) the loss in the indophenol-reducing capacity of a solution of ascorbic acid can be almost entirely re-established by treatment with hydrogen sulphide.

CONCLUSIONS.

A notable feature in this investigation is the great stability of ascorbic acid in the presence of oxygen when metallic catalysts are absent from solution. The negligible deterioration of the vitamin in quartz-distilled water, previously saturated with oxygen, suggests that in absolutely pure water, ascorbic acid is as stable as in the solid condition; in other words oxygen without the aid of catalysts is inert towards it. In practice, however, it is extremely difficult to produce conditions which would favour such stability of the vitamin in solution. Even the purest distilled water, when allowed to remain in glass vessels for some time, becomes contaminated enough to catalyse the oxidation of ascorbic acid.

It is noteworthy that amongst all the tissues examined only the leucocytes were unable to inhibit the oxidation of ascorbic acid in the presence of catalysts. These cells had nevertheless no accelerating action on the oxidation of the vitamin. There seems, therefore, no indication that ascorbic acid is reversibly oxidised in any part of the animal organism. The observation of Johnson and Zilva [1934] that dehydroascorbic acid is excreted in the urine as ascorbic acid suggests that the tissues on the contrary reduce the reversibly oxidised form of the vitamin. The evidence seems to favour the view that dehydroascorbic acid has to be reduced in the organism before it can function as an antiscorbutic.

SUMMARY.

Ordinary laboratory distilled water contains sufficient quantities of metals (copper and iron) to catalyse the irreversible oxidation of dissolved ascorbic acid. In the very early stages of the process dehydroascorbic acid is found in quantities almost equivalent to the amounts of ascorbic acid which are oxidised, but as the reaction proceeds the quantities of the dehydrogenated acid present diminish. This catalytic action is barely perceptible when the vitamin is dissolved in water which has been redistilled several times from glass apparatus and which is used immediately or in water distilled from and received in quartz. When this water is previously saturated with oxygen the disappearance of ascorbic acid is not significantly increased. The addition of aqueous extracts of

liver, kidney, muscle, spleen, large and small intestine and of plasma, intact or haemolysed erythrocytes and *N*/10 NaCl inhibits the oxidation of ascorbic acid in ordinary distilled water or in water to which iron or copper has been added. Leucocytes have no influence on the oxidation. There is a disappearance of ascorbic acid immediately after the addition of haemolysed erythrocytes which is proportional to the quantity of the added corpuscles. This disappearance does not take place when the haemolysed corpuscles are previously treated with carbon monoxide. It is suggested that dehydroascorbic acid has to be reduced in the organism before it can exercise antiscorbutic activity.

One of us (A. E. K.) is indebted to the Medical Research Council for a whole time grant.

CXXVIII. SPECTROPHOTOMETRIC INVESTIGATIONS OF THE NEW VITAMIN A COLOUR TEST.

By EUGENE ROSENTHAL and MARGARET WELTNER.

Budapest, Hungary.

(*Received March 25th, 1935.*)

Colorimetric determination of vitamin A has frequently been based upon the Carr-Price reaction, namely the production of a blue colour when vitamin A is added to a saturated solution of antimony trichloride in chloroform, which shows two absorption maxima at 606 $m\mu$ and at 572 $m\mu$, respectively. This reaction has the following drawbacks: (1) the blue colour is not specific for vitamin A, being given also by carotene, (2) the colour shows a considerable change after the lapse of 30 seconds, rendering colorimetric estimation very difficult. In order to eliminate this difficulty Rosenthal and Erdélyi [1934, 1] devised a new colour test. In this the vitamin-containing material is warmed with a solution of antimony trichloride and catechol in chloroform. The resulting blue colour soon turns into a purplish red. This colour, quite similar to that of a dilute solution of potassium permanganate, is much more stable than the blue colour obtained with the Carr-Price reaction. No other carotenoids except vitamin A produce this colour; the blue colour obtained with other carotenoids does not change on warming. Rosenthal and Erdélyi emphasise the fact that the purplish red hue produced by catechol remains unchanged for some 5 to 10 minutes if fairly pure preparations of vitamin A are used. This fact made possible a more thorough spectrophotometric examination of this purplish red colour.

In our investigations we employed the König-Martens spectrophotometer at a layer depth of 0·2 cm., a Nitra bulb being used as a light source. The extinction coefficient has been calculated according to the following equation:

$$E=\frac{\log tg\alpha_2-\log tg\alpha_1}{d.c},$$

where α_2 and α_1 are the angles measured, d is the layer thickness and c the concentration. A vitamin A concentrate, 0·2 and 0·4 % solution in chloroform has been used.

If reading was performed within the first 10 minutes, two maxima were observed: a broad band at 545 $m\mu$ and a narrower one at 475 $m\mu$. If however the measurement was repeated during the second, third and fourth 10-minute periods, within the first broad maximum two new maxima and a minimum appeared, the latter corresponding to 545 $m\mu$, the maxima corresponding to 535 $m\mu$ and 552 $m\mu$, respectively. At the same time the second maximum also showed a resolution into a lower maximum at 485 $m\mu$ and a considerably higher one at 470 $m\mu$. With the aid of chromatographic analysis Karrer and Morf [1933] recently prepared two fractions of vitamin A, called by the authors vitamin Aα and vitamin Aβ, respectively. Van Eekelen *et al.* [1933] described also a separation of two fractions of vitamin A by fuller's earth. Further research is needed to determine which of these fractions is involved in the production of the above maxima observed by us.

The colour reaction with catechol being more stable is definitely superior to the simple antimony trichloride test; however, the spectroscopic data mentioned above show that the stability even of this colour is not sufficient. This fact induced Rosenthal and Erdélyi [1934, 2] to try to improve and to stabilise their colour test still further. They found that the purplish red hue could be obtained not only with catechol but also with quinol, guaiacol and veratrol. This test therefore can be considered as dependent on the presence of a polyhydric phenol. Other polyhydric phenols however are unsuitable for this test because of their insolubility in absolute chloroform. For quantitative determinations guaiacol has been found optimum among the substances mentioned. A 5 % solution of guaiacol in chloroform has been employed. This modification proved more favourable in several respects: the catechol solution has to be prepared fresh daily, whereas the guaiacol solution may be kept ready for use for days. The final colour of the reaction performed with catechol remains constant only for a short time (5–10 minutes), whereas the final colour of the guaiacol test is quite stable even for 1–2 hours. If very pure preparations are used, the colour does not change even after 24 hours. With the catechol test the fluid becomes turbid after a while, whereas the guaiacol modification has the important advantage in respect of spectrophotometric examination that the fluid remains perfectly transparent.

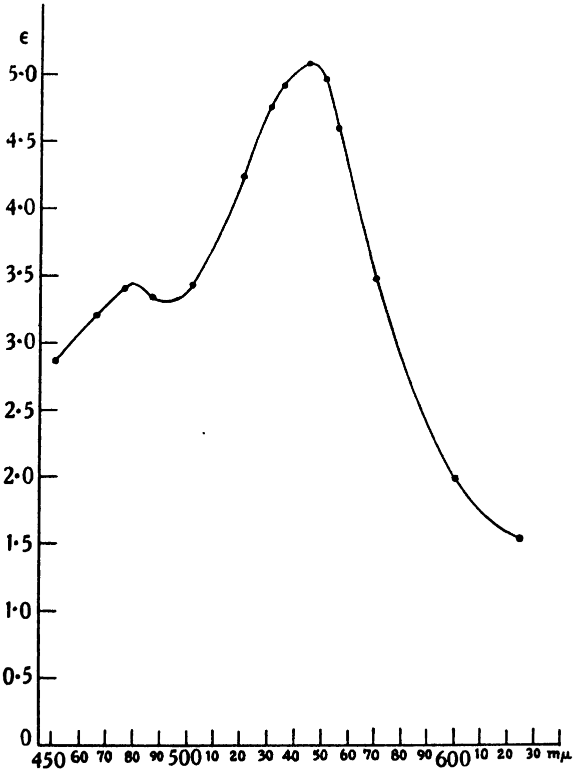

Fig. 1. Absorption curve of colour produced in the antimony trichloride-guaiacol test for vitamin A.

Owing to these circumstances we obtained a quite invariable and characteristic curve when examining the guaiacol reaction spectrophotometrically. It has two maxima, a higher one at 545 $m\mu$, and a lower one at 478 $m\mu$, which are in good accordance with the characteristics of the curve of the catechol test read within the first 10 minutes (see Fig. 1).

As there was no pure vitamin A available, we were unable to determine the quantitative relations of this absorption curve.

SUMMARY.

The purplish red colour of the antimony trichloride-catechol test for vitamin A examined within the first 10 minutes shows two maxima at 545 $m\mu$ and at 475 $m\mu$, respectively. During the second, third and fourth 10-minute periods two other maxima appear.

The purplish red colour of the guaiacol modification of this test remains unchanged for several hours. Spectrophotometric examination of this colour showed two maxima at 545 $m\mu$ and at 478 $m\mu$, respectively.

We are greatly indebted to Prof. J. Gróh, Director of the Chemical Laboratory of the Royal Hungarian Technical College, for valuable suggestions and for providing us with the apparatus needed in our work.

CXXIX. A NEW METHOD OF DETERMINING THE VITAMIN A CONTENT OF BLOOD.

By EUGENE ROSENTHAL and CATHERINE SZILÁRD.

Budapest, Hungary.

(*Received March 25th, 1935.*)

THE first observations relating to the amount of vitamin A in blood are due to Euler and Steffenburg [1928], who stated that the growth of rats kept on a diet devoid of vitamin A was enhanced by adding blood or serum to their ration. Euler also demonstrated that fat extracted from blood serum gives the well-known blue colour reaction with antimony trichloride. The method used for quantitative determination of vitamin A in blood has been published by Rösiö [1929] and consists in a multiple extraction with ether of 25–100 ml. of blood serum, evaporation *in vacuo* of the combined ethereal extracts after drying with sodium sulphate and treatment of the residue with antimony trichloride as described by Carr and Price.

This simple procedure however could not yield accurate results, since not only vitamin A but also carotene is present in variable quantities in blood serum; moreover carotene is extracted by ether, and gives a blue colour with antimony trichloride. Though the growth-stimulating action of carotene upon rats kept on a diet devoid of vitamin A is similar to that of vitamin A, and though in the study of certain questions it may be permissible to determine the quantities of vitamin A and carotene together, it would be fallacious to attribute the results obtained with this method to vitamin A alone, especially since the blue colours produced by allied compounds are of different intensities.

Another method devised by van Eekelen [1931] allows for the presence of carotene by subtraction from the total intensity of the blue colour of that part which is due to carotene. The method of van Eekelen, published later by Menken [1932] and utilised also by Wendt [1935], consists in precipitating 20 ml. of serum with 100 ml. of 96 % alcohol and centrifuging. The supernatant alcoholic fraction is extracted with light petroleum. The slightly yellowish extract is then concentrated *in vacuo* to 1 ml. and utilised for the determination of carotene and later of vitamin A. According to van Eekelen the yellow tinge of this petroleum extract is due solely to carotene, the concentration of which can be determined by colorimetric measurement. The difference between the total blue colour obtained by treatment of the concentrated extract according to Carr and Price and the colour accounted for by the colorimetrically determined carotene is taken to represent vitamin A.

This method of determination seems to be objectionable from several points of view. When determining the carotene content of the blood, Connor [1928] precipitates the serum with 95 % alcohol. After centrifuging, the yellowish alcoholic fraction is discarded on account of its xanthophyll content, whilst the precipitate is extracted with benzene and the carotene content of the serum is determined by colorimetric measurement of this latter extract. Thus the carotene content of the alcoholic fraction and the blue value of carotene to be subtracted finally from the colour of the Carr-Price reaction will vary according to the method of precipitation, the shaking of the tube containing the precipitate and the speed of centrifuging. It must also be remembered that all carotenoids, including vitamin A, are easily adsorbed by different media and it is well-nigh impossible to estimate the amount adsorbed by the protein precipitate. Nor is the yellow colour of the petroleum extract attributable solely to carotene, so that the conversion of the yellow colour into blue units is somewhat uncertain; moreover the reading of the final blue colour must be accomplished within 30 seconds, because of its quick fading. This urgency of reading entails personal error apart from the practical uncertainty of the method, the results of which therefore give at best indirect, and probably often incorrect, information.

These difficulties are overcome by the new colour test of Rosenthal and Erdélyi [1934, 1], which is specific for vitamin A and in which the colour is much more stable, rendering hurried reading unnecessary. The new colour reaction consists in warming the vitamin-containing material with a chloroform solution of catechol or guaiacol [Rosenthal and Erdélyi, 1934, 2] and antimony trichloride, when the initial blue colour of the solution soon turns into a purplish red. This hue remains unchanged for 5 to 10 minutes in the case of catechol and for periods of hours in that of guaiacol, depending on the purity of the material tested. The intensity of the colour obtained is proportional to the concentration of vitamin A and can be measured by means of colorimetric estimation, the colour being identical in tint with that of a dilute solution of potassium permanganate. Since the colour of the permanganate solution changes within a couple of days and the extinction of this changed standard solution does not correspond to that of the coloured solution obtained in the reaction, colorimetric comparison is possible only by constantly adjusting the tube containing potassium permanganate solution to the same point of the scale (10). This difficulty can be overcome by the use of the "absolute colorimeter" of Leitz, which permits colorimetric estimation against a special "grey solution" in monochromatic light, at the wave-length of the maximum absorption of the new test. Concerning the details of the colorimetric estimation we refer to Rosenthal and Erdélyi [1934, 1, 2]; here it may suffice to mention that this new method makes it possible to express the vitamin A content in "grey units."

This new method has been employed for direct determination of vitamin A in blood. At first we proceeded by extracting the serum or plasma with light petroleum. This extract, containing both carotene and vitamin A, was shaken five times in a separating funnel with 86 % methyl alcohol, after which treatment carotene had passed into the top layer (petroleum) whilst vitamin A was contained in the bottom layer (methyl alcohol). The collected and united alcoholic extracts were then diluted with an equal part of distilled water and extracted again with light petroleum, which this time removed the vitamin A. The petroleum extracts were washed with water, dried and evaporated at a low temperature *in vacuo*, and the residues were dissolved in absolute chloroform and used for determination of carotene and vitamin A, respectively.

Later the method has been simplified by the observation that the blue colour given by carotene with antimony trichloride disappears on warming with guaiacol; small amounts of carotene, such as occur in blood, do not therefore interfere with the direct determination of vitamin A.

The final method for determination of vitamin A is thus as follows. The carotene content of the blood to be taken should not exceed the threshold value mentioned (5γ in 1 ml. extract). 10–30 ml. of blood are extracted four times in a separating funnel with 50 ml. of light petroleum (B.P. $< 55°$). The greater the quantity and the lower the specific gravity of the petroleum, the more easily can emulsification be avoided. Should emulsification nevertheless occur, the fluid may be treated with a few ml. of petroleum and centrifuged at low speed for 3–4 minutes.

Addition of one drop of 96 % alcohol to the emulsion may also be of assistance. If alcohol has been employed, the petroleum extract must be thoroughly washed twice with distilled water. The collected petroleum extracts are dried over a minimum amount (0·01–0·02 g.) of anhydrous sodium sulphate for 2 hours, repeatedly filtered through dry filters and evaporated *in vacuo* at 40°. In order to remove the last traces of water the residue is dried once more for 20–30 minutes *in vacuo*.

The residue is tested as follows. Since such small quantities of vitamin may produce a very faint colour the final volume of the solution is reduced to 1 ml. (instead of 5 ml.) and the determination is made with the micro-cell of the Leitz absolute colorimeter. To the dry residue of the extract 0·25 ml. of absolute chloroform, 0·25 ml. of 5 % guaiacol in absolute chloroform and 0·5 ml. of a saturated solution of $SbCl_3$ are added. The mixture is put into a water-bath at 55° for 1½ minutes exactly. During this time the initial blue colour changes into purplish red. Both temperature and duration of warming should be adhered to exactly in order to keep volatilisation of chloroform within constant limits.

It would be most desirable to use a solution of pure vitamin A of known concentration as a standard. As we had no such preparation at our disposal, we had to express the quantity of vitamin A in another way.

A very simple method of comparison was given by the close similarity of the final colour of our reaction to that of 0·001 % potassium permanganate solution. Reading can take place in white or in monochromatic light corresponding to the maximum absorption of the colour in question. In this latter case we used light filter No. 7 (greenish yellow) of the Leitz absolute colorimeter.

The following data will show the results of several determinations (reduced to 1 ml. of serum):

Blood samples	Colorimeter readings with permanganate	The same values expressed in "grey units", calculated to 100 ml. of serum
1	2·71	5·4
2	3·84	7·6
3	2·85	5·5
4	4·05	8·3
5	3·12	6·2

In another method of colorimetric examination we used the "grey solution". In this case we fixed the cell containing 1 ml. of "grey solution" at 10 mm. and varied the layer of the solution to be tested. From the reading of the unknown and from the volume of the serum tested, the value of "grey units" corresponding to the vitamin A content of 1 ml. of serum may be calculated. The following equation serves for conversion into "grey units":

$$\text{Grey units} = \frac{\text{Reading of standard}}{\text{Reading of unknown} \times \text{ml. of serum}}.$$

If we could work with pure vitamin A, the intensity of the colour produced would be proportional to the absolute amount of vitamin A.

It cannot be foreseen what results of clinical and pathological importance may arise from the systematic examination of vitamin A in the blood, but, at any rate, it seems that the method described will furnish interesting and reliable data.

SUMMARY.

1. The new method of determining vitamin A in blood makes it unnecessary to remove carotene, since this substance does not react in the guaiacol test.

2. The new reaction thus permits direct determination of vitamin A in blood.

3. A dilute solution of potassium permanganate or the "grey solution" of the Leitz absolute colorimeter may be used as standards for comparison.

4. Until it becomes possible to determine the absolute amount of vitamin A with the aid of this new colour test, its expression in "grey units" seems suitable for research purposes.

CXXX. THE RESPONSE OF THE ISOLATED UTERUS OF THE GUINEA-PIG TO HISTAMINE.

By HAROLD JOHN PHELPS.

From the Physiology Institute, Cardiff.

(*Received March 26th, 1935.*)

RESEARCHES carried out in the last few years have led to the view that true adsorption of weak electrolytes from aqueous solutions by neutral adsorbing surfaces proceeds through the medium of unionised molecules. Studies of adsorption by charcoal and fuller's earth have shown clearly the distinction between true adsorption and the apparent adsorption resulting from the interaction of dissolved ions with polar groups in the adsorbing surface [Fromageot and Wurmser, 1924, 1, 2; Phelps and Peters, 1929; Phelps, 1929; 1931, 1, 2].

It is obviously most pertinent from the biological standpoint to enquire whether the living cell takes material from its surroundings by true adsorption processes or by a mechanism of ionic exchange. It is of course very probable that the transfer of material from the fluid surrounding the cell to the fluid within the cell takes place by a migration of ions, and indeed the Donnan theory of membrane equilibria provides a theoretical basis for such a migration and, in general, gives a quantitative explanation of the observed facts. Such a scheme, however, takes no account of any specific concentration at the cell boundaries which may result from adsorption processes. Since many of the chemical reactions taking place in the living cell appear to be surface reactions it is reasonable to suppose that they must be preceded by adsorption processes.

This point can plainly be tested experimentally with certain pharmacologically active weak electrolytes, by comparing their pharmacological activities in acid and alkaline media. It is to be expected, for example, that a pharmacologically active base which ionises over the physiological range of p_H will, if it is taken up by the cell by a process of true adsorption, show greater pharmacological activity in alkaline media, in which, of course, the proportion of unionised molecules will be higher. From an acidic electrolyte the reverse result would be expected. Experiments on these lines have been reported from time to time. In particular may be mentioned the work of Andrus [1924] which demonstrated that adrenaline and tyramine had more powerful effects on the auricles of the rabbit heart at p_H 8 than at p_H 7. On the other hand choline and its esters which are presumably potential acids, were more actively depressant in acid media. Clark [1928] has reached a similar conclusion in the case of the action of acetylcholine on the frog's heart and has provided a technical explanation of the opposite result obtained by Voss [1926].

More recently Trevan and Boock [1927] have carried out a comprehensive study of the influence of p_H on the action of certain local anaesthetics on the eye. The correlation between anaesthetising action and the concentration of unionised molecules, as calculated from the known ionisation constants, is very striking. Labes [1922] has shown that atropine and cocaine are markedly less toxic in acid solutions and Werner and Blanchard [1929] have reported a similar result with strychnine. Zipf [1927] finds that frogs' livers take up alkaloids and basic dyes more readily from alkaline than from acid solutions. The same author

[1928] also finds that the contracture of frog's muscle produced by caffeine, quinine, nile blue *etc.*, is increased by increased alkalinity. Remarkably enough Zipf concludes from these results that the uptake of basic substances by tissues is a simple chemical replacement of free basic groups in the surface.

It is of course plain that any of these results considered individually is capable of two interpretations. Either it may be assumed that the neutral molecule of the stimulating substance is specifically active, or, on the other hand one must assume, as does Zipf, that increasing alkalinity induces some change in the cell surface itself which increases its responsiveness by increasing its adsorbing power or otherwise. When the results are considered collectively however the second interpretation seems most improbable. Trevan and Boock, for example, find that the anaesthetising actions of a number of substances in media of different reaction are in every case proportional to the concentration of unionised molecules as calculated from the known ionisation constants of the anaesthetics. If one may not assume that it is the unionised molecule which is adsorbed by the anaesthetised tissues, one must assume that the cell surfaces are so altered by change in reaction that their adsorbing power for each one of a number of different substances is also changed in such a way that in each case the change in adsorption happens to follow exactly the change in ionisation of the substance concerned, which surely is to assume an impossible degree of coincidence.

If however it is legitimate to argue from the analogous results obtained in the study of adsorption by charcoal and fuller's earth, it is surely reasonable to say that Zipf's results indicate rather a true "apolar" adsorption process.

In view of the strong presumptive evidence provided by these and similar investigations in favour of the view that the walls of the living cell take up substances from their surroundings by a mechanism of true "apolar" adsorption, it seemed desirable to study the influence of p_H on the pharmacological activity of some substance the adsorption of which by neutral adsorbents had already been studied. The influence of p_H on the adsorption of histamine has already been studied [Phelps and Peters, 1929]. From these results it appears that the adsorption of histamine increases rapidly over the range of reaction p_H 6–9. Since histamine is well known to have a marked pharmacological action on uterine smooth muscle it was thought that interesting results might be obtained by observing this action in media of varying reaction. It is true that Evans and Underhill [1923] have not found the action of histamine on the guinea-pig uterus to be influenced by changes in p_H, but as will appear in this paper, these workers did not employ a technique likely to disclose the small differences which might be expected to exist.

Work has been in progress on this problem for the last few years, and two brief reports have previously been published [Peters, 1929; Phelps, 1931, 3].

EXPERIMENTAL.

The guinea-pig uterus was chosen as providing suitable material, and the tests were carried out by a technique essentially similar to that described by Dale and Burn [1922] in their Medical Research Council Report on the Standardisation of Pituitary Extracts. The bath and fittings employed were of the modified design described by Gulland [1933].

The tests are beset with grave technical difficulties some of which may be mentioned. In the first place it was found (in confirmation of Dale and Burn [1922]) that not only do uteri from different animals show great differences in their response to histamine, but also that in any one preparation the relationship between response and dose is qualitative rather than quantitative and further that the sensitivity of the preparations generally varied considerably in the course of a series of tests. The Ringer solutions used have been made up to the composition recommended by Dale and Burn. Various methods of adjusting the reaction of the Ringer have been tried. It was found in the first instance that the maximum range of reaction which the guinea-pig uterus would tolerate without becoming subject to violent contractions in the absence of histamine was roughly p_H 7–8·5. Three obvious methods suggest themselves: (*a*) the use of definite buffer solutions such as phosphate or borate, (*b*) aeration of the testing bath with appropriate mixtures of oxygen and carbon dioxide, (*c*) adjustment of the p_H of the Ringer with dilute hydrochloric acid and reliance on the buffering effect of the bicarbonate in the solution to keep the reaction reasonably constant.

Although many successful experiments have been carried out using Ringer solutions buffered with phosphate mixtures to p_H 7·2 and p_H 8, this method has certain disadvantages. The Ringer solution as made up without phosphate has a reaction of about p_H 8·4, but the solution was buffered to a reaction somewhat less alkaline since there was a marked precipitation of calcium in more alkaline solutions in presence of phosphate. It has been established independently that diminution of the calcium content of the Ringer *per se* lowers the sensitivity of the uterus (Sir H. H. Dale tells me that this agrees with his own experience) so that the precipitation of calcium might mask in some degree the effect of change in reaction. The use of phosphate buffers was therefore abandoned.

It was not found possible to keep the isolated guinea-pig uterus alive for any considerable period in borate buffers.

Aeration of the testing bath with O_2/CO_2 mixtures was found to render the uterus preparation very unstable. This was very possibly due to the diffusion of free CO_2 gas into the tissues. On the other hand preadjustment of the bicarbonate balance by the addition of the requisite quantity of hydrochloric acid was found very satisfactory. A similar result could be produced by bubbling CO_2 into the Ringer before use, but more accurately reproducible results could naturally be obtained by adding measured quantities of acid. The actual procedure which was found most satisfactory was to make up a "stock" Ringer solution to the formula given by Dale and Burn [1922], calcium and magnesium chlorides being omitted (a trace of phenol red being added to facilitate subsequent adjustment of p_H). For use the necessary amounts of strong solutions of these salts were added. To the acid Ringer sufficient *N*/10 HCl was added to bring the reaction to approximately p_H 7·15. To the alkaline Ringer sufficient NaCl was added to make $[Cl^-]$ the same as in the acid Ringer.

The acid Ringer so prepared became more alkaline after aeration owing to loss of CO_2 but it was generally found possible to make histamine tests before the reaction had changed significantly, as indicated by the phenol red. It is assumed that, as an average, the more acid histamine tests were carried out at p_H 7·2.

By the use of the two-way tap at the bottom of the testing bath, the latter could be filled with the appropriately buffered solution. When the preparation had become stable a suitable dose of histamine was added as histamine acid phosphate in normal saline in a concentration of 1/50 mg. per ml. When the bath was normally filled the volume of the testing solution was about 80 ml.

The preparation was first sensitised by a dose of histamine more than enough to produce maximum contraction (usually 0·02–0·04 mg.). The difference in response to be expected between p_H 7·2 and p_H 8 is small, the amount of unionised histamine increasing over this range in the ratio of 1/1·3 approximately. The first step therefore was to discover the minimum dose of histamine that would produce a response in alkaline solution. In general this was 0·005–0·01 mg. in 80 ml. Minimum doses were then administered alternately in acid and alkaline media. As the experiment proceeded the sensitivity of the preparation usually altered somewhat and corresponding changes had to be made in the dosage. It was not to be expected that such small differences in response could be demonstrated in every experiment with such a tissue as the excised uterus, or indeed with any biological preparation. In the course of about thirty experiments however no single preparation has consistently given a greater response in acid than in alkaline solutions[1]. In many experiments no difference in response could be detected with certainty; in the majority however there was a definitely greater response to histamine in alkaline media. Tables I and II are protocols of two typical experiments which seemed free from technical fault; one with phosphate buffering and the other in which the reaction was adjusted with hydrochloric acid and in which the minimum dose fortunately was adjusted very exactly.

Table I.

Phosphate buffering; 369 g. guinea-pig.

Test	Histamine vol. solution 1/50 mg. per ml. ml.	p_H	Result
A	0·2	7·8	Large contraction
B	0·2	7·2	No contraction
C	0·2	7·8	Fair response
D	0·4	7·8	Good contracture
E	0·4	7·2	Practically equal to "D"
F	0·4	7·8	Equal to "D" and "E"
	(doses probably too large)		
G	0·3	7·8	Good contracture well maintained
H	0·3	7·2	Some contraction not maintained
J	0·3	7·8	Good contracture, maintained
K	0·1	7·2	Very slight contraction not maintained
L	0·1	7·8	Contracture much greater than "K"
M	0·1	7·2	Smaller contracture less maintained

Table II.

Bicarbonate buffering; 279 g. guinea-pig.

Test	Histamine vol. solution 1/50 mg. per ml. ml.	p_H	Result
A	0·5	8·4	Large contraction
B	0·5	7·2	No response
C	0·5	8·4	Slight contraction
D	1·0	7·2	Fair response, delayed
E	1·0	8·4	Large response
F	1·0	7·2	Slight irregular contraction
G	0·5	8·4	Large contracture
H	0·5	7·8	No response
J	0·5	8·4	Large response delayed
K	0·25	7·2	No response
L	0·25	8·4	Slight response
M	0·25	7·2	No response

---

[1] It is of interest that the most stable preparations have been obtained in the summer months.

DISCUSSION.

It may reasonably be concluded from the results that the guinea-pig uterus shows an increased response to histamine in alkaline solutions, which might be expected if the pharmacological activity of histamine were due to the apolar adsorption of unionised molecules by cell surfaces.

The results of Evans and Underhill who failed to find any difference in the response and those of Hemingway [1926] who finds that the general responsiveness of living tissues is enhanced by alkali *per se* must be considered in the light of the present work. Since it has been observed that the difference in response is so small over the range of reaction in which the tissue may be regarded as in any way normal and can, in fact, only be demonstrated by administering minimum doses, it seems possible that the effect might have escaped the notice of Evans and Underhill entirely owing to the administration of doses in excess of the minimum dose.

Hemingway found that in general, uterus, the plain muscle of blood vessels and intestine in strongly alkaline solutions were pharmacologically hypersensitive. The effect persisted for some time in neutral media and probably depended on an alteration of the internal reaction of the cells, brought about by the large excess of alkali. These conditions are hardly comparable with those of this investigation. Further it was invariably the case that the preparations which I used were less stable and more responsive to purely mechanical stimulation at p_H 7 than at p_H 8, which adds support to the assumption that any increase in response found in alkaline solution must be a property of the stimulating agent rather than of the responding tissue.

It seems therefore that the guinea-pig uterus provides a further example of a tissue which responds to pharmacological reagents in the unionised form and of a tissue of which the cells take up at least some substances by a process of simple apolar adsorption.

In conclusion the author expresses his grateful thanks to Prof. R. A. Peters and Dr A. Hemingway for much valuable advice and to Dr H. M. Carleton for the loan of certain apparatus.

CXXXI. CRYSTALLINE INSULIN.

By DAVID ALYMER SCOTT and ALBERT MADDEN FISHER.

Connaught Laboratories, University of Toronto.

(*Received March 4th, 1935.*)

In a previous communication from these Laboratories [Scott, 1934] attention was directed to the importance of certain metals in the crystallisation of insulin. It was shown that zinc was a constituent of insulin crystals prepared by the pyridine-brucine method of Abel, or by the saponin method of Harington and Scott, and it was found that good yields of crystals were obtained when the chlorides of zinc, nickel, cobalt or cadmium were added to the insulin solution. In fact, it was evident that in cases where the amorphous insulin was free from ash, the addition of one of these metals was essential for the formation of crystals. Moreover, it was suggested that the success of the previously published methods for crystallising insulin depended in part upon the fact that zinc is present in pancreas, in commercial insulin preparations and as an impurity in saponin. We have recently been engaged in the determination of the ash content of samples of insulin crystallised from ammonium acetate buffers to which one of the above metals had been added. The results of this work, together with a discussion of some observations already recorded by one of us (D. A. S.), are presented in the present communication.

In the method of crystallisation previously reported it was shown that insulin crystals can be readily obtained from amorphous preparations of insulin dissolved in phosphate, sodium acetate or ammonium acetate buffers if traces of certain metals are present. There are however a number of minor differences between these buffers which should be borne in mind. In the first place it was found that the addition of about 10 % of acetone to the phosphate or sodium acetate buffers facilitated crystallisation. With ammonium acetate however the best yields of crystals were obtained when the buffer was free from acetone. In fact the addition of this reagent caused the formation of an amorphous, rather than a crystalline, precipitate. Secondly, insulin crystallises best from a phosphate buffer solution at acidities between p_H 6·0 and 6·2 whereas, using ammonium acetate buffer, crystallisation proceeds most readily between p_H 5·8 and 6·0. Thirdly, a phosphate buffer is the most convenient one to use when the work is such that it extends over a lengthy period, in that quantities of this solution can be stored for several months without any change in p_H. Ammonium acetate buffers involve the neutralisation of acetic acid solutions of insulin with ammonium hydroxide; since the strength of the latter solution does not remain constant, considerable manipulation is necessary to reach the requisite acidity of the neutralised insulin solution. Fourthly, insulin crystals prepared by the phosphate buffer method are generally sharper in outline than those separated from an ammonium acetate solution. On the other hand ammonium acetate buffers have a decided advantage over phosphate buffers in the crystallisation of insulin by means of heavy metals in that the former yield crystals of lower ash content; this may perhaps be due to the greater solubility of the acetates of heavy metals as compared with the phosphates. Since it is desirable to have crystalline insulin with as low an ash content as possible, it is therefore advisable to subject the material to a final recrystallisation from ammonium acetate. We have found it convenient to conduct the initial crystallisation of insulin in a phosphate buffer solution containing zinc chloride and acetone, and to recrystallise this material from ammonium acetate without acetone or the further addition of metals. Insulin crystals prepared in this manner have an ash content of 0·65 % when zinc is the metal used to aid in the first crystallisation.

It was previously shown that a large part of the ash could be removed from insulin crystals by precipitating the insulin from aqueous 0·1*N* HCl with the aid of alcohol and ether. Dissolving and reprecipitating the insulin as the hydrochloride a second time however did not materially decrease the ash content. Since zinc chloride is reasonably soluble in acid alcohol, and since a large proportion of the zinc is removed from crystalline insulin by this solvent, it is difficult to understand why an ash-free product is not obtained by this treatment. We recently carried out a great number of experiments to clarify this problem. In this work we dissolved insulin containing 0·7 % ash in various concentrations of hydrochloric acid and precipitated it as the hydrochloride with alcohol and ether, acetone, methylethylketone or dioxan. The ash content of the resultant product was usually 0·2 %. On one lot of crystals an ash content of 0·05 % was regularly obtained when acetone was used. We are at present unable to offer a satisfactory explanation for this phenomenon. It may be that in certain commercial preparations of insulin there is some other metal the chloride of which is not soluble in high concentrations of alcohol and ether, or in acetone. This metal may or may not aid in the formation of insulin crystals. That it is not essential for crystallisation however is shown by the fact that an insulin hydrochloride having an ash content of only 0·02 % crystallises readily in the presence of traces of zinc, nickel, cobalt or cadmium.

In the experiments recorded in the previous paper it was noted that after electrodialysis and precipitation of the insulin as the hydrochloride by alcohol and ether, there was a slight loss in insulin activity. Recent experiments have shown that the loss in activity did not occur during electrodialysis but did occur during the preparation of the insulin hydrochloride. Carr *et al.* [1929] were the first to observe that acid solutions of insulin were inactivated by alcohol and suggested that the inactivation was due to esterification. In our experiments on the precipitation of insulin as the hydrochloride by means of alcohol and ether, it seemed scarcely possible that inactivation was due to esterification since the precipitation of the insulin was effected almost immediately after solution. Nevertheless, to eliminate the possibility of such a reaction, all our recent experiments have been conducted by precipitating the insulin as the hydrochloride by means of acetone or methylethylketone. The acetone was first purified by boiling for 20 hours with potassium permanganate and was then distilled. From a large number of experiments on the precipitation of insulin as the hydrochloride with acetone, varying results have been obtained. In about 60 % of the experiments there was a loss in potency of approximately 15 % during precipitation. In two experiments a 20 % increase in activity was obtained. This material however after being kept in a dry state for 2 months, lost 50 % of its activity. In the remaining experiments no change in activity was detectable. When inactivation occurred, attempts were made to reactivate the insulin with alkali. Some measure of success was attained but the original activity of the crystalline insulin was never secured. These facts again raise the question of the inactivation of insulin with various solvents. We do not believe that it is due to the reducing action of traces of metals since the same insulin can be kept in an aqueous acid solution for several weeks without any loss in activity, nor are we inclined to believe that it is due to esterification since no evidence of such has been found by analytical procedures [Charles and Scott, 1931]. Moreover, inactivation takes place with such solvents as acetone and methylethylketone where esterification is impossible. This inactivation may be due to some molecular rearrangement such as a tautomeric change or to the opening or closing of a ring structure. The proof of such theories however must wait until more is known of the chemical structure of insulin.

The observation was made in the former publication that the insulin after electrodialysis did not flocculate until p_H 6·3 was reached when neutralised with sodium hydroxide. We have verified this observation many times during the past few months and have found that the acidity at which an electrodialysed ash-free product flocculates is between p_H 6·1 and 6·3. Wintersteiner and Abramson [1932–33] found that insulin crystals suspended in *M*/30 sodium acetate buffers are isoelectric at p_H 5·0 and have an isoelectric point of p_H 5·3 as determined by electric mobility experiments using insulin absorbed on quartz in *M*/30 acetate. The difference between the isoelectric point of insulin as found by these authors and the point of maximum precipitation as observed in our experiments may be due to a different concentration of electrolytes. However, another view might be considered. It is possible that after neutralising the dialysed insulin with sodium hydroxide or ammonium hydroxide the amorphous sodium or ammonium salt of insulin is formed. We have repeatedly found that the best acidity for the crystallisation of insulin in the presence of certain metals is between p_H 6·0 and 6·2. If crystallisation is due to the combination of these metals with the free carboxyl groups of insulin, then this process should take place more readily on the alkaline side of the isoelectric point. In other words, crystalline compounds of insulin with various metals should have the characteristics of a substance having an isoelectric point more alkaline than that of the ash-free material. Similarly, if the sodium or ammonium salt of insulin is formed on neutralising a solution of insulin after dialysis, the point of maximum precipitation would be on the alkaline side of the isoelectric point of insulin.

During the past few months a great amount of experimental work has been done on insulin hydrochloride of low ash content. It was felt that should crystalline insulin be a complex compound of two or three chemical entities (such as proteins) bound to each other by combination with a metal, then, after the removal of the metals, there might be a possibility of obtaining a more active insulin by fractional precipitation. Using insulin with an ash content of 0·05 % we have tried fractionation experiments with alcohol and with acetone. This work has been carried out over a wide range of acidities, using either sulphuric acid or hydrochloric acid. Fractionation was also attempted at the isoelectric point with these solvents. In some cases, the solvents were added to insulin solutions which had been made alkaline with sodium hydroxide or with ammonium hydroxide. None of these experiments resulted in a successful fractionation of the insulin.

We have also determined the ash content of insulin crystals formed by the recrystallisation of an ash-free insulin. The metals used were zinc, cadmium and cobalt. The experimental work is presented in detail below.

EXPERIMENTAL.

For the purposes of this research, a large quantity of crystalline insulin was prepared. The first crystallisation was conducted in a phosphate buffer solution containing zinc chloride. The crystals were removed, washed and dried and then recrystallised from ammonium acetate at room temperature without acetone or the further addition of metal. The final product had an ash content of 0·7 % and contained 25 I.U. of insulin per mg.

From this material an ash-free insulin was obtained by the following treatment. 0·5 g. of the crystals was placed in each of two 250 ml. centrifuge-tubes. To each tube were added 10 ml. of 0·1 N HCl. As soon as the crystals had dissolved, 200 ml. of acetone were added to each. The insulin readily precipitated. The tubes were placed in a refrigerator for 2 hours. The mixtures were then centrifuged, the acetone decanted and the precipitates combined by immediately dissolving them in 500 ml. of water containing 2 ml. of N HCl. The solution was then transferred to a litre beaker and electrodialysed using the type of apparatus formerly described. The solution in the beaker was vigorously stirred with a mechanical stirrer. Dialysis was continued for 1¼ hours, during which time 35 litres of acid water, p_H 2·3, circulated through the thimbles. After the completion of dialysis, the solution was filtered into a 600 ml. beaker and very slowly neutralised with N NH_4OH until maximum precipitation was reached. The mixture was placed in the refrigerator overnight. The supernatant liquid was then decanted and the precipitate centrifuged in a 250 ml. tube. The clear solutions were combined and the p_H was determined and was found to be 6·2. The precipitated insulin was then dissolved in 15 ml. of 0·1 N HCl. After the addition of 100 ml. of acetone, the solution was divided into two equal parts and the insulin was precipitated by adding 150 ml. of acetone to each sample. The mixtures were then placed in the refrigerator overnight. After centrifuging, the supernatant liquids were discarded and the precipitates dried *in vacuo*. Samples of the dried insulin hydrochloride were then removed for ash estimations which gave the values of 0·01 and 0·03 %. The test for zinc was faintly positive. A physiological assay in which 300 mice were used showed that the material contained 23 I.U. per mg. From this material the various crystalline metallic salts were prepared and their respective ash contents were determined.

Samples of this ash-free insulin hydrochloride were crystallised by means of various metals from ammonium acetate. Ammonium acetate was chosen in preference to phosphate buffer for reasons already stated. Acetic acid, which yielded no residue on evaporation, and freshly distilled ammonium hydroxide were used to prepare $N/3$ solutions. 100 mg. of the insulin powder were weighed into a dry beaker and 50 ml. of $N/3$ acetic acid were added. After the insulin had dissolved, 5 ml. samples of the solution were measured into each of ten 15 ml. centrifuge-tubes previously treated with cleaning solution and washed several times with distilled water. 0·1 ml. of 0·5 % $ZnCl_2$ was added to each sample. The acidity was adjusted to approximately p_H 5·9 with $N/3$ NH_4OH. The tubes were inverted to ensure thorough mixing (but were not scratched) and kept at room temperature for 2 hours. They were then put in the refrigerator overnight. At the same time a control tube was prepared containing 0·5 ml. of the zinc chloride solution in the same volume of buffer, but no insulin. The following morning each tube except the control contained well-defined crystals. About 5 ml. of each supernatant liquid were decanted and the precipitates from every two tubes mixed, centrifuged and the supernatant liquids discarded. The five crystalline precipitates thus obtained were allowed to drain for 15 minutes by inverting the tubes over filter-paper. 2 ml. of distilled water were then measured into each tube and the crystals washed by gentle shaking. After centrifuging, the tubes were allowed to drain for 15 minutes over filter-paper. This washing process was repeated three times; during this washing, any amorphous material was carefully removed from the crystals. After the final washing and draining, the precipitates in each of the five tubes were dried *in vacuo*, and the ash content of each sample was determined. These values are reported in Table I.

Table I. *Ash estimations of zinc-insulinate.*

Weight of crystals mg.	Weight of ash (ZnO) mg.	ZnO %		Zn %
8·09	0·048	0·60		0·48
8·92	0·060	0·67		0·54
12·31	0·089	0·72		0·58
7·71	0·050	0·65		0·52
7·84	0·043	0·55		0·44
10·61	0·070	0·70		0·56
			Mean	0·52

The insulin crystals which were formed with cadmium and cobalt were prepared in a similar manner except that 0·1 ml. of 0·5 % $CdCl_2$ or 0·1 ml. of 0·5 % $CoCl_3$ was added to each tube instead of the zinc chloride. The crystals were washed as previously described. The ash contents are shown in Tables II and III.

Table II. *Ash estimations of cadmium-insulinate.*

Weight of crystals mg.	Weight of ash ($CdSO_4$) mg.	$CdSO_4$ %		Cd %
8·14	0·118	1·45		0·78
8·49	0·113	1·33		0·72
6·88	0·104	1·51		0·81
			Mean	0·77

Table III. *Ash estimations of cobaltous-insulinate.*

Weight of crystals mg.	Weight of ash (Co_3O_4) mg.	Co_3O_4 %		Co %
5·40	0·033	0·61		0·45
7·91	0·049	0·62		0·46
8·01	0·044	0·55		0·41
			Mean	0·44

Further quantities of crystalline insulin were prepared in the manner described above, using zinc chloride. After washing and drying, a sample of the material was removed and found to contain 0·7 % ash. The remainder was recrystallised from an ammonium acetate buffer without further addition of metal. The ash of this material was also 0·7 %.

Ash determinations were made by burning a known weight of the crystals in a current of oxygen [Emich-Schneider, 1932]. Difficulty was encountered in determining cadmium as the oxide because of the volatility of this substance. Hence it was estimated as the sulphate by adding one or two drops of strong sulphuric acid to the sample before ashing. The ash from the zinc experiments gave a negative chloride test.

We have also determined the nitrogen contents of a number of samples of insulin crystallised from phosphate and from ammonium acetate buffers using zinc chloride. A series of eight samples of crystals was prepared from sodium phosphate and a similar series from ammonium acetate. In the former series, the buffer was neutralised with $N/3$ NaOH instead of NH_4OH. After centrifuging, the crystals were washed and dried as already described. The average of eight estimations on each series showed that the crystals isolated from the phosphate buffer contained 14·0 % N while those prepared from the ammonium acetate buffer contained 14·7 % N.

DISCUSSION.

From a quantity of insulin hydrochloride having an ash content of 0·02 % and containing 23 I.U. per mg., several crystalline preparations of insulin were made. Crystallisation of the insulin was conducted in an ammonium acetate buffer solution containing traces of either zinc, cobalt or cadmium. All the crystals had the same microscopic appearance. The ash contents of the various kinds of crystals are reported in Tables I, II and III, from which it will be observed that the agreement between the ash values of different preparations of the same insulin salt is within the limits of experimental error and further that the percentage of ash varies with the metal used to aid in the crystallisation of the insulin.

The problem of the formula weight of insulin has been discussed by at least two groups of workers. Basing their estimate on data obtained by chemical treatment, Freudenberg and Dirscherl [1931] have advanced the suggestion that the formula weight of insulin may be 10,000 or 20,000. Accepting the latter figure, and using the data of Tables I, II and III in the present paper, a simple calculation shows that each formula weight of insulin contains 1·6 formula weights of zinc, 1·4 formula weights of cadmium or 1·5 formula weights of cobalt. If however we assume double the value suggested by these authors, then the metallic content of the crystals, in formula weights, can be expressed as whole numbers within the limits of experimental error. Using the ultracentrifuge, Svedberg [1931] estimated the formula weight of insulin to be 35,100. However, our knowledge of the chemistry of insulin may still be advanced without having an exact value for its formula weight.

Crystalline preparations of insulin containing either zinc, cadmium or cobalt have been described in this paper. It was found that the ash content of each sample was proportional to the formula weight of the metal which it contained. Furthermore, this ash value seemed to be characteristic in that it was not decreased by recrystallisation. These facts suggest that the metal occurs as a chemical constituent of the crystals and not merely as an impurity. The manner in which each metal is combined cannot however be decided. One might advance the suggestion that a metallic salt had been formed through the carboxyl groups. The large proportions of the dibasic amino-acids, glutamic acid and cystine in this hormone [Jensen and Wintersteiner, 1932] seem to bring this idea within the realm of possibility. If the formula weight of insulin is 40,000, the metallic content of the crystals could account for six carboxyl groups. This represents but a small number of the possible free carboxyl groups from the dibasic acids in insulin. On the other hand, the formation of protein salts through free carboxyl groups has been questioned by Robertson [1924]. The tendency of zinc, cadmium and cobalt to form many complex salts with amines should not be overlooked. There also remains the possibility of formation of a ring structure by combination of these metals with both amino- and carboxyl-groups.

In our work on the crystallisation of insulin it was found that crystals prepared from an ammonium acetate buffer had a higher nitrogen content than those obtained from a sodium phosphate buffer. In the past this fact has been attributed to traces of ammonium acetate adhering to the crystals. However, since repeated washing of the crystals failed to decrease the nitrogen content, we are inclined to believe that the nitrogen is chemically combined. Here again, combination through carboxyl groups could be suggested. It is also reasonable to suppose that the ammonia has formed a molecular complex with the metal in the insulin, for it is well known that certain salts of cobalt form as many as six molecular complexes with ammonia.

SUMMARY.

A quantity of insulin hydrochloride having an ash content of only 0·02 % was prepared. Different samples of this insulin were crystallised from an ammonium acetate buffer solution by means of zinc, cobalt or cadmium. Ash estimations made on different samples of the crystalline products showed constant values for the respective metals. Further, the average ash content of each insulin salt was proportional to the atomic weight of the metal which it contained. This fact strongly indicates that crystalline insulin contains the metals as chemically combined constituents and not as impurities. The percentage ash values are discussed in respect to certain observations regarding the chemistry of insulin. The crystallisation of insulin and certain other aspects of earlier work on this problem are also considered.

CXXXII. ZINC CONTENT OF BOVINE PANCREAS.

By ALBERT MADDEN FISHER and DAVID ALYMER SCOTT.

Connaught Laboratories, University of Toronto.

(*Received March 4th, 1935.*)

In a recent publication from these Laboratories, data were presented concerning the relative quantities of insulin which could be extracted from the pancreas of cows and calves of various age groups [Fisher and Scott, 1934]. It was found that the yield of insulin per kg. of young foetal pancreas was about twenty times greater than that of the pancreas of old cows. It has also been shown that certain metals have a very close association with insulin in that traces of zinc, nickel, cobalt or cadmium facilitated the crystallisation of this hormone [Scott, 1934]. Further, commercial preparations of insulin and also insulin crystals prepared by the brucine or saponin methods gave positive tests for zinc. These facts suggested that certain of the metals might be associated with insulin in the pancreas. If such were the case, it would be of interest to determine the quantity of each of these metals in bovine pancreas of various age groups and to correlate the values, if possible, with the amount of insulin found in the pancreas of similar age groups. An investigation of this problem is reported in the present paper.

Many workers have reported the occurrence of zinc in the pancreas of various species [Lutz, 1926; Delezenne, 1919]. The presence of cobalt and nickel is also the subject of other communications [Bertrand and Macheboeuf, 1926]. None of these researches however was performed with reference to the age of the animals from which the pancreas was obtained.

In the present work it was decided to determine the relative quantities of cobalt and nickel in various samples of pancreas by means of some of the well-known colour tests for these metals. Zinc could be determined either by the fluorescence method of Lutz or gravimetrically in the manner outlined by Delezenne. In view of the difficulty of securing a sufficient quantity of satisfactory stercobilin used in the former method, it was decided to follow the procedure described by Delezenne. Moreover, this method obviates the necessity of dry ashing—a feature which has often been criticised on the ground of the possible loss of zinc by volatilisation.

EXPERIMENTAL.

The pancreatic glands were removed from cattle of the following age groups: hairless foetal calves, under 5 months; haired foetal calves, 5–7 months; calves, 6–8 weeks; and cows, 9 years and over. In the older age groups, the glands from at least 10 animals were minced and an aliquot was removed for the investigation. For the foetal groups, it was necessary to collect the glands from a much larger number in order to obtain samples of sufficient size for the determinations. The glands in each group were minced, weighed and kept *in vacuo* over concentrated sulphuric acid for several days. After the tissue had been thoroughly dried, the glands were weighed again. For the determinations, 15 or 20 g. samples of this material were placed in 500 ml. Erlenmeyer flasks.

The procedure used in the estimation of the metallic content of each of these weighed samples was as follows. A solution of equal parts of concentrated sulphuric and nitric acids was added dropwise to the tissue, using about 1 ml. for each g. of tissue. The flask was shaken and very gently heated until copious fumes were formed. After cessation of fuming, the heating was resumed and concentrated nitric acid added dropwise. Vigorous heating and the addition of nitric acid were continued until a pale yellow solution was obtained. This was poured into a small porcelain evaporating dish and evaporated to dryness. Washings from the original flask were added from time to time. The dry white residue was intimately mixed with about 10 ml. of concentrated hydrochloric acid and then evaporated to dryness. The residue was again stirred with 10–15 ml. of concentrated hydrochloric acid and washed into a 15 ml. centrifuge tube. After centrifuging the supernatant liquid was measured and poured into a 50 ml. beaker. The spot tests described by Feigl [1931] for cobalt and nickel were conducted on this solution. For the former metal we used the various modifications of tests with α-nitroso-β-naphthol. Dimethylglyoxime tests described by Feigl were used for nickel. With all samples of pancreas used in this investigation, tests for cobalt and nickel were negative. As a control, drops of the various reagents were added to one drop of a solution containing 0·015 mg. of nickel per ml. or 0·030 mg. of cobalt per ml. One drop of such a standard solution contained sufficient nickel or cobalt to give a strongly positive test, either when the test was conducted directly upon the standard solution acidified with one drop of concentrated hydrochloric acid or when one drop of the standard was mixed with one drop of the unknown solution.

Upon completion of the spot tests for cobalt and nickel, the procedure for the determination of zinc was resumed. The unknown solution in the beaker was gently boiled until the volume had been decreased to about 5 ml. After adding an equal volume of water, the acid solution was poured slowly into 40 % of its volume of concentrated ammonium hydroxide—sufficient to render the mixture distinctly ammoniacal. About 3 ml. of a suspension of calcium hydroxide and a few drops of "superoxol" were added. After standing for a few hours, the mixture was centrifuged and the supernatant liquid decanted into a 200 ml. flask. The precipitate was dissolved in concentrated hydrochloric acid and reprecipitated with ammonium hydroxide. After centrifuging, the supernatant liquid was added to that from the first precipitation. This solution was boiled and a suspension of calcium hydroxide was added from time to time, until the evolution of ammonia could not be detected by moist litmus paper, even when the solution itself was distinctly alkaline. The mixture was centrifuged in a 50 ml. pointed centrifuge-tube and the precipitate washed with distilled water. The precipitate was then dissolved in hydrochloric acid, using a sufficient quantity to ensure that the final solution contained 5–10 % hydrochloric acid. The solution was saturated with hydrogen sulphide, the tube stoppered and kept overnight. After centrifuging, the supernatant liquid was transferred to a small porcelain dish and evaporated to dryness. The residue was stirred thoroughly with four 10 ml. quantities of a 10 % solution of ammonium acetate acidified with glacial acetic acid. The clear solution was then transferred to a 50 ml. pointed centrifuge-tube and the zinc precipitated by saturation with hydrogen sulphide. The tube was stoppered and kept for 3–4 days. The mixture was then centrifuged and the white precipitate of zinc sulphide dissolved in a few ml. of concentrated sulphuric acid. This solution was slowly evaporated to dryness on a weighed platinum dish. Strong heating was avoided in order to eliminate the possible decomposition of the zinc sulphate noted by Delezenne.

From the weight of the residue—zinc sulphate—the amount of zinc per kg. of pancreas was calculated. Similar determinations were carried out for each age group. The values are recorded in Table I.

Table I. *Zinc content of bovine pancreas.*

Description of animal	Pancreas		Zinc per kg. dry tissue mg.	Zinc per kg. wet tissue mg.	Insulin per kg. wet tissue* I.U.
	Wet weight g.	Dry weight g.			
Cows	500	130	57	15	1,800
(9 years and over)			80	21	
			60	16	
Calves	200	56	90	25	11,400
(6–8 weeks)			75	21	
Foetal calves	370	94	55	14	23,000
(haired, 5–7 months)			70	18	
			75	19	
Foetal calves	155	33	153	33	33,200
(hairless, under 5 months)					

* Fisher and Scott [1934].

DISCUSSION.

The zinc content of bovine pancreas, reported in Table I, shows no relation between the age of the cattle and the metallic content of the glands. The pancreas was found to contain about 20 mg. of zinc per kg. of fresh tissue. This value is in agreement with that reported by Delezenne. The fact that there is no simple relation between the zinc content and the amount of insulin which can be extracted from the glands is not surprising when it is remembered that crystalline zinc insulinate contains only 0·5 % zinc. There is thus in the pancreas many times the quantity of zinc necessary to account for the available insulin in the pancreas as the zinc salt.

The fact that the presence of nickel and cobalt was not detected in the pancreas of cattle of any age group may mean that only traces of these metals are present and that the amount is beyond the sensitivity of our method. Bertrand and Macheboeuf [1926] reported 0·715 mg. of nickel and 0·357 mg. of cobalt per kg. of dried ox pancreas. Although there is a wide difference between some of the values reported by them for ox pancreas, there is no significant difference between the quantity of these metals in ox pancreas and that found in calves' pancreas. Their values were obtained by comparing the weight or colour of the compounds which these metals form with dimethylglyoxime in their unknown solutions with the weight or colour formed by a known quantity of nickel or cobalt with the same reagent. They used samples of approximately 200 g. In our work it would be rather difficult to obtain sufficient foetal pancreas to conduct duplicate determinations with this size of sample. In view of the fact that, in the present investigation, tests for these metals were positive when a drop of the standard nickel or cobalt solution was added to the unknown solution, our inability to detect these metals in the pancreas was not due to the presence of an interfering substance.

SUMMARY.

Bovine pancreas was found to contain about 20 mg. of zinc per kg. of fresh tissue, irrespective of the age of the animal from which the gland was obtained. The quantity of insulin which can be extracted from bovine pancreas bears no simple relation to the amount of zinc contained in the glands. Cobalt and nickel were not detected in the pancreas.

The authors wish to express their thanks to Canada Packers, Toronto, for their assistance and to the Federal Inspectors of the Department of Agriculture for making a careful estimation of the age of the cattle.

CXXXIII. THE EFFECT OF HALOGEN SALTS ON THE CLOTTING OF MILK BY TRYPSIN.

By WINIFRED MARY CLIFFORD.

From the Physiology Department, King's College of Household and Social Science, Campden Hill Road, W. 8.

(*Received March 12th, 1935.*)

Whilst working on the effect of halogen salts on steaptic digestion [Clifford, 1934], it was noticed that many of them enabled trypsin to coagulate milk. Since such a function is generally ascribed to Ca alone, it was decided to carry out further experiments.

Mellanby [1912] investigated the coagulation of milk by trypsin but added $CaCl_2$ in nearly all his experiments; he also compared the action of the latter with those of $MgCl_2$ and $BaCl_2$, finding that they also increased the milk clotting activity, though in a less degree than did the Ca salt.

In the same year Mellanby and Woolley [1912] stated that enzymes acting in an alkaline medium, *e.g.* trypsin, need extra Ca to produce typical coagula in milk.

This idea was followed up by Seth [1924] who used $CaCl_2$-milk to investigate tryptic activity, and still later Kleiner and Tauber [1934, 1, 2] found the clotting of $CaCl_2$-milk to be a function of low concentrations of crystalline trypsin. They did not try the effect of adding any other salt.

Experiments were therefore made to determine the effect of various halogen salts on tryptic clotting.

Experimental.

The method used was that described in a previous paper [Clifford, 1927] on the effects of halogen salts on peptic milk clotting.

10 ml. of milk and 2 ml. of water, or halogen salt solution of the requisite concentration, were warmed to 37°. To this mixture was added 1 ml. of a 2 % solution of pancreas substance. The tube was inverted to mix, and the time of clotting was determined by means of a stop-watch.

An average of the times of clotting of six tubes was taken for each concentration of salt used, and in no set of six was the difference greater than 10 seconds.

Three separate batches of commercial pancreas substance (2 powdered and 1 liquid) and at least two separate samples of each halogen salt were used in the experiments described.

The amount of halogen salt varied from 2 ml. of 3·24 *M* to 2 ml. of 0·05 *M*, each dilution being twice that of the previous one. Since the total volume in a tube was 13 ml. the concentrations of salt in the tubes varied from 0·5 to 0·008 *M*. With the alkaline earth halogen salts the dilutions were continued down to 0·001 *M*.

Results.

No firm coagulum was ever obtained on the addition of 1 ml. of 2 % pancreas substance to 10 ml. of milk and 2 ml. of water, and in practically every case the appearance of the mixture remained unaltered. With three samples of milk there was a fine granulation in the tube after keeping it at 37° for 30 minutes but never a definite coagulum. Probably these three samples of milk had a high content of calcium, chloride, or both.

Fluorides (Table I). The fluorides of Na, K and NH_4 at higher concentrations of salt (0·5–0·06 *M*) gave a definite coagulum with trypsin and milk. The acidity of the ammonium salt was sufficient to curdle the milk, and therefore, before using it in an experiment it was neutralised with anhydrous sodium carbonate.

Table I. *Fluorides.*

Concentration *M*	Time to produce clot		
	Na	K	NH_4
0·5	—	1 min. 41 secs.	4 mins. 13 secs.
0·25	—	2 mins. 55	4 10
0·125	4 mins. 18 secs.	3 48	4 10
0·06	4 27	4 37	5 18
0·03	No clot in 45 mins.	No clot in 1 hr. 10 mins.	No clot in 1 hr. 5 mins.
0·015	”	”	”
0·008	”	”	”
Standard	No clot in 1½ hrs.	No clot in 1 hr. 18 mins.	No clot in 2 hrs.

Below a concentration of 0·06 *M* the three fluorides did not give rise to a clot with milk and trypsin.

Chlorides (Table II). Li, Na, K and NH_4 chlorides all cause trypsin to coagulate milk, when added in concentrations of 0·5–0·008 *M*. With the chlorides of Mg, Ca and Ba, similar results were obtained, but the clotting time was shortest between 0·06 and 0·015 *M*; above and below these limits the action was marked, but less powerful.

Table II. *Chlorides.*

Concentration *M*	Time to produce clot			
	Li	Na	K	NH_4
0·5	1 min. 59 secs.	1 min. 26 secs.	1 min. 7 secs.	1 min. 1 sec.
0·25	1 54	1 17	1 8	0 53 secs.
0·125	1 53	1 25	1 13	0 57
0·06	2 mins. 14	1 44	1 29	1 12
0·03	2 53	2 mins. 15	2 mins. 8	1 33
0·015	3 52	2 57	2 59	2 mins. 22
0·008	5 2	4 27	4 29	4 38
Standard	No clot in 1 hr. 30 mins.	No clot in 2 hrs.	No clot in 1 hr. 30 mins.	No clot in 1 hr. 20 mins.

Concentration *M*	Time to produce clot		
	Mg	Ca	Ba
0·5	1 min. 38 secs.	1 min. 17 secs.	—
0·25	1 4	0 55	—
0·125	0 48	0 34	0 min. 53 secs.
0·06	0 38	0 26	0 37
0·03	0 38	0 26	0 29
0·015	0 49	0 36	0 37
0·008	1 8	0 57	0 58
0·004	1 37	1 24	1 25
0·002	2 mins. 25	2 mins. 5	2 mins. 20
0·001	4 10	3 40	4 21
Standard	No clot in 2 hrs.	No clot in 1 hr. 30 mins.	No clot in 1 hr. 45 mins.

The alkaline earth chlorides showed greater power to aid coagulation than did those of Li, Na, K and NH_4, but not to the extent previously noted with peptic clotting [Clifford, 1927].

There was no great difference between members of either group of chlorides in their capacity to aid tryptic coagulation, though $MgCl_2$ was rather less powerful in its action than $BaCl_2$ or $CaCl_2$.

0·001	No clot in 30 mins.	No clot in 45 mins.	No clot in 1 hr. 25 mins.
Standard	No clot in 1 hr. 8 mins.	No clot in 2 hrs. 40 mins.	No clot in 1 hr. 5 mins.

Bromides (Table III). The results are similar to those obtained with chlorides, except that Li and Na bromides were inactive at a concentration of $0{\cdot}008M$.

Again the salts of Mg, Ca and Ba were less powerful at the highest concentration ($0{\cdot}5M$) and at the lower concentrations ($0{\cdot}008$–$0{\cdot}001M$), and $MgBr_2$ gave a less marked effect than $CaBr_2$ or $BaBr_2$.

Iodides (Table IV). Iodides also show a marked effect in enabling trypsin to clot milk. This action is not quite so powerful as that of the chlorides and bromides, since the salts of Li, Na, K and NH_4 show no effect at $0{\cdot}008M$, and those of Mg, Ca and Ba are inactive at $0{\cdot}001M$.

The slight inhibitory action of the high concentrations of the Mg, Ca and Ba salts is again marked, together with the less effective action of MgI_2 as compared with the other two iodides.

DISCUSSION.

All the halogen salts investigated enable trypsin to coagulate milk, irrespective of the cation. The reaction was least marked with the fluorides which showed no effect at concentrations below $0{\cdot}06M$. The chlorides and bromides of the alkaline earths caused trypsin and milk to form a coagulum in a concentration as low as $0{\cdot}001M$, but the iodides needed a concentration of $0{\cdot}002M$. At the highest concentrations used ($0{\cdot}5M$) the coagulating aid of the Li, Na, K and NH_4 halogen salts was as powerful as that of Mg, Ca and Ba, but the latter were more effective at concentrations below $0{\cdot}125M$.

From these results it seems that the acceleration of tryptic activity in clotting milk so often noticed when $CaCl_2$ is added is quite as much a function of the Cl as of the Ca, and that the addition of any other soluble halogen salt would be equally effective over a wide range of concentrations.

This accords with the theory of Kleiner and Tauber [1934, 2] who state that the clotting of milk by trypsin is due to a depression of proteolytic action, thus allowing the casein stage to show, since in a previous paper [Clifford, 1933] it has been shown that the halogen salts of Li, Na and K tend to depress the proteolytic action of trypsin.

This is not, however, a full explanation, since the fluorides are the greatest depressors of proteolytic action and are at the same time the least active in promoting milk coagulation, and the concentration of bromides at which no appreciable effect on proteolytic activity can be seen is considerably higher than that at which no effect on milk coagulation is demonstrable.

SUMMARY.

1. Milk does not give a firm clot with trypsin.

2. If the halogen salts of Li, Na, K, NH_4, Mg, Ca or Ba be added to milk it gives a firm clot with trypsin.

3. This coagulating action is least with fluorides (ceases at $0{\cdot}03M$).

4. The halogen salts of the alkaline earths are only slightly more efficient than those of Li, Na, K and NH_4.

5. At concentrations above $0{\cdot}25M$ the halogen salts of Mg, Ca and Ba are less effective than at concentrations between $0{\cdot}125$ and $0{\cdot}015M$.

6. The Mg salts are less powerful than those of Ca or Ba in promoting the clotting of milk by trypsin.

The expenses of this research were defrayed by a grant from the Medical Research Council.

CXXXIV. VITAMIN A-ACTIVE SUBSTANCES IN EGG-YOLK.

BY ALBERT EDWARD GILLAM AND ISIDOR MORRIS HEILBRON.

From the Chemistry Department, Manchester University.

(*Received March 16th, 1935.*)

ALTHOUGH biological experiments by numerous workers have shown that egg-yolk exhibits the growth-promoting properties usually associated with vitamin A, no wholly satisfactory explanation of the source of this activity has yet been advanced.

The presence of carotene in egg-yolk was first suggested by Willstätter and Escher [1911], being later confirmed by Kuhn and Brockmann [1932] in several varieties of hen's eggs, whilst the detection of vitamin A itself was claimed by Euler and Klussman [1932; 1933] using the antimony trichloride blue test as a criterion. As, however, these last authors were unable to detect with certainty the absorption band at 328 $m\mu$ characteristic of vitamin A, and as no details were given of any steps taken to remove xanthophylls before applying the antimony trichloride blue test, the results need confirmation. The detection of vitamin A in egg-yolk presents some difficulty on account of the smallness of the gross vitamin A activity (some of which is due to carotene), and the large amounts of lutein and zeaxanthin normally present in the yolk. As both of these latter substances absorb ultra-violet rays near 328 $m\mu$ and also give blue colours with antimony trichloride qualitatively similar to that given by vitamin A, the two main criteria for the vitamin are seriously interfered with unless a separation from the carotenoids is first obtained.

EXPERIMENTAL.

Vitamin A. In a preliminary experiment designed to detect the presence of vitamin A in egg-yolk the following procedure was tried. The gross unsaponifiable matter of thirty egg-yolks, after removal of sterols, was dissolved in light petroleum and about 10 mg. of a genuine vitamin A concentrate were added to one-half of the solution, whilst the other was left untouched. Both extracts were carefully treated with animal charcoal until the yellow colour of the carotenoids was just removed. Each solution was filtered and evaporated *in vacuo*, the residue being dissolved in chloroform and tested for vitamin A both by means of its ultra-violet absorption spectrum and by the antimony trichloride blue test. Whilst the genuine egg extract failed to give any positive data for the vitamin by either test, the one containing added vitamin A gave definite evidence of its presence. The conclusions to be drawn from this experiment are either that egg-yolk contains no vitamin A, or that, if present at all, the amount must be so small that a much finer method of separation is needed to detect it. With this object in view the following alternative procedure was adopted. The yolks of 60 eggs were mixed with anhydrous sodium sulphate and completely extracted with ether. After saponification of the extract with alcoholic potash the unsaponifiable portion was taken up in ether and the solvent-free residue crystallised from methyl alcohol. The sterols (18 g., M.P. 147°) were filtered off and the carotenoids transferred to light petroleum (B.P. 70–80°), the solution then being extracted 10–15 times with 90–92 % methyl alcohol. In this manner a light petroleum phase (A) containing only the carotenes [Kuhn and Brockmann, 1932] and a methyl alcoholic phase (B) containing the lutein, zeaxanthin and the major part of the vitamin A [Wolff *et al.*, 1930] were obtained. The constituents of B were again transferred to light petroleum (B.P. 40–60°), washed with water, dried and adsorbed on a column of calcium carbonate. The chromatogram was developed with petroleum-ether-benzene, a procedure whereby the xanthophylls would remain on the column while any vitamin A would pass through unadsorbed [Karrer and Schöpp, 1932]. The filtrate was evaporated *in vacuo* and the residue taken up in chloroform. On spectroscopic examination the solution exhibited a definite absorption band at 328 $m\mu$, whilst with antimony trichloride in chloroform a blue colour was obtained showing an obvious 618 $m\mu$ band together with the usual masked band at 583 $m\mu$ [Castle *et al.*, 1934]. The vitamin A in this particular batch of eggs was of the order of 0·05 mg. per 100 g. of yolk, and is probably lower than normal as the eggs were obtained from hens fed on a heavy maize ration, the yolks being paler than usual. In the yolks produced by hens on a richer grass diet approximately twice this amount of vitamin was found to be present. These experiments therefore provide definite confirmatory proof of the claim of Euler and Klussmann [1932; 1933] that vitamin A occurs in egg-yolk.

The carotene fraction. The dried light petroleum solution (A) obtained in the phase separation was passed through an alumina column and washed down with light petroleum. The resulting chromatogram indicated the presence of more than one carotenoid, usually as a broad yellow-brown zone near the top, a strong yellowish ring below and a weak pink-brown ring lower still. Each ring was separately eluted with methyl alcohol and spectroscopically examined, with the result that they were found to exhibit absorption maxima identical with each other and with those of authentic β-carotene. The slight difference in their adsorption behaviour suggests that the upper yellow-brown ring is due to kryptoxanthin [Kuhn and Grundmann, 1933] whilst the lower one is due to the typical

Table I. *Alumina adsorption of "carotene" fractions from the egg-yolks of maize-fed hens.*

	Zone 1	Zone 2	Zone 3
Colour of adsorbed pigment	Brownish yellow	Strong yellow-brown with bright yellow background	Several weak pink bands
Location in column	Very near the top	Lower down than 1	Below 2
Absorption spectrum of the pigment in light petroleum (B.P. 70–80°)	Indefinite	Bands at 478 and 450 $m\mu$	Bands at 480 and 451 $m\mu$
Phase tests:			
1. Petroleum and 90 % CH_3OH	Mainly alcohol-phasic	Wholly petroleum-phasic	Wholly petroleum-phasic
2. Petroleum and 95 % CH_3OH	Mainly alcohol-phasic	Partly alcohol-phasic	
Adsorption on $CaCO_3$	Held strongly	Weakly adsorbed as a yellow band	Unadsorbed
Nature of pigment	Xanthophylls *plus* oxidation products	Kryptoxanthin	Carotene
Relative amounts present	—	13	1

β-carotene. The presence of the former carotenoid in egg-yolk is almost certainly attributable to the ingestion of maize, which contains kryptoxanthin [Kuhn and Grundmann, 1934] in addition to zeaxanthin [Karrer *et al.*, 1929]. The presence of kryptoxanthin in egg-yolk was suggested as a possibility (although not submitted to test) by Brockmann and Völker [1934] to explain the relatively high values obtained by Euler and Klussmann [1933] for the carotene content of of egg-yolk.

In order to confirm, if possible, the occurrence of kryptoxanthin in egg-yolk we obtained eggs from hens specially fed on a rich maize diet, and extracted 60 yolks according to the above scheme. In this case the adsorption column exhibited three main coloured zones, the characteristics of which are given in Table I. These results and a comparison with authentic kryptoxanthin extracted from *Physalis* by the method of Kuhn and Grundmann [1933] confirm the presence of this pigment. A further comparison of the kryptoxanthin with lutein and β-carotene shows that its adsorption affinity is intermediate between those of these two substances, as its constitution and observed properties would lead one to expect.

Quantitative evaluation of the pigments in several batches of eggs gave the results shown in Table II.

Table II.

Batch no. ...	1	2	3	4	
No. of eggs	60	17	24	24	
Diet of hens	Heavy maize ration	Grass	No grass	Grass	
Total carotenoids	2·0	4·2	4·4	11·0	mg. per 100 g. yolk
Kryptoxanthin	0·19	0·14	0·013	0·17	
Carotene	0·015	0·02			
Vitamin A	Order 0·05	Order 0·10	—	—	
% kryptoxanthin in total carotenoids	9·5	3·3	—	—	

It is thus evident that the "carotene" fraction of egg-yolk consists largely of kryptoxanthin, which is remarkably similar in properties to β-carotene and easily mistaken for it.

SUMMARY.

Using chromatographic methods with spectroscopic control an examination has been made of the unsaponifiable matter of egg-yolk with a view to elucidating the cause of its growth-promoting activity. After a phase test separation of the carotene from the xanthophyll, followed by adsorption of the latter on calcium carbonate, it has been possible to obtain the vitamin A free from carotenoids and to confirm its presence both by the antimony trichloride blue test and by the characteristic absorption band at 328 $m\mu$. The petroleum-phasic carotenoids have also been examined and found to consist of kryptoxanthin and β-carotene. By feeding fowls on a diet rich in maize it has been found possible to increase the kryptoxanthin content of the resulting egg-yolks, although the final value for the content of this vitamin A-active carotenoid in egg-yolk is still very small (order 0·2 mg. per 100 g. yolk).

We are indebted to Dr S. J. Watson and Mr W. S. Ferguson, of Messrs Imperial Chemical Industries Ltd. Research Station, Jealotts Hill, for the collection and preparation of the egg samples.

CXXXV. THE STARCH AND RELATED POLYSACCHARIDES OF CERTAIN HARDWOODS.

I. THE PREPARATION AND PROPERTIES OF OAK AND WALNUT STARCH.

By WILLIAM GEORGE CAMPBELL.

From the Section of Chemistry, Forest Products Research Laboratory, Princes Risborough, Bucks.

(*Received March 18th, 1935.*)

So far as it can be ascertained the presence of starch in the parenchymatous cells of certain hardwoods has never been doubted. At the same time it is frequently admitted that the methods which have been used for its quantitative estimation are in the main unsatisfactory. Further it would appear that the polysaccharide itself has never actually been isolated from woody tissues and subjected to detailed chemical examination. In connection with the biological work [Fisher 1929], which has been in progress in this Laboratory for some years on the feeding habits of *Lyctus* powder-post beetles, it was shown [Campbell, 1929] that the larvae of this insect which bore in the sapwood of oak derive their nourishment from cell contents. Mer [1903] had already indicated that wood which is depleted of its starch is not attacked by *Lyctus canaliculatus* and *Anobium* sp. and this has recently been confirmed by Wilson [1933].

The importance of this biological work has rendered it desirable to enquire into the composition and properties of wood starch, and, if possible, to find reliable methods both of removing it from wood in commercial sizes and of estimating it quantitatively in experimental material. The substance is readily detected in woody tissues by means of iodine-potassium iodide solution, but in view of the absence of knowledge concerning its composition and properties a method has had to be developed for isolating it quantitatively from sawdust. The present communication is confined to a description of the general properties of wood starch and the method adopted for its isolation together with a record of preliminary evidence regarding its composition.

EXPERIMENTAL.

Microscopical examination has confirmed that the optical properties of the grains of starch in the parenchymatous cells of oak sapwood are similar to those of other starches. The grains are generally spherical or ovoid in shape and have a maximum diameter of 6–10 μ. Groups of grains suitable for microscopical examination were obtained free from the parent wood substance as follows. Small samples of dry sapwood sawdust were shaken with ether and, immediately the wood had settled, portions of the supernatant ether were placed on dry slides. When the ether evaporated large numbers of starch grains were found on the slides. In the dry condition the grains were opaque, but under reflected light their surfaces were brightly illuminated. On moistening with cold water the grains appeared suddenly to swell to a slight extent, whereupon they became

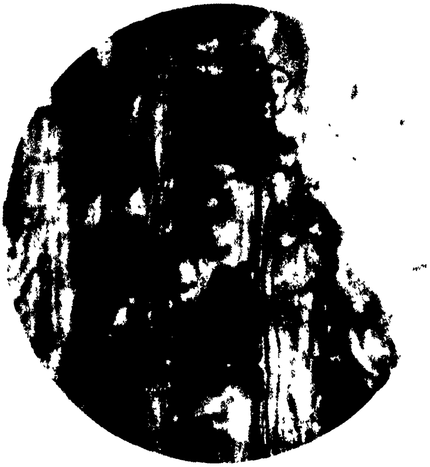

Fig. 1. Ray cell of oak sapwood (× 1000) containing starch grains lightly stained with iodine-potassium iodide solution.

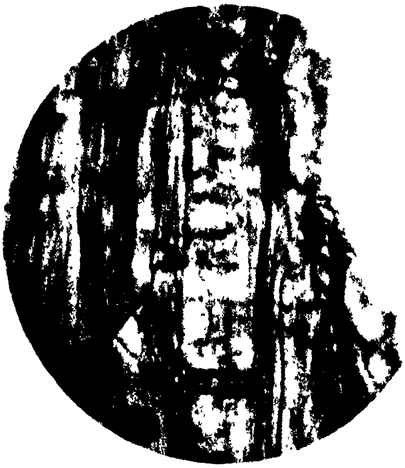

Fig. 2. Same cell after immersion in boiling water for 10 minutes.

Fig. 3. Same cell after final staining with iodine-potassium iodide solution.

translucent. Under crossed nicols a distinct black interference cross was discernible at approximately 600 diameters. The grains appeared to be structurally homogeneous and the presence of a hilum could not be detected.

Examination of wood starch in situ.

A small chip of oak sapwood was cut so as to expose a portion of a medullary ray. After moistening in cold water and staining lightly with a dilute iodine-potassium iodide solution a single cell containing upwards of 20 starch grains was brought into focus under the microscope. The individual grains were clearly discernible. After photographing, the chip was immersed in boiling water for 10 minutes and the same cell was brought into focus again. It appeared to be entirely devoid of starch, but on adding a drop of iodine solution the entire cavity of the cell and part of the walls stained a deep uniform blue. These results are illustrated in the accompanying series of photographs (Plate II, figs. 1–3) for assistance in the preparation of which the author is indebted to Messrs S. H. Clarke and W. R. Hutchins.

It would thus appear that the starch of oak wood occurs naturally in parenchymatous cells in the form of minute particles of a gel which is readily dispersed to a sol by hot water. It will be indicated later that under certain conditions it can be dispersed to some extent even by cold water. In the form of a sol the material diffuses out of the wood.

The isolation of wood starch.

The physical properties of the substance suggested that it might readily be removed from a wood meal by extraction with hot water, but early attempts to isolate it in a reasonably pure form from green oak sapwood were unsuccessful owing to contamination by soluble colouring matter, tannins, sugars *etc.* After experimenting with a number of different procedures the following proved to be satisfactory.

The green winter-felled sapwood of oak, previously found to contain starch by the iodine test, was converted to sawdust and dried as rapidly as possible in a current of air. When the moisture content reached approximately 12 % the material was screened and the portion which passed a 50-mesh and was retained by a 60-mesh screen was selected for extraction. Material of finer mesh was found to be unsatisfactory for reasons which will be apparent later. It was found by experiment that air-dry 50–60-mesh sapwood could be extracted with water at temperatures up to 60° in such a manner as to extract practically all the tannin and colouring matter and leave the starch grains apparently intact. Thereafter by extracting with water at 100° the starch could be removed with the minimum of contamination. The method used was as follows.

A series of 250 g. (air-dry) batches of the 50–60-mesh meal were extracted for 3 hours with constant stirring with 3 litres of water in 5-litre flasks maintained at 60° in a water-bath. After the wood had settled, the extract was siphoned off. The process was repeated usually four times until the final extract failed to give a tannin reaction with ferrous ammonium sulphate solution. Each extract was tested for starch with iodine-potassium iodide solution and it was found that while oak sapwood from one source gave no reaction in any of its 60° extracts a sample from a different source gave a definite starch reaction after the first extraction, but no reaction subsequently. So far, it has not been possible to explain this result for even after drying at 105° the second sample still yielded traces of starch at 60°. Examination of samples of the extracted wood meal under the microscope at this stage revealed that the ray cells still retained their starch in the form of grains.

The batches of wood meal were now subjected to a series of 3-hour extractions at 100° using 3 litres of water in each case. The resulting pale yellow colloidal solution, when cold, gave a pronounced starch reaction with iodine. Extraction was continued until the last extract gave no definite starch reaction. On the average four such extractions were sufficient. Microscopic examination of the wood at this stage revealed that all the starch grains had disappeared, but, on staining with iodine, cell walls and cavities here and there were coloured a pale blue. This was especially apparent in cells towards the interior of individual particles of wood. It was found that, if the 100° extractions were continued beyond this stage, another product, the colloidal solutions of which gave a royal purple colour with iodine was obtained. This will be referred to later.

The combined 100° extracts from groups of two batches of the original meal were concentrated *in vacuo* at 25–30° to a volume of 1·5 litres. The resulting dark brown colloidal solution was heated to approximately 70° in the water-bath, and acidified with 30 ml. of glacial acetic acid. An excess of hot 97 % ethyl alcohol was then added. The pale brown flocculent precipitate was allowed to settle and the supernatant alcoholic liquor containing tannin, colouring matter, soluble sugars *etc.*, was siphoned off. The product was then taken up in approximately 750 ml. of hot water and after the addition of a further 30 ml. of glacial acetic acid a further excess of hot alcohol was added. This operation was repeated 4-6 times until all colouring matter was removed, and the product was washed several times by decantation with alcohol until acid-free. It was then transferred to an extraction thimble and subjected to a series of 6-hour extractions with (1) absolute alcohol-dry benzene (1:2), (2) absolute alcohol and (3) dry ether. After removal of excess ether the product was transferred to a tared weighing bottle and the rest of the ether allowed to evaporate at room temperature, care being taken to stir frequently during this last operation. Final drying to constant weight was carried out in an air-oven at 105°. The final product was a pale pinkish buff impalpable powder which gave an intense blue coloration with iodine.

A sample of winter-felled English walnut sapwood was subjected to the same procedure as the oak and a final product of identical appearance was isolated. In the sample of walnut the starch was found to be confined to the outer layers of the sapwood, hence these only were converted. The actual yields obtained from typical extractions are recorded in Table I.

Table I. *Yields of starch from 50–60-mesh sapwood of winter-felled English oak and walnut.*

Results expressed as percentages by weight of original oven-dry wood meal.

	Oak sapwood					Walnut outer sapwood		
	1	2	3	4	5	1	2	3
Moisture content of original wood prior to extraction	11·39	11·25	11·13	11·15	11·14	9·37	8·87	8·87
Total loss in weight	10·62	9·93	10·65	Not determined	Not determined	8·94	10·60	9·17
Yield of starch	1·16	1·06	1·54	1·87	1·26	0·43	0·42	0·43
Average yield of starch	1·38					0·43		

The starch content of Lyctus *frass.*

It has already been shown [Campbell, 1929] that the frass of *Lyctus* powder-post beetles is so fine in texture that it readily passes a 120-mesh screen. A sample of frass was examined and found to contain traces of starch as revealed by the iodine test. A 200 g. (oven-dry) sample of each of 120-mesh oak sapwood and *Lyctus* frass obtained from a number of specimens of infested oak sapwood were extracted by the procedure outlined above (see Table II).

Table II. *Yields of starch from* Lyctus *frass and oak sapwood of the same particle size compared.*

	Sound oak sapwood 120-mesh	*Lyctus* frass from oak sapwood
Dry weight of original material	200 g.	200 g.
Total loss in weight	12·17 %	10·70 %
Yield of starch	0·90 %	0·28 %

The product in both cases was dark in colour and therefore probably contaminated to some extent by other substances. The preparation from material of such fine texture was much more difficult than from the 50–60-mesh material, the yield from the sound wood being lower than the average from 50–60-mesh material (Table I) although both were obtained from the same source. As would be expected the total loss in weight is greater in the fine material, owing to its state of division. It is noteworthy that total loss by exhaustive extraction with water is less in the frass than in the sound wood.

The physical and chemical properties of isolated wood starch.

On exposure to air the dried product from the sapwood of both oak and walnut absorbed moisture. After attaining an equilibrium moisture content of approximately 12 % there was no change in physical appearance. The starch was very slightly soluble in cold water, but more soluble in hot water to give a pale yellow colloidal solution. The solutions gave the characteristic blue colour with iodine which was discharged on heating and regenerated on cooling. There was no reduction of Fehling's solution until after hydrolysis with dilute HCl. When mixed with a little cold water on a glass plate the powder reverted to a brown-coloured gel which set hard on drying. In thin films the dried gel was almost colourless and transparent.

A sample of the powdered starch was dried to constant weight at 105°. After moistening with cold water it was again dried at 105° and yielded exactly the original weight.

It would thus appear that even in the solid form the material retains no more water at 105° than the powder.

Ultimate analyses of the product from the two different species of wood gave the following results.

Oak sapwood starch	Walnut sapwood starch
1. C, 43·95 %; H, 6·50 %	1. C, 44·29 %; H, 6·41 %
2. C, 44·11 %; H, 6·41 % N, 0·12 %	2. C, 43·96 %; H, 6·44 % N, 0·51 %
Mineral ash, trace	Mineral ash, 1·13 %

In view of the low yields of walnut material the following exploratory experiments were confined to the material from oak sapwood.

Specific rotation. A clear colloidal solution of the substance could only be obtained with difficulty. 0·4968 g. (oven-dry, 105°) was incorporated with 50 ml. of cold water and allowed to stand for several hours. The mixture was raised to 100°, but even after 4 hours at this temperature a considerable proportion of the starch remained undispersed. The mixture was transferred with a minimum of extra water to an alundum crucible of porosity R.A. 360 and filtered at the pump. The optical rotation of the pale yellow colloidal filtrate was measured after noting its volume at 20°. The undissolved residue was dried at 105° and weighed; c was found by difference: found $[\alpha]_D^{20^\circ} + 164{\cdot}3^\circ$ ($c = 0{\cdot}286$). A portion of the solution gave the characteristic blue colour with iodine and did not reduce Fehling's solution.

0·4968 g. (oven-dry 105°) of the substance dissolved in 75–80 ml. of 2 % NaOH in about 2 hours to give a dark brown colloidal solution. This was made up to 100 ml.: found $[\alpha]_D^{20^\circ} + 128{\cdot}8^\circ$ in a 25 mm. tube.

Action of takadiastase on oak sapwood starch. In the following experiments the actions of takadiastase on the soluble form of potato starch (B.D.H. preparation) and on oak sapwood starch were compared. The method used was similar to that used by Widdowson [1931]. Two samples of approximately 0·2 g. of each of the two substances were mixed with 100 ml. of water, heated in a water-bath for 30 minutes and cooled to room temperature. While the potato starch gave a clear solution the oak starch was not all dispersed. Part of it remained suspended as a gelatinous precipitate. 10 ml. of a 1 % solution of takadiastase were added to each sample and after acidifying with acetic acid and adding a little toluene the series was maintained at 38–40° in an air-oven. A blank consisting of 100 ml. of water and 10 ml. of 1 % takadiastase solution was subjected to the same treatment. At regular intervals a portion of one of each pair of samples was tested for starch with an iodine-potassium iodide solution. After 22 hours the potato starch solution gave a pale orange colour with iodine, but the wood starch solution gave a greenish colour. The suspended matter was stained a faint blue. A pale orange colour was only obtained with the wood starch solution after 64 hours at 38–40°. The remaining one of each pair of solutions and the blank were now removed from the oven, raised to boiling to remove toluene and destroy the enzyme and transferred to tared alundum filter crucibles (R.A. 360) with small quantities of water. There was a small residue in each case. This was washed with water and filtered at the pump. The residues were dried at 105° and weighed and the filtrates *plus* washings were examined optically after their volumes had been measured at 20° (Table III). In view of the slow rate of action of takadiastase in small concentrations on wood starch, the experiment was repeated using the modified technique advocated by Denny [1934]. Each sample weighed approximately 0·5 g. To each were added 25 ml. of water in a small conical flask and after heating at 100° for 30 minutes and cooling, 25 ml. of acetate buffer solution at p_H 4·5, 25 ml. of a 4 % takadiastase solution and a little toluene were added. The flasks were plugged with cotton-wool and incubated at 38–40°. A blank without starch was subjected to the same treatment. After 19 hours control solutions gave a pale orange colour with iodine. The suspended matter in the wood starch solution stained faintly blue. A small amount of suspended matter in the potato starch solution, consisting apparently of the ruptured envelopes of starch grains, also stained blue. The solutions were boiled for 1 minute and filtered, the residues being washed and dried and the filtrates examined as before (Table III). While in the first experiment the takadiastase blank had no detectable rotation, in the second experiment a marked dextrorotation was observed, so that in this latter case the angular readings for the hydrolysed starch solutions were corrected to exclude the amount of deflection due to takadiastase. The observation of Denny [1934] that ordinary pharmaceutical preparations of takadiastase contain reducing substances was confirmed. Even after boiling in the presence of the buffer solution as described above reducing substances were still present: found $[\alpha]_D^{20^\circ} + 53{\cdot}1^\circ$ ($c = 0{\cdot}89$ by difference). A separate sample of the buffer solution in water was found to be optically inactive.

Table III. *The effect of takadiastase on the soluble form of potato starch and oak sapwood starch respectively at 38–40°.*

Determination of the starch content of wood by means of takadiastase.

A number of experiments were carried out in order to determine the effect of takadiastase on the starch in the parenchymatous cells of oak wood. 10 ml. of a 4 % solution of the enzyme at p_H 4·5 were found to remove all traces of the starch from parenchymatous cells of 2 g. (air-dry) of 60-mesh oak sapwood in 17 hours. The following method was used to determine the starch content of the wood and also of the *Lyctus* frass (Table II) from the same species.

Two 2 g. samples of each material were incorporated with 25 ml. of water in 250 ml. flasks and heated at 100° for 30 minutes. After cooling, 25 ml. of acetate buffer at p_H 4·5 and 10 ml. of 4 % takadiastase were added. A little toluene was now added, the flasks were plugged with cotton wool and incubated at 38–40° for 17 hours. Two further samples were subjected to the same treatment except that 10 ml. of water were substituted for takadiastase solution and a blank was introduced without the "wood flour." After incubation each flask was boiled for 1 minute and the contents filtered with 100 ml. of water. The residues were dried at 105° and weighed (Table IV).

Acid hydrolysis of oak starch.

11·7145 g. (oven-dry) of the starch were hydrolysed with 500 ml. of 2 % sulphuric acid at 100° for 6 hours. A dark brown precipitate formed at an early stage and at the end of the hydrolysis this was removed by filtration, washed with water till free from acid, dried at 105° and weighed. The hydrolysate was neutralised with hot barium hydroxide solution and barium carbonate [Wise *et al.*, 1933]. The inorganic barium salts were removed by filtration and the neutral sugar solution was concentrated *in vacuo* to a stage when a gummy precipitate formed. A small quantity of ethyl alcohol was added and the solution was filtered and concentrated *in vacuo* to a volume of 10–15 ml. Using the method of crystallisation from alcohol recommended by Anderson [1926] four crops of crystals were obtained. The combined yield was washed with alcohol and ether and dried to constant weight *in vacuo*. The yield was 7·2 g. which together with the unhydrolysed residue (6·14 %) and mineral ash (0·24 %) accounted for approximately 66 % of the starting material. The crystals had $[\alpha]^{20^\circ}_{''}$ +57° (in water), but no definite melting-point. A portion appeared to melt at 134–135° and the remainder at 175° with decomposition. The crystals obviously consisted of a mixture of sugars, but the rotation suggested that glucose was predominant. This was to some extent confirmed by the fact that under the conditions prescribed by Browne [1912, p. 349] a copious precipitate of glucosazone was obtained in 7 minutes.

Attempts to separate the components of the sugar mixture were unsuccessful, and it was therefore decided to examine the original substance for components other than anhydroglucose residues and to investigate the course of its hydrolysis with sulphuric acid polarimetrically.

On distillation with 12 % HCl the substance yielded small quantities of furfuraldehyde. When determined in a series of 1 g. samples by the Tollens method a yield of furfuraldehyde phloroglucide of 4·26 % (average of three determinations) was obtained. The substance also contained a trace of methoxyl. (Found OMe, 0·69 %, average of two determinations.) The Tollens naphthoresorcinol test for hexuronic acids [Browne, 1912, p. 384] gave a faint but positive result.

The amount of CO_2 given off by the substance on distillation with 12 % HCl was determined by the method of Dickson *et al.* [1930]. This when calculated as uronic acid anhydride gave a result of 4·65 % (average of six determinations). On the usual assumption [Lefèvre and Tollens, 1907] that uronic acid anhydride residues yield in this way one-third of their weight of furfuraldehyde phloroglucide it can be calculated that the original substance may have contained 2·22 % of pentosan (calculated as xylan). It will be seen later that this is unlikely.

Graded hydrolysis of oak starch with sulphuric acid.

A series of 0·5 g. (oven-dry) samples of the original substance was hydrolysed with 100 ml. of 2 % H_2SO_4 at 100° for periods ranging from ½ to 16 hours. At the end of each hydrolysis the unhydrolysed residue was filtered off and washed free from acid with water. The combined filtrate and washings was in each case cooled to 20° and examined for optical rotation before and after neutralisation with powdered barium carbonate (Table V).

Table V. *The influence of time of hydrolysis of oak sapwood starch with 2 % H_2SO_4 at 100° on the specific rotation of the hydrolysis products in acid and neutral solution respectively.*

Duration of hydrolysis in hours	Residue %	$[\alpha]_D^{20°}$ in acid solution	$[\alpha]_D^{20°}$ in neutral solution
0	0	—	+164·3°
½	6·92	+155·6°	+159·5°
1	6·22	+124·4°	+124·4°
2	5·07	+ 88·4°	+116·3°
4	4·12	+ 62·6°	+ 46·1°
6	4·69	+ 50·6°	+ 59·0°
8	4·33	+ 50·8°	+ 58·8° unchanged after 12 hours
12	4·23	+ 63·1°	+ 63·1°
16	5·47	+ 64·3°	+ 64·3° → + 55·7° after standing 24 hours

A specific rotation-time curve based on the results in Table V is given in Fig. 1.

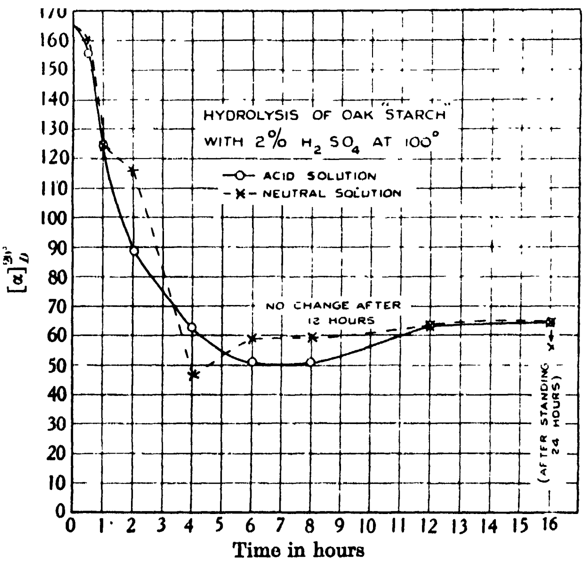

Fig. 1.

DISCUSSION.

From the experimental evidence cited above it would appear that a reliable method has been found for isolating the starch present in the parenchymatous cells of certain hardwoods in a reasonably high degree of purity. The essential feature of this method is that success or failure depends on the colloidal condition of the wood substance prior to extraction with water. The wood starch grain is readily dispersed in water. It can be removed from the green wood in the form of a sol by warm water. If, however, the moisture content of the wood substance as a whole be rapidly reduced to a value of 12 % or less the partially dehydrated starch grains become much more stable towards water. Advantage can be taken of this fact to remove the greater part of certain other water-soluble wood components in the first instance, so that the starch is ultimately obtained in a pure condition. It has already been shown that, during drying, wood substance as a whole undergoes certain changes which are reflected in the results of comparative analyses of green and dried material [Campbell and Booth, 1930; 1931; O'Dwyer, 1931], but this would appear to be the first direct evidence of a change in the colloidal condition of a minor wood component due to partial dehydration.

Although the experimental evidence suggests that this important wood component is intermediate in composition between starch and the known wood hemicelluloses, to designate it as other than "wood starch" at this stage would merely lead to confusion. There are some grounds for the belief that both oak and walnut sapwood contain the same substance, although in widely differing amounts, and, from experimental work at present in progress, it would appear that good yields can be obtained from the endosperm of the acorn.

The amounts of starch that can be isolated from the cell cavities of woods (Table I) are surprisingly small, and in the case of oak sapwood it can be seen by comparison of the results in Tables I and IV that estimation by means of takadiastase gives a much higher figure. In this latter method it can be seen that the average particle size of the wood sample has a definite influence on the result. Although it is freely admitted that the yields of starch obtained gravimetrically can only be approximately quantitative the results in Table IV might be taken to indicate a high degree of inefficiency in the method of extraction and precipitation which were adopted were it not for the fact that the cell walls of oak sapwood appear to contain a related polysaccharide. Reference has already been made to the observation that, if the extraction of oak sapwood with water at 100° be continued after all but the last traces of starch have been removed from the cavities of parenchymatous cells, another product, the colloidal solutions of which give a royal purple colour with iodine, can be isolated. For the present, little is known concerning this latter product apart from the fact that it is much more difficult to disperse with water than the starch proper. So far, an amount corresponding to 1·2 % of the dry weight of the original wood has been obtained from oak sapwood but more recently it has been found that the extractions of the wood with water at 100° must be prolonged for a total period of not less than 90 hours after the removal of the starch before the whole of this second product is obtained and it is expected that the yield will be greater. It has been found that part at least of this substance is converted into reducing sugars by takadiastase, but no quantitative data are yet available. The frequent assumption that takadiastase acts on substances other than the starch of the cell contents of wood is therefore apparently justified.

A significant chemical difference between potato starch and wood starch is brought out by the results in Table III. The action of takadiastase is much slower on the latter, but the specific rotations in the second experiment suggest that under optimum conditions the conversion products are the same in both cases. It must, however, be concluded that only approximately 90 % of wood starch can be composed of anhydroglucose units. The specific rotations suggest that the conversion products contain a proportion of maltose in the case of both the potato starch and wood starch. A further point which emerges from the results is that takadiastase itself even after heating to 100° for a short period contains reducing substances. The omission of any correction for the presence of these substances is as Denny [1934] has pointed out certain to lead to high results in the determination of starch when the amounts of the enzyme used are considerable. When the enzyme is used in the proportions suggested by Widdowson [1931], however, no appreciable error appears to be introduced (Table III). It has been seen above that the general accuracy of the determination of the starch content of wood, even by the modified takadiastase method used above (Table IV), cannot be assessed until more is known concerning the related polysaccharides of the cell walls.

Graded hydrolysis of the starch of oak sapwood.

The results in Table V which are illustrated graphically in Fig. 1 afford further important evidence concerning the composition of wood starch. The efficacy of the experimental procedure employed has recently been pointed out by O'Dwyer [1934], who has shown that a definite indication can thereby be obtained of the nature of the acid residues in oak hemicellulose A. It can therefore be deduced from the results (Table V) that, in the course of the hydrolysis of oak starch by dilute sulphuric acid at 100°, there is no appreciable splitting off of acid residues until the 2-hour stage is reached. Since the specific rotation of the hydrolysis products at this stage is higher in neutral than in acid solution, it is reasonable to conclude that the acid residues which are split off are combined with sugar residues in all probability to form an aldobionic acid. As the hydrolysis proceeds the main part of the starch molecule continues to break down to sugars and the aldobionic acid simultaneously breaks down to uronic acid and sugar until a stage is reached (4 hours) at which the predominance of uronic acid is sufficient to lower the specific rotation of the whole after neutralisation. Because of its relative instability towards mineral acids, however, the uronic acid is rapidly broken down to CO_2 and a pentose which ultimately yields furfuraldehyde, until at the 6- and 8-hour stages the aldobionic acid again predominates. No observations were made between 8 and 12 hours, but it is not unlikely that between these times the cycle of events already recorded was repeated. The specific rotations in acid and neutral solution finally become constant after 12 hours' hydrolysis and after 16 hours the specific rotation is reduced to 55·7° after mutarotation. There can be little doubt that the end-product is *d*-glucose.

An interesting dip in the curve (Fig. 1) for the acid solution is observed between 6 and 8 hours. This is no doubt explained by the formation of xylose from the uronic acid. Incidentally it can be deduced from this curve that after 6 hours' hydrolysis with 2 % sulphuric acid the hydrolysis products are likely to consist of a mixture of glucose, maltose, xylose, aldobionic acid and uronic acid, so that the failure, recorded above, to separate the components of such a mixture is largely explained. The specific rotation of +57° obtained for the products of hydrolysis of the large sample compares favourably with the value of +59° (Table V) for the small sample.

The data in Table V suggest strongly that the acid-building units in the original polysaccharide consist of an aldobionic rather than a uronic acid anhydride and that the anhydride in question is probably glucose-glucuronic anhydride. If the figures obtained for the amount of CO_2 given off on distillation with 12 % HCl be recalculated as aldobionic anhydride by means of the factor 7·7 an average result of 8·96 % of the dry weight of the original polysaccharide is obtained. This result, taken in conjunction with the results of the takadiastase experiments (Table III), is sufficient to account for 98·45 % of the original polysaccharide. Since, however, the yield of furfuraldehyde phloroglucide obtained from aldobionic acid anhydrides in general is not known, the actual percentage yield of the phloroglucide obtained above cannot at present be used to verify the position. No evidence has as yet been obtained to show whether the methoxyl groups determined are part of the molecule. For the present it can merely be stated that in all probability the starch of oak sapwood is composed of approximately 90 % of anhydroglucose residues, the remainder consisting of an aldobionic acid anhydride (probably glucose-glucuronic) which may or may not be partly methylated. The course of future work is obvious, and it will be pursued as soon as sufficient supplies of the polysaccharide are available.

Wood starch as a source of nourishment for the larvae of powder-post beetles.

There would appear to be little doubt that the polysaccharide which has been isolated is the substance to which Wilson [1933] has referred as the food of *Lyctus* larvae. The experimental evidence suggests that it contains approximately 90 % of available carbohydrate which can be converted into sugars by enzymic hydrolysis. The author is indebted to his colleague Mr E. A. Parkin for showing that the polysaccharide can also be converted into sugars by the gut enzymes of *Lyctus* larvae. Full details concerning this result will be published elsewhere in due course. If the nitrogen associated with the product is available in the form of protein the food value of the starch will thereby be enhanced although as yet there would appear to be no evidence of the presence of proteolytic enzymes in wood-eating insects [Mansour and Mansour-Bek, 1934]. It is noteworthy that *Lyctus* frass contains apparent starch which amounts to slightly less than one-third of the amount which can be isolated from sound wood of the same particle size (Tables II and IV). This result in itself might be taken to indicate the disappearance of the polysaccharide due to larval activity were it not for the fact that the starch content of woods is normally subject to seasonal variations. It may be argued that the presence of starch in the frass of this insect indicates that part of the wood actually comminuted by the larvae cannot be ingested. If this view be accepted it can readily be calculated from the data in Table II that the proportion of the total borings actually discarded might amount to one-third in some cases. The fact that *Lyctus* frass contains starch at all, however, indicates that the accurate determination of the starch content of a sufficient number of samples from a given species of wood, is certain to yield valuable information concerning the so-called immunity starch level of certain woods [Wilson, 1933].

Having regard to the small amounts of starch which have now been shown to occur in certain woods and also to the variations in composition known to exist between different samples of the same species of wood it can readily be appreciated why no significant differences in chemical composition could originally be detected between sound oak sapwood and *Lyctus* frass from the same species [Campbell, 1929]. Thus, despite recent criticisms [Wilson, 1933; Mansour and Mansour-Bek, 1934], the contention [Campbell, 1929], based on purely chemical evidence, that the source of larval nourishment is within the cells of the sapwood of oak and not in the cell wall substance, loses none of its force unless and until it be shown that the related cell wall polysaccharide referred to above is also a source of food. It may be repeated therefore that a complete solution of this question from the chemical point of view will only be attained when it is possible to feed the larvae of wood-boring insects on weighed samples of wood of known composition so that the losses in weight due to attack can be determined.

Another aspect of the feeding habits of *Lyctus* larvae merits consideration. It is asserted in some quarters [Fisher, 1928] that the insects only infest recently seasoned timber. It would be of interest to determine therefore whether, during the natural ageing of converted timber, the starch of the cell contents undergoes any chemical changes which might be likely to render it unsuitable to the insect. An early investigation of this question is contemplated.

The relationship of the starch of wood to certain other components.

The chief point of fundamental chemical importance which emerges from this exploratory examination of wood starch is that, until it can be proved to be other than a true chemical compound, this substance must be classified as an acid polysaccharide or hemicellulose. Hemicelluloses of this type have hitherto been considered to be of comparatively rare occurrence. The question naturally arises as to whether the starch of all "starch trees" is of the same composition. Much has been written on the chemistry of wood hemicelluloses and their relation to lignin, but the steps in the formation of these two wood components are still obscure. Buston [1934] has recently indicated after an extensive review of existing evidence that the hemicelluloses of lignified cell walls are probably not derived from pectin. The same author further postulates that because of their chemical composition such hemicelluloses must be derived from hexose polysaccharides. The composition of the wood starch which has now been isolated would appear not only to support this view but to provide a hitherto missing link between the hemicelluloses of the woody cell wall of certain species and the products of the chloroplasts of the leaf. The study of the chemistry of wood starch and the related polysaccharides in the cell walls is therefore being continued.

SUMMARY.

1. The starch present in the parenchymatous cells of certain woods is shown to resemble the known starches in some of its physical properties and to differ from them in others.

2. A method is described for the quantitative isolation of the substance in a high degree of purity from the sapwood of English oak and walnut.

3. Errors introduced into the determination of wood starch by means of takadiastase are discussed.

4. Wood starch is shown to be an acid polysaccharide approximately 90 % of which appears to be composed of anhydroglucose residues. It is suggested that the remainder consists of an aldobionic acid anhydride (probably glucose-glucuronic anhydride) which may or may not be partly methylated.

5. It is indicated that the cell walls of oak sapwood contain a polysaccharide which is chemically related to the starch of the cell contents.

6. Wood starch is considered to be a suitable source of nourishment for the larvae of *Lyctus* powder-post beetles.

The author is especially indebted to Mr D. F. Packman for his assistance in the preparation of the material for this study. He is also indebted to Dr Margt. H. O'Dwyer for several helpful suggestions, to Sir James Irvine, Chairman of the Forest Products Research Board, for criticising the manuscript and to Mr W. A. Robertson, Director of Forest Products Research, for permission to communicate this paper.

CXXXVI. A METHOD FOR THE MICRO-DETERMINATION OF MAGNESIUM.

By GEORGE CRUESS-CALLAGHAN.

From The Department of Physiology and Biochemistry, University College, Dublin.

(*Received March 27th, 1935.*)

Two organic chemical reagents are convenient for the detection and estimation of small amounts of magnesium, *viz.* *op*-dihydroxyazo-*p*-nitrobenzene and 8-hydroxyquinoline. Kahn and Vieweg [1927] have described an accurate gravimetric determination of magnesium with the aid of 8-hydroxyquinoline. Hough and Ficklen [1930] have worked out the ranges over which this reagent can be used for the estimation of magnesium gravimetrically, volumetrically and colorimetrically. They used the gravimetric method for quantities from 10–1 mg. At the lower end of the range the error was about 10 %. Their colorimetric method had a range of 5–0·5 mg. but here again the percentage error at the lower end of the range was high. The volumetric method, involving titration with permanganate, was employed over a range 5–0·1 mg.; above 0·2 mg. the results were good but below this the method became inaccurate.

For physiological work an accurate method for determining quantities of magnesium down to 0·05 mg. (50γ) in ashed residues was desirable. This has been worked out and analyses down to 20γ are described in this communication. The useful application of a method of magnesium determination requires that calcium shall not interfere; it will be shown that 50γ of magnesium can be accurately determined in presence of more than 200γ of calcium.

The method involves formation of the magnesium complex of 8-hydroxyquinoline, its hydrolysis, and subsequent determination of free hydroxyquinoline, by bromination with excess bromine and determination of excess halogen. Hydroxyquinoline is brominated readily and quantitatively to 5:7-dibromo-8-hydroxyquinoline. Berg [1927] made use of this fact to determine 8-hydroxyquinoline in acid solution by titrating in a standard bromide-bromate solution until excess bromine was indicated by indigocarmine and determining this excess. Kolthoff [1927] employed the same method but used methyl red to indicate the excess bromine. Recently Harden and Wirjodihardjo [1934], using methyl red as an indicator, carried out a direct titration with a standard bromide-bromate solution. They estimated quantities of magnesium in soil from 24·01 to 5·55 mg. and gave the error as $-0{\cdot}18$ to $+0{\cdot}24$ mg. Modification of this method to deal with quantities of the order of 20–100γ was found by the author to be impracticable owing to the unsatisfactory nature of the end-point.

The method finally used for the analyses of quantities of magnesium down to 20γ is based on Berg's [1927] principle of adding a known excess of bromide-bromate solution and determining the residual bromine by titration with sodium thiosulphate after the addition of excess potassium iodide, starch being used as an indicator. Such iodimetric titrations of minute quantities of bromine can be accurately and conveniently carried out with the Conway micro-burette [1934] which delivers volumes of 0·1 ml. with the same percentage accuracy as 1·0 ml. is delivered from the standard 2 ml. Bang burette. The micro-technique involved required the introduction of several modifications in the procedure heretofore employed by workers using 8-hydroxyquinoline. These include the method of obtaining the complex free from the excess of 8-hydroxyquinoline, bromination without loss of bromine and the method of titration.

EXPERIMENTAL.

Formation of magnesium complex of 8-hydroxyquinoline. Three ml. or less of the fluid containing the magnesium to be estimated are introduced directly into a small centrifuge-tube of about 4 ml. capacity. A moderate excess of 8-hydroxyquinoline reagent (soln. 1) is added, and the fluid volume is brought up to approximately 3·5 ml. with distilled water. The centrifuge-tube is corked with a rubber stopper through which a capillary tube passes. This arrangement allows the air to escape on heating, and at the same time prevents the solution from overflowing owing to frothing. The centrifuge-tube is then placed in a small beaker (100 ml.) of water which comes about three-quarters of the way up the tube. The water is gradually heated to 90–95°, the magnesium 8-hydroxyquinoline complex separating out. The tube and its contents are maintained at the above temperature for a few minutes, then cooled and centrifuged for ten minutes. The supernatant liquid is syphoned off leaving only about 0·1 ml. This is diluted to about 3·5 ml. with approximately *N* ammonia solution. The sediment is disturbed to free it from any excess of the reagent and the tube is centrifuged again. As before the supernatant liquid is siphoned off. It may be shown that no disturbing excess of 8-hydroxyquinoline remains after the one washing.

Bromination of the equivalent amount of 8-hydroxyquinoline. To the washed precipitate a volume of standard bromide-bromate solution (soln. 2), sufficient to give an excess of bromine is added. When 100γ of magnesium are present 2·0 ml. of the bromide-bromate solution will be found to give a convenient excess, while 0·5 ml. will suffice when 20γ of magnesium are being determined. The volume is made up to approximately 2·5 ml. with distilled water and 1 ml. of 4*N* hydrochloric acid is added. This hydrolyses the complex, giving an equivalent of free hydroxyquinoline, and liberates bromine from the bromide-bromate solution. The centrifuge-tube is immediately stoppered and inverted for a moment while the sediment is disturbed by gentle tapping. The bromine is left in contact with the 8-hydroxyquinoline at room temperature for three minutes during which time the 8-hydroxyquinoline is converted quantitatively into 5 : 7-dibromo-8-hydroxyquinoline.

Estimation of excess bromine. A crystal of potassium iodide is added to the solution and the free iodine is titrated, using a micro-burette as described by Conway [1934] containing standard sodium thiosulphate solution (approx. *N*/40; see below) which is added until the colour of the iodine almost disappears. A drop of starch solution is then added and the titration is continued until the blue colour disappears. When the end-point is approached the rate of delivery of the burette may be slowed down, if it is inconveniently fast for accurate regulation, by reducing the delivery pressure of the burette as described by Conway [1934].

The colour change at the end-point can be seen quite clearly on adding about 0·002 ml. of *N*/40 thiosulphate solution which corresponds to about 2–3 graduations on the burette scale. This amount is in turn equivalent to approximately 0·15γ of magnesium. The end-point may therefore be regarded as satisfactory.

A blank determination for the whole procedure must be carried out simultaneously.

Solution 1. (*8-hydroxyquinoline reagent*): 1 g. of 8-hydroxyquinoline is dissolved in 89 ml. of absolute alcohol and 10 ml. of ammonia (sp. gr. 0·880) and 1 ml. of hydrochloric acid (sp. gr. 1·180) are added. 0·2 ml. of this reagent will suffice for the estimation of 100γ of magnesium. Corresponding amounts of the reagent may be used for less quantities.

Solution 2 (*bromide-bromate*): About 2·7 g. of potassium bromate and about 25 g. of potassium bromide are dissolved in 500 ml. of distilled water and the solution diluted 1 : 10. This will give approximately 1·6 mg. of bromine per ml. and is accurately standardised against the thiosulphate solution.

NOTE. Various methods of testing for an excess of bromine after bromination were tried. The most satisfactory found was to remove a small platinum loopful of the solution and bring it into contact with potassium iodide solution containing starch on a white background. A blue colour indicates excess of bromine.

Solution 3 (*sodium thiosulphate*): Using a micro-burette with a graduated tube of about one mm. bore, approximately $N/40$ thiosulphate will be found convenient. This is made up by dissolving about 6 g. of $Na_2S_2O_3, 5H_2O$ in one litre of distilled water. The solution may be standardised against $N/200$ potassium iodate solution (0·1775 g. KIO_3 per litre). One ml. of this is introduced into a centrifuge-tube, using an Ostwald pipette. A crystal of potassium iodide and a few drops of $N/10$ sulphuric acid are added. The titration is carried out in the usual way, using a drop of starch solution towards the end-point.

The absolute normality of the thiosulphate solution is not determined, but it is standardised in terms of length of fluid column in the graduated tube of the Conway burette, corresponding to 1 mg. or to 1 γ of bromine.

RESULTS.

The above method was used in the micro-determination of magnesium in standard solutions of magnesium sulphate containing about 6 g. of pure crystalline $MgSO_4, 7H_2O$ in 100 ml. of distilled water. The exact quantity of magnesium in 10 ml. of this solution is determined in duplicate by precipitating as magnesium ammonium phosphate, igniting and weighing as magnesium pyrophosphate. The solution thus made up and standardised for its exact magnesium content is suitably diluted and the requisite volumes used in the analyses.

Table I shows the results of analyses which were carried out using the method described with varying amounts of standard magnesium solution. It will be seen that down to 20γ the method may be relied on to give a result of an individual determination to within 10 % of the theoretical quantity.

Table I.

Theoretical amount of mg. γ	Analyses. Mean value γ	Number of analyses	% deviation of mean value from theoretical	Coefficient of variation of individual determinations
114·2	120·4	6	+5·0	1·2
76·1	74·3	6	−2·4	2·9
50·8	53·5	7	+5·3	3·9
25·4	24·2	6	−4·7	4·7
19·0	20·2	6	+6·3	4·3
12·7	13·2	6	+7·9	10·3
5·1	5·5	6	+7·8	6·1
3·8	3·3	5	+13·2	14·5
Blank	1·5	13	—	27·5

Table II gives individual analyses carried out on 25·4γ of magnesium. The percentage deviation of each analysis from the mean is given and it will be seen that the greatest is $-7·0$. The percentage deviation of the mean value of the six analyses from the theoretical is $-4·7$.

Table II. *Six estimations of 25·4γ Mg.*

Volume of bromide-bromate soln. used (ml.)	Thiosulphate soln. Divisions on micro-burette scale	Mg as estimated. Corrected for blank* (γ)	Deviation from mean γ	% deviation from mean
0·7	10·87	23·6	−0·6	−2·5
0·6	5·89	25·3	+1·1	+4·5
0·6	6·82	23·9	−0·3	−1·2
0·6	6·24	24·8	+0·6	+2·5
0·6	7·73	22·5	−1·7	−7·0
0·6	5·84	25·4	+1·2	+5·0

* Corrected by subtracting blank value = 1·5γ.

1 division (100 small graduations on) microburette scale used = 0·04435 ml.

1 ml. bromide-bromate solution is equivalent to 1·58 mg. Br.

1 division (100 small graduations) on micro-burette scale used, containing approximately $N/80$ thiosulphate solution is equivalent to 0·041 mg. Br. (A weaker thiosulphate solution was used here than was subsequently considered more generally suitable.)

Mean value of the six analyses of 25·4γ of magnesium is 24·2γ.

Six determinations of the blank value were carried out, using 0·1 ml. of 8-hydroxyquinoline and seven estimations using 0·2 ml. The mean values of these two series were practically the same (1·5γ) though individual values varied from 1·0γ to 2·5γ. This blank value is due to the glass and it will be seen that the variation between the individual blanks (up to 1·0γ from the mean) may account to a large extent for the high deviation of individual analyses where quantities less than 20γ are determined.

Determination of magnesium in the presence of calcium.

Table III gives the results of determinations of magnesium in presence of varying amounts of calcium.

Table III.

Wt. of calcium added γ	Mean value of four analyses γ	Apparent increase of magnesium due to presence of calcium γ
0	53·5	—
10	54·4	0·9
25	54·5	1·0
80	53·9	0·4
100	53·1	−0·4
200	55·8	2·3

In each case four analyses were carried out and the mean value of these determinations is given in column 2 of Table III. From these figures it will be seen that the analysis of 50γ of magnesium in 3·5 ml. may be carried out without any appreciable error due to the presence of four times this quantity of calcium.

SUMMARY.

1. A method is described whereby quantities of magnesium down to 20γ in 3 ml. or less can be reliably determined in standard solutions or in solutions from ashed residues.

2. Analyses were carried out on known quantities of magnesium varying from 114·2 down to 3·8γ. The results of these analyses are given and the figures show that over a range 114 to 20γ the coefficient of variation of the individual determination is 1·2 at the higher and 4·3 at the lower level. An individual

analysis therefore down to 20γ of magnesium may be relied on to within 10 % of the theoretical quantity. With this amount of magnesium the error of estimate is chiefly due to the glass of the centrifuge-tubes used.

3. It has been shown that, by the method described, 50γ of magnesium in 3·5 ml. can be determined in the presence of four times as much calcium without any increased error due to the calcium.

CXXXVII. THE FORMATION OF HYPONITROUS ACID AS AN INTERMEDIATE COMPOUND IN THE BIOLOGICAL OR PHOTOCHEMICAL OXIDATION OF AMMONIA TO NITROUS ACID.

II. MICROBIOLOGICAL OXIDATION[1].

By ALEXANDER STEVEN CORBET.

From the I.C.I. Agricultural Research Station,
Jealotts Hill, Bracknell, Berks.

(*Received March 27th, 1935.*)

The present investigation is concerned with the oxidation of ammonium salts to nitric acid in soil. In Part I [Corbet, 1934] the chemical aspects of the subject were dealt with, and in this paper the reactions effected by bacterial agency are considered.

For work on the biological oxidation of ammonia, aqueous solutions of ammonium sulphate containing small amounts of nutrient salts were inoculated with nitrifying organisms from soil. No particular attention was paid to the species of organisms present, but difficulty was experienced frequently in obtaining a culture capable of effecting complete and rapid nitrification under experimental conditions. On many occasions inoculation of Beesley's medium with small quantities of soil from arable land failed to produce more than traces of nitrite, even after prolonged incubation. With a few soil samples obtained at Jealotts Hill, nitrite production in Beesley's medium was strong and rapid but usually less than 5 % of the ammonium salt was decomposed after several weeks' incubation at 32°.

In one instance only did nitrification proceed beyond the stage of nitrite formation, and no attempt was made to ensure nitrate production, as the present investigation was concerned primarily with the intermediate compounds formed during the oxidation of ammonia to nitrous acid.

The formation of intermediate compounds.

It has been found in this investigation that the microbiological oxidation of ammonium (as sulphate) can proceed by the following stages:

$$NH_3 \rightarrow NH_2OH \rightarrow H_2N_2O_2 \rightarrow HNO_2 \rightarrow HNO_3.$$

There appears to be no doubt that hydroxylamine occurs as an intermediate compound during the early stages of nitrification, although on account of the reaction of the medium it is present in quantity too small to admit of accurate estimation. In some series of experiments, when nitrification had begun, this compound was detected by its reducing action on Fehling's solution and on iron alum, but it was never present when appreciable quantities of nitrite had accumulated.

---

[1] Some aspects of the work described in this paper were considered in a paper read at the Annual General Meeting of the Association of Applied Biologists held in London on 15th February 1935.

It was shown experimentally that cultures of soil micro-organisms able to convert ammonium (as sulphate) into nitrite transformed hydroxylamine into nitrite under the same conditions. In one such experiment, 95 % of the nitrogen originally present as hydroxylamine disappeared, leaving the residue in the form of nitrite. It was evident that the hydroxylamine had undergone oxidation to nitrite, and obviously the resulting hydroxylamine nitrite had broken down to nitrous oxide and water.

Although hydroxylamine was detected as an intermediate product on occasions, it could not accumulate in the culture flasks since it becomes progressively less stable with increasing alkalinity of the medium. The data given in Table V show that some decomposition of hydroxylamine takes place at p_H 4·6, while at higher values the breakdown is rapid. In presence of nitrite, hydroxylamine is unstable whatever be the reaction of the medium (Table VI). Addition of nitrite is an easy and effective means of removing hydroxylamine from solution, and advantage was taken of this fact in the analytical procedure.

Hyponitrous acid was frequently detected as an intermediate compound during the early stages of nitrification and, with some cultures of soil micro-organisms, it was present in quantity.

In one series of experiments with ammonium sulphate, a considerable portion of the nitrogen known to be present could not be accounted for as ammonia, hydroxylamine, nitrous or nitric acid, and this deficit was greatest between the disappearance of ammonia and the formation of nitrite. It was concluded that the nitrogen was present in the form of hyponitrite.

This experiment was carried out in the early stages of the investigation, before a satisfactory method of estimating hyponitrous acid had been elaborated. Later work however fully confirmed the tentative conclusion. This substance was often detected during the early stages of nitrification, but in one series of experiments it constituted an important intermediate substance in a biological reaction, whereby the nitrogen in ammonium sulphate was finally lost, presumably in a gaseous form.

Calcium hyponitrite is stable in aqueous solution and in presence of nitrite, but on warming it decomposes and the nitrogen is lost in gaseous form. Although no chemical mechanism is known whereby hyponitrites are oxidised to nitrite, when an aqueous solution of calcium hyponitrite was inoculated with soil micro-organisms, there was an accumulation of nitrite and no gas evolution took place.

Attention has already been drawn [Corbet, 1934] to the autoxidation of nitrous acid which takes place rapidly in media of $p_H < 5$.

DISCUSSION.

In Tables I–IV and Figs. 1–3 are given some of the results obtained during the present investigation. It was found preferable to work with a number of separate culture flasks, since nitrification was neither vigorous nor rapid when a large bulk of liquid medium was inoculated and aliquot portions were withdrawn at intervals, and so in some instances the experimental points do not lie on a smooth curve.

It will be seen that while hydroxylamine was hardly ever present in measurable amount, hyponitrous acid constituted an important intermediate compound in the first and fourth series of experiments. Since the mutual presence of hydroxylamine and nitrite results in loss of nitrogen, it is not surprising that these two compounds do not co-exist at any stage during the biological nitrification of Beesley's medium. The fact that hydroxylamine and hyponitrous acid occur during the initial stages of the decomposition and are absent later, when appreciable amounts of ammonia still remain to be oxidised, is discussed on p. 1089.

Table I. *First series of nitrification experiments.*

	Nitrogen present in mg. per 100 ml. solution							
Days after inoculation	0	8	14	18	24	30	42	76
Nitrogen present as:								
Ammonia	19·6	15·0	4·7	10·7	9·0	7·8	8·8	0·1
Nitrous acid	.	1·7	3·0	7·1	9·8	11·0	10·3	19·6
Total accounted for	19·6	16·7	7·7	17·8	18·8	18·8	19·1	19·7
Deficit	.	2·9	11·9	1·8	0·8	0·8	0·5	.
Hyponitrous acid-N present according to titration with $KMnO_4$	.	3·0	11·4	3·6	0·8	0·8	0·3	.

No nitrate was found in any of the culture flasks. These results are expressed graphically in Fig. 1. There was, of course, no actual regeneration of ammonia: the apparent increase in ammonia-nitrogen on the 18th day is attributable to the fact that the reaction did not proceed at the same speed in all the culture flasks.

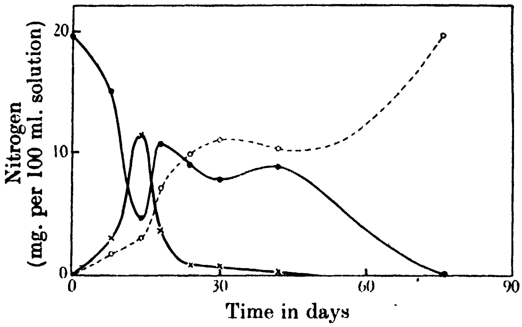

Fig. 1. First series of nitrification experiments.
•—• Ammonia-N. o- - -o Nitrous-N. x — x Hyponitrous-N.

Table II. *Second series of nitrification experiments.*

	Nitrogen present in mg. per 100 ml. solution							
Days after inoculation:	0	11	15	21	27	33	40	48
Nitrogen present as:								
Ammonia	19·2	18·8	18·5	18·0	18·5	18·9	18·3	18·6
Hydroxylamine	.	.	.	0·1	.	.	.	.
Nitrous acid	.	0·4	0·2	0·7	0·3	0·2	0·4	0·6
Total accounted for	19·2	19·2	18·7	18·8	18·8	19·1	18·7	19·2
Deficit	.	0·0	0·5	0·4	0·4	0·1	0·5	0·0

No nitrate was detected in this series of experiments.

Subcultures from this experiment and many other cultures of soil micro-organisms gave similar results. In one experiment, in which the course of nitrification was followed by measurement of the diminution in pressure, it was found that biological activity ceased when a small proportion of the ammonia had been oxidised.

The culture flasks were incubated at 32°, and qualitative experiments showed that the course of nitrification was similar when incubation took place at 4°.

Table III. *Third series of nitrification experiments.*

Nitric acid	–	–	–	–	–	–	–	–	–	–	–

* No satisfactory explanation of this low value was discovered.

A subculture from the above experiment gave similar results.

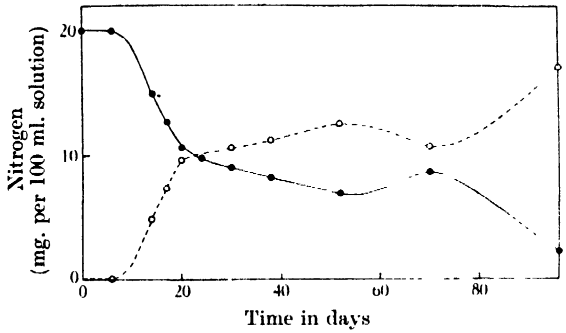

Fig. 2. Third series of nitrification experiments.
●—● Ammonia-N. o- - -o Nitrous-N.

In Part I attention was drawn to work carried out by Beesley [1914] on the biological oxidation of ammonium salts, in which, at one stage during an experiment, a considerable proportion of the nitrogen known to be present was unaccounted for, although finally it appeared in the form of nitrate. That the missing nitrogen was present partly, if not entirely, as calcium hyponitrite there can now be little doubt. The results obtained by Beesley were closely paralleled in the first series of nitrification experiments performed by the present writer (Table I and Fig. 1). Although in this case the hyponitrite was not estimated gasometrically, the qualitative tests leave no room for doubt that the missing nitrogen existed at least partly, and probably entirely, in the form of calcium hyponitrite. Chemical evidence has been adduced to show that there could have been no accumulation of hydroxylamine under the circumstances.

The evidence available strongly suggests that nitrification may be effected by a number of different species or strains of bacteria. It is unlikely that cultivation in the laboratory has produced drastic changes in the enzymic activities of the micro-organisms, for subcultures invariably gave the same type of reaction as the original cultures. The only way in which artificial conditions appeared responsible for any change was that in the type detailed in the third series of experiments production of hydroxylamine and hyponitrous acid was definitely associated with the logarithmic increase phase of growth, although repeated subculturing reduced these intermediates to vanishing point.

Table IV. *Fourth series of nitrification experiments.*

	Nitrogen present in mg. per 100 ml. solution									
Days after inoculation	0	2	3	6	8	10	13	17	35*	55
Nitrogen present as:										
Ammonia	19·8	18·0	18·0	16·5	15·8	15·0	14·0	14·0	10·2	5·9

Hyponitrous acid	−	+	+	+	+	+	+	+	+	+
Nitric acid	−	−	−	−	−	−	−	−	−	−

n.d. means not determined.

* Determination of the total nitrogen by the Kjeldahl method (using selenium as a catalyst) in a parallel flask on the 35th day gave a value of 10·0 mg. nitrogen per 100 ml. solution.

The results are plotted in Fig. 3. Subcultures gave precisely similar results. In one series, a solution which contained initially 20·3 mg. NH_3-N per 100 ml. solution contained 4·4 mg. NH_3-N and 1·0 mg. $H_2N_2O_2$-N and no hydroxylamine or nitrate and only a trace of nitrite after 81 days.

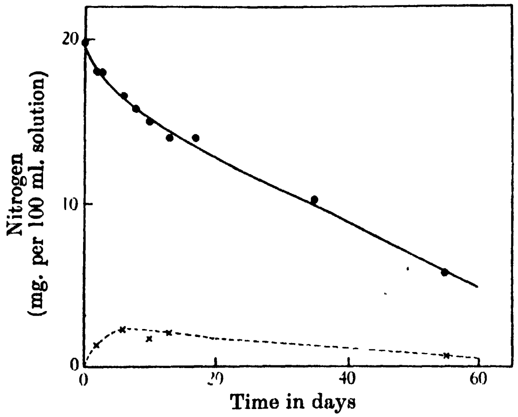

Fig. 3. Fourth series of nitrification experiments.
●—● Ammonia-N. ×---× Hyponitrous-N.

The most interesting type of biological nitrification encountered is that detailed in the fourth series of experiments (Table IV and Fig. 3) with a culture obtained from soil under grass which had been treated with "nitrochalk" some 6 months previously. This particular soil was selected since it repeatedly gave a strong positive reaction for hyponitrous acid with the resorcinol and potassium periodate test. With this culture, disappearance of ammonia was rapid, and after about 10 % of the nitrogen had accumulated in the form of hyponitrite, the proportion of the latter remained constant throughout the experiment. Presumably the missing nitrogen escaped in gaseous form.

Nitrification in soil.

It appears that the biological production of nitrite from ammonia in soil takes place in a variety of ways. The repeated failures to isolate nitrate-forming bacteria from soil suggest that *Nitrobacter* is by no means so widely distributed as the nitrite-forming organisms, and that the further oxidation of nitrite to nitrate may be attributable to autoxidation in acid media.

Evidence obtained from laboratory experiments indicates that hyponitrites may occur in soils, at least under some conditions, and tests at Jealotts Hill have shown that small amounts of hyponitrite are in fact present in certain soils. On the other hand, evidence has been advanced by Gopala Rao and Dhar [1931; Gopala Rao, 1934] and by the writer, showing that in exposed soils in the tropics, nitrification is, at least partly, a chemical process. Nitrite formation may be effected by a photochemical reaction and, to a lesser extent, by alternate wetting and drying-out of soils.

The depth to which ultraviolet light can penetrate the soil is an important matter in this connection in the tropics. It is believed that photonitrification of ammonium salts is effected by light of the wave-length 3100–2900 Å. The mercury arc emits radiations down to 1800 Å., while the solar spectrum does not penetrate into ultraviolet regions beyond 2900 Å. It was found in the laboratory that whilst light from a mercury vapour lamp effected nitrite-formation in a silica gel impregnated with ammonium sulphate to a depth of several inches, no liberation of iodine from potassium iodide occurred through 0·25 inch of moist or dry soil. Nevertheless, the question of penetration of soil by chemically active radiations from sunlight cannot be readily dismissed: Hoerlin [1934] states that the ultraviolet radiation in equatorial latitudes is of different intensity and composition from that in temperate regions. Many of the chemical reactions caused by ultraviolet light are effected also by the action of hydrogen peroxide (*e.g.* liberation of iodine from potassium iodide, nitrite production from ammonia [Weith and Weber, 1874] and the formation of a pink substance from ammonium thiocyanate), and this may have some bearing on the question of the depth of photonitrification in exposed tropical soils which are wetted daily. It must also be borne in mind that ammonium salts often occur "free" in such soils, not being adsorbed by the soil colloids, and in equatorial latitudes the top soil layer is much more shallow than in temperate regions.

Once nitrite is formed in the acid soils of equatorial countries, the further oxidation to nitrate must be largely effected by chemical means.

The criticisms advanced by Fraps and Sterges [1935] against the work of Dhar and Gopala Rao are without substance, since in their experiments soil was exposed to the sun in pyrex beakers covered with glass. The writer has confirmed that no ultraviolet radiations of wave-length capable of oxidising ammonium salts to nitrite can penetrate these materials.

Denitrification in sunlight.

Recently Dhar [1934] has sought to explain the losses of nitrogen from soil, known to take place under certain conditions in presence of readily oxidisable organic matter, as a result of the decomposition of ammonium nitrite in sunlight. Dhar has found that when mixed with sterilised or unsterilised soil, or in presence of a photosensitiser such as titania, zinc oxide or ferric oxide, ammonium nitrite undergoes decomposition with liberation of free nitrogen: since nitrite is an intermediate in nitrification, it is supposed that ammonium nitrite is formed and then disrupted under the action of light.

The present writer found that a solution of ammonium chloride and sodium nitrite in stoichiometrical proportions (p_H 6·8) showed no decomposition in the dark during a period of 3 months, and only slight losses of ammonia occurred, the nitrite content remaining unchanged, after 87 hours' irradiation by the mercury arc (Table VII). In presence of freshly-ignited titania however, both in sunlight and under the mercury arc, small quantities of gas were liberated. In view of the fact that nitrite is so readily transformed into nitrate in acid soils, it seems doubtful if any considerable losses from soil can occur in this way except, possibly, in arid regions where nitrite accumulation takes place.

While discussing nitrogen losses from the soil, attention may be drawn to the importance of the results of the fourth series of nitrification experiments.

Jenny [1929] has shown that, in general, the nitrogen content of the soil is a function of the mean annual temperature and humidity, and thus for any given mean annual temperature and humidity, the potential nitrogen content of the soil has a maximum value. Apart from this it is evident that the nitrogen content of the soil cannot be raised indefinitely, and that some means must exist of ridding the soil of surplus nitrogen when the potential nitrogen content is exceeded as, for instance, in heavy applications of nitrogenous fertilisers. The nature of this mechanism is obscure, and it may be biological or chemical in character.

In the fourth series of nitrification experiments described in this paper, a loss of nitrogen followed the conversion of ammonium sulphate into hyponitrite, and the only plausible explanation is that the missing nitrogen has been released in gaseous form. This may be an example of a biological mechanism effecting the escape of excessive amounts of nitrogen from the soil. In the present case however the detection and estimation of gaseous forms of nitrogen released by bacterial agency is difficult, since the reaction can proceed only in presence of adequate supplies of oxygen.

EXPERIMENTAL.

The decomposition of hydroxylamine.

Solutions of hydroxylamine hydrochloride were prepared, and the reaction was adjusted by addition of sulphuric acid or sodium hydroxide; the p_H values were determined colorimetrically. The solutions were preserved in the dark in stoppered flasks, and the hydroxylamine content was determined by boiling with ferric alum and sulphuric acid, followed by titration of the reduced iron with potassium permanganate.

Table V. *Loss of hydroxylamine from aqueous solution at different* p_H *values.*

Initial conc. 0·0073 g. NH_2OH per 100 ml. Temperature 32°.

	% Loss				
p_H of solution	After 1 day	After 7 days	After 14 days	After 23 days	After 38 days
2·2	0·0	0·0	0·0	0·0	0·0
4·6	1·0	1·7	9·8	—	—
5·9	46·1	46·9	59·4	61·1	60·2
8·4	46·1*	66·3	75·2	81·7	86·9

* Determination of other forms of nitrogen in this solution gave NH_3-N nil; nitrite-N, trace; nitrate-N, 0·001 %.

It is evident that the decomposition of hydroxylamine which occurs in solutions not strongly acid is an oxidation, for vigorous boiling of hydroxylamine hydrochloride with $N/10$ NaOH in an inert atmosphere resulted in but slight decomposition.

Losses of hydroxylamine from solution occurred in the presence of nitrite, whatever the reaction of the medium. For example, a solution was prepared containing 0·039 g. NH_2OH-N and 0·005 g. nitrite-N per 100 ml. solution. Immediately after preparation, the hydroxylamine content dropped to 0·036 g. NH_2OH-N per 100 ml. solution, and 23 hours later the solution contained 0·034 g. NH_2OH-N and no nitrite-N per 100 ml. solution. Thus, the whole of the nitrite *plus* a stoichiometrically equivalent amount of hydroxylamine had disappeared within a day.

In a further experiment, a solution containing initially 0·030 g. NH_2OH-N and 0·057 g. nitrite-N per 100 ml. solution had the composition 0 g. NH_2OH-N and 0·043 g. nitrite-N per 100 ml. solution on the following day. Both experiments were carried out at 32°.

It is evident that the course of the reaction between hydroxylamine and nitrous acid must be affected by the reaction of the medium, and accordingly experiments were carried out, in stoppered flasks, at different p_H values (Table VI).

Table VI. *Loss of nitrogen from solutions of hydroxylamine and nitrous acid at different* p_H *values.*

Initial conc. 0·036 g. NH_2OH-N and 0·034 g. nitrite-N per 100 ml. solution. Temperature 32°.

p_H of solution	NH_2OH-N after 1 day	Nitrite-N after 1 day
2·4	0·001	0·000
4·8	0·000	0·000

7·6	0·000	0·028

The photochemical decomposition of ammonium nitrite.

Irradiation of an aqueous solution of ammonium nitrite by means of a 100 D.C. mercury arc gave the results shown in Table VII.

Table VII. *Irradiation of ammonium nitrite by ultraviolet light.*

Initial conc. 0·028 mg. NH_3-N and 0·027 mg. nitrite-N per 100 ml. solution (prepared from ammonium chloride and sodium nitrite).

Treatment	NH_3-N	Nitrite-N
3 months in dark	0·027	0·028
87 hours' irradiation by mercury arc	0·023	0·028

The biological oxidation of ammonium sulphate. Beesley's medium.

The medium employed for the culture of the nitrifying organisms was that recommended by Beesley [1914] and prepared according to the formula:

Nitrogen (in combination as ammonium sulphate) 0·20 g.; KH_2PO_4 0·20 g.; NaCl 0·20 g.; $MgSO_4, 7H_2O$ 0·066 g.; $CaCO_3$ 20·0 g.; distilled water 1000 ml.

The p_H of the medium was 6·9 (quinhydrone electrode) 1½ hours after preparation.

Usually about 2 litres of Beesley's medium were prepared and inoculated with about 1 ml. of a vigorous culture of nitrifying organisms obtained from soil: after standing overnight, quantities of 100 or 200 ml. were placed in a number of 500 ml. conical flasks which were closed with rubber bungs or cotton-wool: when rubber bungs were employed, an adequate supply of air was present for complete nitrification. The flasks were incubated at 32° and the contents analysed at convenient intervals.

Analysis of the nitrifying solutions.

Routine analysis of Beesley's medium, after inoculation with nitrifying organisms, was carried out as follows. The calcium carbonate was removed by filtration and the filtrate made up to a standard volume with water. After qualitative tests for hydroxylamine (Fehling's solution), hyponitrous acid (resorcinol and potassium periodate), nitrous acid (Griess) and nitric acid (reduction to nitrite), aliquot portions of the liquid were analysed as follows.

(*a*) Ammonia was estimated by distillation with magnesia into standard sulphuric acid solution.

(*b*) Nitrite and nitrate together were determined by addition of Devarda's alloy to the solution, after the ammonia estimation had been completed, followed by distillation of the ammonia formed by reduction into standard acid as before.

(*c*) Nitrite was determined by the Griess-Ilosva colorimetric method.

(*d*) The solution was titrated with potassium permanganate in presence of sulphuric acid before and after boiling: in this way the nitrite *plus* hyponitrite, and nitrite alone were estimated, but see the remarks on p. 1095. Permanganate titrations were carried out only in the first series of experiments, a gasometric method being subsequently employed for the estimation of hyponitrite.

(*e*) When present in sufficient quantity, hydroxylamine was estimated by boiling with ferric alum and sulphuric acid, followed by titration with potassium permanganate.

(*f*) *The estimation of hyponitrous acid.* The method of estimating hyponitrous acid entailed collection and examination of the gases evolved on boiling. 100 ml. of the solution were placed in a Claisen distillation flask, and after displacement of the air by a current of pure carbon dioxide from a Farmer's apparatus [1920], the contents of the flask were maintained at boiling-point for about 1 hour. The liberated gases (nitrous and nitric oxides and nitrogen) were swept into a Schiff's nitrometer, over strong potassium hydroxide (saturated with nitrous and nitric oxides), by a further current of carbon dioxide. Nitric oxide was estimated by measurement of the diminution in volume after shaking with ferrous sulphate, and nitrous oxide by determination of the volume decrease after sparking in presence of excess of hydrogen. As air was often present, particularly during the initial stages of nitrification experiments, the amount of hydrogen used was found by noting the diminution in volume after further sparking with oxygen. Attempts to measure the proportions of the three gases present by measuring the volume changes, first after sparking with hydrogen and then after exploding with oxygen, often gave results explicable only on the supposition that any nitric oxide present had been largely reduced to ammonia. Nevertheless, the absorption of nitric oxide by ferrous sulphate solution is not an entirely satisfactory procedure, for the reaction is somewhat slow, and it is necessary first to saturate the absorbent with nitrous oxide; moreover, the precipitate formed as a result of potash from the nitrometer coming into contact with ferrous sulphate is often troublesome in the gas burette.

In some experiments, the hyponitrite in the culture solution was actually separated as the silver salt by precipitation with excess of silver nitrate; after standing overnight, the precipitate was washed free from silver nitrate and decomposed by boiling with sulphuric acid. Analysis of the mixed nitrogen gases evolved was carried out in the manner described. Vigorous boiling of a solution of ammonium nitrite with a small amount of calcium carbonate, the first-named being present in the maximum concentration in which it could occur in the culture liquid, resulted in the liberation of so small a quantity of gas that it was evident that no appreciable error was introduced into the hyponitrite estimation as a result of nitrogen gas liberated by the decomposition of any ammonium nitrite present.

The estimation of hyponitrous acid is not easy, and to this fact, doubtless, must be attributed the former lack of convincing evidence that this acid constitutes an intermediate in the oxidation of ammonia to nitrous acid.

Experiments were first conducted with silver hyponitrite, which was prepared as a pale greenish yellow, flocculent precipitate by addition of excess of silver nitrate to a solution of sodium hyponitrite. The salt dried to a green powder, which rapidly darkened when exposed to light. The silver was estimated as chloride and the hyponitrite determined by oxidation of the salt by $N/10$ $KMnO_4$, acidified with sulphuric acid, and collection of the nitrogen gases evolved on heating in a Schiff's nitrometer over potash, as described above. In this procedure a portion of the nitrogen present in the hyponitrite remained in the flask as nitrate (see equations on p. 1096), and was subsequently estimated in the form of ammonia, after reduction with Devarda's alloy. The nitrogenous gases collected in the nitrometer were analysed in the manner already described.

Analysis of the silver salt gave the following results (%):

	Found				Calculated for $Ag_2N_2O_2$
	Preparation (*a*)		Preparation (*b*)		
Ag		75·7 %		74·8	78·25
N as NO	1·51		1·09		
N as N_2O	6·40		8·79		
N as N_2	0·00				
N as NO_3'	2·55		0·08		
*N_2O_2''		22·4		21·6	21·75
		98·1		96·4	100·00

Calcium hyponitrite was prepared by addition of excess of calcium nitrate to a solution of sodium hyponitrite: the resulting precipitate was washed with water, then with alcohol and finally with ether and dried on filter-paper.

Analysis of calcium hyponitrite:

	Found		Calculated for $CaN_2O_2,4H_2O$
Ca		23·35 (23·34) %	23·29
N as NO	1·85		
N as N_2O	9·57		
N as N_2	0·00		
N as NO_3'	4·17		
Total N	15·59		
*N_2O_2''		32·76	34·80
CO_3''		1·43	—
N_2O (by difference)		42·47	41·86

On heating to constant weight at 105°, the loss in weight was 35·41 %.

* This figure was arrived at by addition of the nitrogen found as NO, N_2O, N_2 and NO_3'' and multiplication by the appropriate factor.

In routine analysis of soil, ammonia is estimated by distillation with magnesia and collection in standard acid, whilst nitrite and nitrate together are determined by measurement of the further ammonia liberated by distillation with magnesia after reduction by Devarda's alloy. With pure hydroxylamine hydrochloride practically no "ammonia"-nitrogen is found by distillation with magnesia, but the value for the "nitrate"-nitrogen is between 70 and 90 % of the hydroxylamine-nitrogen known to be present. Hyponitrite is not detected during such soil analysis, since the nitrogen is lost in gaseous form on warming.

Fortunately, hydroxylamine was never present in more than very small amount during the present investigation, so that no error was introduced from this source. Hyponitrite and nitrite do not react but aqueous solutions of calcium hyponitrite slowly decompose on standing. In presence of hyponitrite, nitrite can be accurately estimated by permanganate titration, provided that the hyponitrite is first decomposed by boiling the solution for 10 minutes.

The action of potassium permanganate on hyponitrites. The action of permanganate on hyponitrites was investigated, but the results obtained are somewhat inconclusive.

Kirschner [1898] stated that oxidation of hyponitrous acid by potassium permanganate entailed the consumption of only one atom of oxygen per mol. of acid, but subsequent investigators have disagreed with this view. The present research showed that considerable variation occurs in the ratio $O/H_2N_2O_2$ during the oxidation of hyponitrites by addition of the latter to a cold, acidified solution of potassium permanganate. In general, the equation

$$4H_2N_2O_2 + 4O = 2HNO_3 + 3H_2O + 3N_2O$$

is satisfied, giving a value of unity to the ratio $O/H_2N_2O_2$, as claimed by Kirschner.

Eighteen determinations of the hyponitrite in silver hyponitrite by this method gave a mean value of 20·94 ± 1·31 % as against the theoretical value of 21·75 for pure $Ag_2N_2O_2$, but the figures varied between 11·02 and 31·94 %.

It appears that the equation given above may represent the sum of two reactions:

$$(a)\quad H_2N_2O_2 = H_2O + N_2O,$$

$$(b)\quad H_2N_2O_2 + 4O = 2HNO_3.$$

Under laboratory conditions with cold permanganate and sulphuric acid, the reaction shows a definite tendency to proceed so that three-fourths of the hyponitrous acid decomposes according to (*a*) and one-fourth is oxidised according to (*b*), although this relationship appears to be fortuitous.

SUMMARY.

The oxidation of ammonia (as ammonium sulphate) by cultures of soil micro-organisms proceeds in a variety of ways. The type most frequently encountered was that in which oxidation ceased after about 5 % of the ammonium salt had been converted into nitrite: with other cultures nitrite formation was vigorous and rapid.

The question of the presence of intermediate compounds during the course of nitrification has been investigated in detail and it has been established that, while hydroxylamine has only an ephemeral existence at p_H values of 6 and above, calcium hyponitrite constitutes an important intermediate compound during nitrification by certain strains of soil bacteria. The presence of hyponitrite was detected by the colour given with resorcinol and potassium periodate, and its estimation was effected by collection and examination of the nitrogenous gases liberated by boiling the culture liquids, or by separation of the silver salt, followed by measurement of the nitrogenous gases evolved by heating with sulphuric acid.

In one series of nitrification experiments, ammonia was oxidised to hyponitrite and this was followed by loss of nitrogen: in this particular series neither nitrite nor nitrate was detected at any time. In all cases, subcultures gave precisely similar results.

Nitrification in soils, by biological and chemical agencies, is discussed in the light of the results obtained during the present investigation.

The author wishes to express his indebtedness to the Research Council of Messrs Imperial Chemical Industries, Ltd. for a grant which rendered this investigation possible, and to Mr H. J. Page and Prof. H. Raistrick for their continued interest.

Note added April 26th, 1935. It has been found that the losses of nitrogen in gaseous form, which occurred in the fourth series of experiments, are attributable, at least in part. to the release of nitrous oxide. Berthelot and Gaudechon [*Compt. Rend. Acad. Sci.* (1910) **150**, 1517] found that nitrous oxide was decomposed into its elements under the action of ultraviolet light and this would explain why no accumulation of this gas takes places in the atmosphere.

CXXXVIII. STUDIES IN TISSUE METABOLISM.
VI. LACTIC DEHYDROGENASE, XANTHINE OXIDASE AND NUCLEOSIDASE IN TUMOUR AND MUSCLE EXTRACTS.

By ERIC BOYLAND AND MARGARET ESTHER BOYLAND.

From the Research Institute, The Cancer Hospital, London, S.W. 3.

(*Received March 29th, 1935.*)

In a previous communication [Boyland and Boyland, 1934] two distinct lactic dehydrogenases were described, one present in yeast and one in mammalian muscle. Tumour tissue (Jensen rat sarcoma) extracts made by the method previously used with muscle reduced methylene blue rapidly in the presence of lactic dehydrogenase coenzyme (prepared after Banga *et al.* [1932]) in the absence of any other substrate. Extracts of J.R.S. were also made by the method of freezing and thawing described by Boyland and Mawson [1934] with similar results. No amount of washing of the tissue or dialysis of the extract appeared to reduce the activity. In some cases the time of reduction of methylene blue was slightly decreased by the addition of lactate but the differences appeared to bear no relation to the time of dialysis, which precluded the possibility that the extract was acting on some dialysable substrate which it contained. Similarly extracts of rat and mouse muscle contained some lactic dehydrogenase but also reduced methylene blue without the addition of lactate. Some typical results for muscle extracts are given in Table I. All the results described in this paper were obtained by observation of the time necessary to decolorise methylene blue solution in evacuated Thunberg tubes at 38°.

Table I. *Reduction of methylene blue by frozen muscle extracts.*

1 ml. extract, 0·5 ml. $M/15$ Na_2HPO_4, 0·5 ml. substrate + water, 0·5 ml. 1/5000 methylene blue p_H 8·0–8·2.

Muscle	Rat skeletal		Rat heart		Mouse skeletal		Rabbit heart		Rabbit skeletal	
Additions	T mins.	Activity (100/T)	T mins.	Activity (100/T)	T mins.	Activity (100/T)	T mins.	Activity (100/T)	T mins.	Activity (100/T)
None	>180	0·0	>800	0·0	>600	0·0	>180	0·0	>180	0·0
Lactate ($M/50$)	>180	0·0	—	—	>600	0·0	>180	0·0	>180	0·0
Coenzyme (0·4 mg.)	29	3·4	24	4·2	70	1·7	>180	0·0	>180	0·0
Coenzyme + lactate	18	5·5	1½	66·0	36	2·8	17	5·9	16	6·2
Adenyl pyrophosphate ($M/1000$)	22	4·3	16	6·2	90	1·1	>180	0·0	>180	0·0
Hypoxanthine ($M/6000$)	19	5·2	16	6·2	35	2·9	>180	0·0	>180	0·0

It can be seen that extracts of rabbit heart or skeletal muscle will not decolor methylene blue in the presence of coenzyme without added lactate.

Extracts of some tumours (carcinoma 63, sarcoma 37, Crocker 180 and Mal sarcoma of mice and rat sarcoma R. 10) gave results comparable with those obtained with muscle, *i.e.* a lactic dehydrogenase was present but its effect was partly masked by the presence of another enzyme system. It will be shown that this could be adenine nucleosidase and xanthine oxidase. The optimum reaction for the lactic dehydrogenase of heart muscle is at about p_H 9, while at p_H 7 the enzyme has about half the optimum activity [Boyland and Boyland, 1934]. Experiments showing the effect of p_H on a tumour extract are given in Table II and Fig. 1.

Table II. *Reduction of methylene blue by extracts of frozen J.R.S.*

	p_H	Coenzyme mg.	Lactate (M/50)	T mins.	Activity (100/T)
Extract 1	6·0	0·4	–	5	20·0
	6·0	0·4	+	8½	12·0
	8·5	0·4	–	7	14·0
	8·5	0·4	+	5½	18·0
Extract 2	8·0	0·4	–	9	11·0
	8·0	0·4	+	8	12·0
	8·0	0·1	–	90	1·1
	8·0	0·1	+	34	2·9

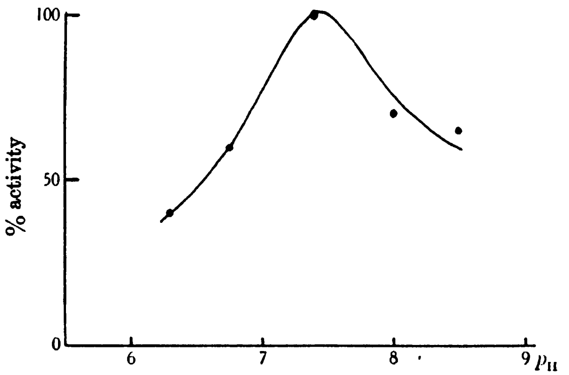

Fig. 1. Reduction of methylene blue by extract of frozen J.R.S. In each tube 1 ml. extract, 1 ml. M/15 phosphate, adenylpyrophosphate (M/1000), and 1 ml. M/5000 methylene blue.

Table II also shows the effect of adding small quantities of coenzyme, sufficient to activate the lactic dehydrogenase but barely enough to act as substrate for xanthine dehydrogenase, thus revealing the effect of lactic dehydrogenase. With sarcomata 37, Crocker 180 and Mal[1] the proportion of the lactic dehydrogenase to the nucleosidase-xanthine oxidase systems is much higher as shown in Table III.

The rate of oxidation of hexosediphosphate in the presence of coenzyme was determined in some extracts and was found to be similar to that of lactic acid in all experiments. It is therefore not tabulated in Table III.

Xanthine oxidase.

The addition of hypoxanthine solution (final concentration 1 in 2000) to the tissue extracts produced decoloration of methylene blue in all cases except those of rabbit skeletal and heart muscle. Figures for xanthine oxidase activity are given in Tables I and III under hypoxanthine.

A measure of the relative amounts of the various enzyme systems is given by the figures in Tables I and III for the "activity" (100/T) with the corresponding substances. The figure for lactic dehydrogenase (column headed lactate

[1] A tumour produced in mice by Mr H. Burrows by subcutaneous injection of sodium 1:2:5:6-dibenzanthracene-9:10-endo-$\alpha\beta$-succinate [Cook, 1931].

Table III. *Activity of frozen tumour extracts.*

1 ml. extract, 0·5 ml. $M/15$ Na_2HPO_4, substrate and water 0·5 ml., 0·5 ml. 1/5000 methylene blue.

In all cases the reduction times with extract alone, and with lactate+extract were long compared with the other times.

(*a*) and (*b*) refer to extracts of different batches of tumours.

Substrate		Activity 100/T		
		Lactate $M/50$	Adenylpyrophosphate $M/1000$	Hypoxanthine $M/6000$
Tumour				
J.R.S.	(*a*)	0·0	12·5	33·0
	(*b* 1)	4·4	20·0	20·0
	(*b* 2)*	2·2	17·0	18·0
R. 10	(*a*)	0·0†	17·0	18·2
	(*b*)	0·0	9·5	15·4
Crocker 180	(*a*)	3·5	3·2	4·5
	(*b*)	12·0	5·0	8·0
C 63	(*a*)	0·9	2·7	10·0
	(*b*)	0·0	1·4	6·0
S 37	(*a*)	19·0	12·0	17·0
	(*b*)	16·0	12·0	12·0
Mal. sarcoma	(*a*)	3·9	1·0	3·2
	(*b*)	12·2	6·0	6·0

* Second extraction of same tumour. † With half quantity of coenzyme 100/T was 0·4.

$M/50$) in Table III was obtained by subtracting the "activity" with coenzyme alone from that with coenzyme+lactate. Zero activity therefore implies that the reduction times with coenzyme, with and without lactate, were the same. In some cases the times were actually longer with lactate than without. This may be due to a protection of the coenzyme by lactate. The figures for lactic dehydrogenase are therefore minimum values. The same effect is shown with adenylpyrophosphate and lactate or hexosediphosphate in Table IV.

Table IV. *Reduction of methylene blue by extracts of Mal. sarcoma.*

Additions	Extract 1		Extract 2	
	T mins.	Activity (100/T)	T mins.	Activity (100/T)
Adenylpyrophosphate ($M/1000$)	14	7·2	16	6·2
Adenylpyrophosphate+lactate ($M/50$)	19	5·3	39	2·5
Adenylpyrophosphate+hexosediphosphate ($M/50$)	27	3·7	38	2·6
Coenzyme (0·4 mg.)	27	3·7	37	2·7
Coenzyme+lactate	7	14·0	16	6·2
Coenzyme+hexosediphosphate	6½	15·0	16	6·2

Table IV also shows that adenylpyrophosphate has no activity as lactic dehydrogenase coenzyme. This has been confirmed by testing with the lactic dehydrogenase preparation of rabbit muscle, which contains no xanthine oxidase (see Table I) and does not decolorise methylene blue in the presence of adenylpyrophosphate alone.

Nucleosidase.

Szent-Györgyi's coenzyme, adenylpyrophosphate (prepared according to Lohmann [1932]) and adenylic acid reduced methylene blue in the presence of tumour extracts, but not with rabbit muscle extracts. The effect is probably due to the combined actions of a nucleosidase (adenine nucleosidase) and xanthine oxidise. It cannot be due to the latter enzyme acting with an impurity in the preparations, for there is a definite optimum p_H at about 7·4 (see Fig. 1), whereas xanthine oxidase has an almost constant activity between p_H 6·5 and 8·5. Levene *et al.* [1924] have shown that nucleosidase has an optimum at p_H 7·5.

A minimum figure for the nucleosidase activity of the extracts is given by the activity in the presence of adenylpyrophosphate, for the enzyme must act on this before the dehydrogenation can occur. That the limiting factor is often the amount of xanthine oxidase present can be seen from the fact that the reduction times are in many cases nearly the same for hypoxanthine and adenylpyrophosphate. On the other hand milk xanthine oxidase reduces methylene blue 100 times more rapidly in the presence of hypoxanthine than in the presence of adenylic acid [Dixon and Lemberg, 1934]. Rabbit muscle extracts do not reduce methylene blue with adenylpyrophosphate or hypoxanthine. The lack of activity with adenyl pyrophosphate may be due to the absence of xanthine oxidase only and not of nucleosidase.

Incubation of rabbit muscle extract with coenzyme for 50 minutes did not however destroy the latter, for its power of acting as lactic dehydrogenase coenzyme was unimpaired. If adenine nucleosidase is present it must therefore be only in relatively small amounts.

DISCUSSION.

The foregoing experiments show that the tissue of the tumours examined contains lactic dehydrogenase, which requires a coenzyme for its action and shows optimum activity in alkaline solutions. It therefore appears to be identical with the enzyme present in mammalian muscle. Many tumour extracts however oxidise the coenzyme so rapidly that the lactic acid oxidation is not readily observed. Rat and mouse muscle extracts resemble the tumour extracts to some extent in this respect as they reduce methylene blue in the presence of coenzyme or adenylpyrophosphate. In this they differ markedly from rabbit muscle extract which does not oxidise the coenzyme, nor does it contain xanthine oxidase. It is possibly for this reason that Meyerhof found that rat muscle did not give glycolytically active extracts, as his first experiments were made without addition of coenzyme or adenylpyrophosphate. Boyland and Mawson [1934] were able to prepare glycolytically active rat muscle extracts by adding sufficient adenylpyrophosphate to compensate for its destruction.

Tumour extracts generally attack adenylpyrophosphate and lactic dehydrogenase coenzyme even more rapidly than does rat muscle extract. There is a large variation in the rate of attack with different tumour extracts. Extracts of J.R.S. oxidise the coenzyme so rapidly that it is difficult to determine the lactic dehydrogenase activity with any degree of accuracy. On the other hand some extracts of rapidly growing mouse tumours do not react so rapidly with the coenzyme and therefore show lactic dehydrogenase activity.

SUMMARY.

1. Rat, mouse and rabbit muscle and mouse and rat tumours (C 63, S 37, Crocker 180, Mal. sarcoma, R. 10 and J.R.S.) contain lactic dehydrogenase similar to that found in heart muscle.

2. Rabbit muscle extract does not contain xanthine oxidase or adenine nucleosidase but rat and mouse muscle extracts contain both these enzymes.

3. All the rat and mouse tumour extracts examined contain xanthine oxidase and attack adenylpyrophosphate or lactic dehydrogenase coenzyme rapidly. The rate at which the adenine derivatives are attacked varies with different tumour strains.

One of us (M. E. B.) has pleasure in thanking the House Committee of the Cancer Hospital for a scholarship held during the progress of this work.

CXXXIX. STUDIES IN THE BIOCHEMISTRY OF MICRO-ORGANISMS.

XLIV. FULVIC ACID, A NEW CRYSTALLINE YELLOW PIGMENT, A METABOLIC PRODUCT OF *P. GRISEO-FULVUM* DIERCKX, *P. FLEXUOSUM* DALE AND *P. BREFELDIANUM* DODGE.

BY ALBERT EDWARD OXFORD, HAROLD RAISTRICK
AND PAUL SIMONART.

From the Division of Biochemistry, London School of Hygiene and Tropical Medicine, University of London.

(*Received March 29th, 1935.*)

It has already been reported in Parts XIX and XXIX of this series that when *Penicillium griseo-fulvum* Dierckx is grown on liquid media containing glucose as sole source of carbon, and sodium nitrate as sole source of nitrogen, the following products are to be found in the metabolism solution when most of the glucose has been utilised: 6-methylsalicylic acid [Anslow and Raistrick, 1931]; gentisic acid, fumaric acid and mannitol [Raistrick and Simonart, 1933]. The factors governing the formation of these products are temperature of incubation and ratio of glucose to sodium nitrate. The presence of the two phenolic acids mentioned above causes the metabolism solutions to give respectively a purple or blue coloration with ferric chloride. Further experiments have now shown that when the nitrogen source is changed from NO_3^- to NH_4^+ the course of the metabolism of the glucose is entirely changed. The coloration given with ferric chloride is now no longer purple or blue but green, and in place of the above two colourless phenolic acids there is formed a much more complex yellow phenolic acid, of empirical formula $C_{14}H_{12}O_8$, which gives a deep green colour with aqueous ferric chloride, and for which we propose the name *fulvic acid*. The yield of fulvic acid from this organism is however small and its isolation in a pure state from the metabolism solution is very difficult. The reaction given by fulvic acid with ferric chloride and also certain of its other properties are very similar to those of the complex mould product citromycetin, $C_{14}H_{10}O_7$, produced by species of *Citromyces* [Hetherington and Raistrick, 1931], hitherto the only mould metabolic product known to give an intense green colour with ferric chloride.

Subsequently to the above observations on *P. griseo-fulvum* our colleague, Mr G. Smith, has found that two other species of *Penicillium*, *viz. P. flexuosum* Dale and *P. Brefeldianum* Dodge[1] give rise to metabolic solutions giving intense green colorations with ferric chloride, when grown in test-tubes on Raulin-Thom medium containing glucose and tartaric acid as sources of carbon, and ammonium tartrate, phosphate and sulphate as sources of nitrogen. We have isolated the metabolic product responsible for these reactions and have found that it is in fact fulvic acid in each case. Furthermore, the yield, especially with *P. Brefeldianum*, is very much larger than with *P. griseo-fulvum*, the greater part of the fulvic acid being found however in the mycelium in the case of *P. Brefeldianum*.

---

[1] This name has recently been altered to *Carpenteles Brefeldianum* by Shear [1934].

A further point of interest is that the metabolism solution from *P. flexuosum* also contains 6-methylsalicylic acid, but this acid was not detected as a metabolic product of *P. Brefeldianum*. The fact that both *P. griseo-fulvum* and *P. flexuosum* give rise to fulvic and 6-methylsalicylic acids is not surprising in view of the close morphological relationship of these organisms. Thom [1930] places *P. griseo-fulvum* in section 5 of the *Asymmetrica* division of species of *Penicillia*, *viz.* among the *Asymmetrica-funiculosa*, with possible affinities with the next section, *viz.* the *Fasciculata*, in which he places *P. flexuosum*.

The relationship between these organisms and *P. Brefeldianum* appears however to be remote. Dodge [1933] has recently made a careful study of the last-named organism, which was first isolated by Dr Rhoda Benham in America from the human alimentary tract, and reports that in its conidial stage it belongs to the *Monoverticillata* section of *Penicillia* (as do *Citromyces* species) with the further note that in this stage it may possibly belong to Thom's *Asymmetrica* section. It is of great interest that *P. Brefeldianum* readily produces perithecia, quite unlike those of species in the *P. luteum* series but comparable with those described long ago by Brefeld [1874] as typical of the so-called *P. glaucum* Link, an organism which no later worker has been able to isolate and the very existence of which has been doubted by many mycologists. Dodge, in fact, is of the opinion that *P. Brefeldianum* is morphologically very near to the classical *P. glaucum* described by Brefeld. It may be noted here that *P. javanicum* van Beijma [van Beijma, 1929] which is morphologically very close to *P. Brefeldianum*, and which also forms similar perithecia, appears to metabolise glucose in a medium containing NH_4NO_3 as source of nitrogen in an entirely different way [Lockwood *et al.*, 1934], to yield citric acid, a product which was not detected among the metabolic products of *P. Brefeldianum*. We intend at an early date to study in detail the metabolism of *P. javanicum* when grown on Raulin-Thom medium and also the metabolism of both organisms when grown on Czapek-Dox medium with sodium nitrate as sole source of nitrogen.

The mycelium of *P. griseo-fulvum* has been shown to contain a colourless, crystalline, nitrogenous substance (M.P. 165° decomp.) while the mycelium of *P. Brefeldianum* yields, in addition to fulvic acid, a different nitrogenous compound, as colourless crystals, M.P. 132–135°. The description of these two metabolic products is reserved for a later communication.

In this paper we propose to record the isolation, properties, derivatives and reactions of fulvic acid, together with the evidence for the empirical formula we have assigned to it, *viz.* $C_{14}H_{12}O_8$. The question of its structural formula is left for a later communication.

EXPERIMENTAL.

Section A. Metabolic products of P. griseo-fulvum *grown on media containing glucose and tartaric acid as sources of carbon, and ammonium salts as sources of nitrogen*[1].

The standard media used in this laboratory are Czapek-Dox medium (glucose, 50 g.; $NaNO_3$, 2·0 g.; KH_2PO_4, 1·0 g.; KCl, 0·5 g.; $MgSO_4, 7H_2O$, 0·5 g.; $FeSO_4, 7H_2O$, 0·01 g.; distilled water, 1 litre), and Raulin-Thom medium (glucose, 50 g.; tartaric acid, 2·7 g.; ammonium tartrate, 2·7 g.; diammonium hydrogen phosphate, 0·4 g.; K_2CO_3, 0·4 g.; $MgCO_3$, 0·27 g.; $(NH_4)_2SO_4$, 0·17 g.; $ZnSO_4$, $7H_2O$, 0·05 g.; $FeSO_4$, $7H_2O$, 0·05 g.; distilled water, 1 litre).

Preliminary experiments in test-tubes indicated that when the mould was grown on Raulin-Thom medium, the metabolism solution, after a few days' incubation, gave a green colour with ferric chloride. The optimum temperature for the production of the substance responsible for the coloration appeared to be about 20°, but there still remained 3·28 % of glucose after 42 days' incubation. The medium, initially at p_H 4·1, became much more strongly acid during the incubation period, *e.g.*, in the instance quoted above the p_H was below 2·8 after 42 days' incubation. On the other hand, when the mould was grown on Czapek-Dox medium at the same temperature the metabolism solution was slightly alkaline when all the glucose had been utilised, and gave a purple colour with $FeCl_3$. Hence it obviously became desirable to find out which constituents of Raulin-Thom medium are essential for the formation of the product giving the green coloration with $FeCl_3$.

A comparison of the respective compositions of Raulin-Thom and Czapek-Dox media shows that the former contains NH_4^+, CO_3^{--}, Zn^{++} and tartaric acid, all absent from the latter, whilst the latter contains Na^+, Cl^- and NO_3^- all absent from the former. Experiments were therefore conducted with the following four media:

A. Czapek-Dox medium omitting KCl but with $ZnSO_4$ added.
B. Czapek-Dox medium omitting $NaNO_3$ but with NH_4NO_3 added.
C. Czapek-Dox medium omitting $NaNO_3$ but with ammonium tartrate added.
D. Czapek-Dox medium with K_2CO_3 added.

After 14 days' incubation at 20°, only the metabolism solutions from B and C gave the green ferric chloride reaction. It appeared therefore that replacement of NO_3^- by NH_4^+ was responsible for the new mode of metabolism (tartrate not being essential), and different sources of NH_4^+ were next tried, *viz.* ammonium tartrate, sulphate and phosphate at concentrations of 1, 2, 3, 4 and 5 g. per litre. The results indicated that ammonium tartrate at a concentration of 5 g. per litre was the best source of NH_4^+. Finally a number of media were made up containing the salts of Czapek-Dox medium but with ammonium tartrate (5 g. per litre) replacing sodium nitrate, and with varying concentrations of glucose up to 10 %. The tubes were incubated for 30 days at 21°. The results are summarised in Table I and show that good production of phenolic substances took place on media containing 3–10 % glucose. In all cases a dark green colour was obtained with $FeCl_3$.

Isolation of the metabolic product responsible for the green coloration with ferric chloride. The medium selected for large scale work had the following composition: glucose, 50 g.; ammonium tartrate, 5 g.; KH_2PO_4, 1·0 g.; KCl, 0·5 g.; $MgSO_4$,

---

[1] The results in this section are taken from a thesis presented in 1934 by Dr P. Simonart for the degree of Ph.D. in the University of London.

$7H_2O$, 0·5 g.; $FeSO_4$, $7H_2O$, 0·01 g.; distilled water, 1 litre. One hundred and fifty 1 litre flasks each containing 350 ml. of this medium were sterilised by steaming on each of three successive days, sown with a suspension of spores of *P. griseo-fulvum* (obtained from 15-day old cultures at 30° on beer-wort agar in Roux bottles) and incubated at room temperature (19–21°) for 50 days. The mycelium and the filtered metabolism solution, which gave an intense green colour with $FeCl_3$, were then dealt with separately. The mycelial constituents of *P. griseo-fulvum* grown on Czapek-Dox medium and on the above modification of this medium will form the subject of a separate paper. In this place it will be sufficient to say that both mycelia contained considerable amounts of an ether-soluble, colourless, crystalline nitrogenous substance (M.P. 165° decomp.) the isolation of which in a crude state (M.P. about 150°) was mentioned by Anslow and Raistrick [1931] in their first biochemical study of this mould; and that the mycelium from the modified Czapek-Dox medium appeared not to contain any of the phenolic substance (fulvic acid) present in the metabolism solution.

Estimations carried out on an average sample of the metabolism solution gave the following results: apparent glucose content (by polarimeter) 1·82 %; Br absorption value (Koppeschaar's method) 2·1 mg. per ml. The metabolism solution was evaporated to small volume *in vacuo* below 50°, made strongly acid to Congo red by addition of 2*N* H_2SO_4 and extracted 12 times with an equal volume of chloroform. The extract was dried over anhydrous sodium sulphate and the solvent removed *in vacuo* at 40°. The brown, gummy residue was treated with a large volume of boiling water, the aqueous extract boiled with a little decolorising charcoal and filtered. On cooling, 0·42 g. of yellow needles separated, M.P. 241° decomp. The substance was further purified by crystallisation from ethyl acetate. Analysis and mixed M.P. with specimens of fulvic acid produced by *P. flexuosum* and *P. Brefeldianum* will be found later (p. 1111).

Section B. Metabolic products of P. flexuosum *Dale grown on Raulin-Thom medium.*

A preliminary investigation of the course of metabolism of glucose by this mould was made exactly as described in Part XXXIX of this series [Oxford and Raistrick, 1934] for *P. crateriforme* Gilman and Abbott. A quantity of Raulin-Thom medium (for composition see p. 1104) was distributed in 350 ml. lots in 49 one-litre conical flasks. After sterilisation each flask was sown with a spore suspension of *P. flexuosum* and incubated at 24°. Single flasks were removed periodically and tests made on the filtered metabolism solution. The quantitative results so obtained are summarised in Table II.

Table II.

Period of incubation days	Apparent % glucose by polarimeter	% glucose by Shaffer-Hartmann method	p_H	Titratable acidity ml. $N/10$ per 10 ml.	Br absorption value mg./ml.
0	5·35	5·20	3·9	2·5	0·10
3 (complete mycelial felt)	4·70	—	3·5	3·7	0·30
6	2·76	2·70	2·8	4·6	0·49
9	1·23	1·21	3·0	2·6	0·68
13	0·50	0·50	3·6	0·8	0·88
16	0·25	—	4·2	—	1·00
22	Practically nil	Present	5·6	—	1·20
27	Nil	Nil	6·3	—	1·22

The only qualitative results of note were the following: the green coloration with ferric chloride was perceptible on the third day, of moderate intensity on the ninth day and a deep emerald green on the thirteenth and subsequent days. Tartrate was still present on the ninth day but absent later. A moderate yellow precipitate was given with normal lead acetate on the 13th and subsequent days. The metabolism solution in the later stages was pale yellowish brown, deepening to reddish brown in colour on the twenty-second day; when brought to p_H 7 a deeper orange-brown or red colour was obtained. The mycelial felt, coherent at first, began to disintegrate about the twenty-second day and marked autolysis had set in by the twenty-seventh day. It is evident that the mould grows, and metabolises glucose, rapidly, but the yield of dry mycelium (5·1 g. per flask) was not excessively large. Solvent extraction of this mycelium yielded a minute amount of fulvic acid, but none of the nitrogenous substance, M.P. 165°, found in the mycelium of *P. griseo-fulvum*.

Isolation of fulvic acid from the metabolism solution. 44 flasks were removed after 16 days' incubation and the filtered metabolism solution was evaporated to 400 ml. *in vacuo* below 40°. A dark-coloured precipitate (A) separated during the evaporation (4·6 g.), which was found to contain the greater part of the fulvic acid produced by the mould. A minute amount of fulvic acid (M.P. 236° decomp.) was with difficulty obtained from the filtrate from this precipitate by a method similar to that previously described for *P. griseo-fulvum*, or by addition of normal lead acetate, treatment of the lead precipitate with dilute H_2SO_4, extraction with ether and crystallisation from water.

The dry precipitate (A) was extracted with ether in a Soxhlet apparatus for 3 working days. About 1·5 g. of yellow material separated from the ethereal extract and was crystallised first from 20 ml. dioxan, then from 16 ml. dioxan. Yield: 0·4 g. of lemon-yellow rods; M.P. 242° decomp. The material in the thimble unextracted by ether still contained some fulvic acid, as was proved by extraction with boiling dioxan. No other crystalline substance was obtained from it.

Isolation of 6-methylsalicylic acid from the metabolism solution. The dark brown filtrate from precipitate (A) was made acid to Congo red by addition of $2N$ H_2SO_4 and extracted 3 times with an equal volume of ether. Evaporation of the dried ethereal extract yielded a brown gum (1·4 g.) which, by fractional crystallisation from water, was shown to contain a little fulvic acid together with small amounts of 6-methylsalicylic acid. This substance was obtained as colourless crystals which were purified by sublimation in a high vacuum to yield colourless prisms, M.P. 170–171°, alone or mixed with authentic 6-methylsalicylic acid, which gave a beautiful purple colour with aqueous ferric chloride.

Section C. Metabolic products of P. Brefeldianum *Dodge grown on Raulin-Thom medium.*

A preliminary survey carried out as outlined previously for *P. flexuosum* Dale indicated that the course of metabolism was very similar to that of the latter mould. Growth was fairly rapid with production of a thick tough mycelial felt which, after becoming depressed at the edges, eventually became waterlogged, sank and was replaced by a new similar surface felt. The turbid metabolism solution was brown in colour and was obtained clear only after repeated filtration through paper. Its p_H was always well on the acid side (4 or below) and the titratable acidity (ml. $N/10$ NaOH required to bring 10 ml. of metabolism solution to p_H 7) initially 2·5, rose to 5·8 on the sixth day and then fell to 1·0 on the twenty-seventh day when all the glucose had been metabolised. When brought to p_H 7 the metabolism solution became deep brownish red in colour (or even clear wine-red when made slightly alkaline), but the colour became lighter on making strongly alkaline. The bromine absorption value of the metabolism solution steadily increased with incubation and when all the glucose had been utilised was 2·40 mg./ml. At all times the glucose content as estimated polarimetrically was practically identical with the value obtained by the Shaffer-Hartmann method. At the end of the incubation period the only striking reactions given by the metabolism solution were the following: an intense emerald-green coloration with aqueous or aqueous-alcoholic ferric chloride, given definitely on the sixth day and later becoming more striking; a heavy, brown precipitate with mercuric chloride solution; a heavy, yellow precipitate with normal lead acetate; reduction of $AgNO_3$ on standing. At p_H 7 the ferric chloride coloration is brown, becoming green on addition of a drop or two of dilute HCl.

Since the yield of fulvic acid given by *P. Brefeldianum* is considerably larger than with *P. griseo-fulvum* or *P. flexuosum*, *P. Brefeldianum* was used for the preparation in quantity of fulvic acid. The following are the results for a typical large-scale experiment: 100 flasks, each containing 350 ml. of medium, were taken after 33 days' incubation (residual glucose, nil) and the mycelium was separated from the bulk of the metabolism solution by filtration through muslin (weight of dried mycelium, 496 g.). The turbid filtrate was filtered through paper and the dark brown, slimy precipitate (product A, 15 g.) collected. The final clear brown filtrate was evaporated to about 400 ml. *in vacuo* below 50° and left in the cold room for several days. The brown, partly crystalline precipitate which separated was filtered off, washed with water and dried (product B, 42 g.). Further acidification of the final filtrate threw down a little tarry material from which no crystalline product could be isolated. Repeated ethereal extraction of the acid filtrate from this tar yielded a brown gum from which a minute amount of fulvic acid was eventually isolated by repeated crystallisation from water (charcoal) and finally from aqueous dioxan. The various aqueous mother liquors from these crystallisations were evaporated down in stages, but no product was obtained which gave other than a green coloration with ferric chloride. Hence 6-methylsalicylic acid was almost certainly absent.

Further batches of 100 flasks each gave very similar results save that the weight of dry mycelium fluctuated somewhat, *e.g.* weights of mycelium from successive batches were 452; 496; 371; 184; 351 g.; the probable explanation being that the last 3 batches were given longer periods of incubation (40–50 days), *i.e.* until several days after all the glucose had disappeared, with resulting partial autolysis of the mycelial felt. The yield of fulvic acid appeared not to be adversely affected thereby, but in these instances product B was small, its counterpart being the precipitate obtained by acidification of the mother liquor from product B (previously a tar).

Isolation and separation of fulvic acid from other metabolic products. The isolation of fulvic acid in quantity and in a high state of purity proved to be difficult for many reasons:

(*a*) Fulvic acid is only very sparingly soluble in hot ether or chloroform. To extract all the fulvic acid from the mycelium, or from product B, by use of these solvents in a Soxhlet apparatus requires weeks or even months.

(*b*) The crude fulvic acid so obtained cannot be satisfactorily purified from solvents such as hot ethyl acetate or dioxan, in which it is moderately soluble, because the accompanying nitrogenous substance, M.P. 132–135°, is very similar to fulvic acid in solubilities and crystalline shape.

(*c*) Even when the fulvic acid has been separated from this nitrogenous substance and other neutral substances by solution in aqueous sodium bicarbonate, the product recovered on acidification contains other phenolic acids, which are more sparingly soluble in dioxan than is fulvic acid and cannot be removed with certainty by crystallisation from that solvent. It is necessary first to extract the fulvic acid with boiling ethyl acetate in which the other phenolic acids are practically insoluble.

(*d*) The most efficient method of purification, *viz.* conversion into the potassium salt and recrystallisation of the latter, is impracticable on a large scale since the solubility of this salt in boiling methyl alcohol is only of the order of 0·1 %.

The following paragraphs give an account of the method finally adopted for the separation of the metabolic products and the purification of the crude fulvic acid. The mycelium and products A and B were worked up separately.

Treatment of the mycelium. The dried mycelium was finely powdered and extracted with light petroleum (B.P. 50–60°) in a large Soxhlet apparatus for two working days. This treatment removes fats and sterols, in which the mycelium is particularly rich. Thus, if the extract is evaporated to small bulk and allowed to stand for several weeks in the cold room, a copious crystalline precipitate of ergosterol (long needles) and, probably, ergosteryl esters (groups of small crystals) is produced; or if the extract is evaporated to dryness and treated with cold alcohol [Oxford and Raistrick, 1933] a relatively large amount of insoluble ergosteryl esters is obtained. The defatted mycelium was then similarly extracted with ether until it appeared to be entirely exhausted of ether-soluble material. This process required at least 40–50 working days and the mycelium was reground and redistributed among the thimbles after about 20 days' extraction. The yellowish brown solid crust which separated from the ether on the walls of the flasks was removed periodically, and the solvent itself was likewise renewed every 5 or 6 days, the ethereal mother liquors being kept and later combined, evaporated to dryness and worked up separately. The material which separated from the ether during the first 2 or 3 days' extraction was worked up separately, since it contained the bulk of a new, colourless, crystalline compound containing nitrogen, M.P. 132–135°.

Purification of crude fulvic acid. The crude fulvic acid so obtained (15–20 % by weight of the mycelium) was finely powdered and treated (in 50 g. lots in a large filtrate jar) with stirring, with excess of cold, nearly saturated sodium bicarbonate solution. After the effervescence had subsided, the mixture was allowed to stand for several hours, filtered and the dark-coloured filtrate acidified with $2N$ HCl and then kept in the cold room overnight. The impure fulvic acid, now free from neutral substances, was collected, well washed with water and dried *in vacuo* over solid KOH. It was further worked up in 40 g. lots, each being extracted many times with about 1600 ml. boiling ethyl acetate until the last extract deposited no crystalline material, or a mere trace of a sandy powder on long standing. Four or five extractions were usually necessary. The first was always deep red in colour, and subsequent extracts were orange-red, orange and finally pale yellow or brown. Fulvic acid was deposited in a hard cake of large brown or brownish yellow prisms on the bottoms and walls of the flasks, and since crystallisation was slow, 4 or 5 days were allowed before proceeding to the next stage. Detachment of the deposit by scraping with a spatula is a laborious task and it is better and quicker to decant off the supernatant liquid, wash once or twice with a little ethyl acetate, and dry *in situ* in a stream of air. Tared one-litre conical flasks were used for these crystallisations. Second and third crops of more impure fulvic acid were obtained by evaporating the ethyl acetate mother-liquors in stages and were separately crystallised from dioxan.

The volume of dioxan per g. required for the final crystallisation depends on the purity of the fulvic acid at this stage. If the acid is moderately pure, 10–12 ml. per g. will be required, but if still highly coloured and impure, 6 ml. per g. will be sufficient to bring the material into solution. The mixture of dioxan and crystals was heated to boiling with constant stirring in an oil-bath, boiled for a few minutes and filtered immediately. To the filtrate was added about 10 % of its volume of water and the whole, when cold, was left in the cold room for at least 2 days. Fulvic acid then separated as a yellow, sandy, crystalline powder (very small rods) which showed no tendency to adhere to the walls of the flask. The precipitate was collected, washed with dioxan containing 10 % of water, then with ethyl acetate and dried in air. Second, third, fourth and final crops were obtained by diluting successive mother liquors each time with 20 % of water and allowing to stand for several days in the cold room. The melting point and colour of each crop were noted. In general the lighter the colour, the higher the decomposition point when heated in a M.P. tube at a standard rate. The limiting values of the decomposition point were taken as 235° and 248°. Material melting or decomposing below 235° was again recrystallised from dioxan.

Treatment of product A. Product A was treated in a similar manner. In one instance, the proportion of the crystalline nitrogenous substance, M.P. 132–135°, was exceptionally large. The material remaining unextracted by ether after some 3 weeks' extraction was triturated with sodium bicarbonate solution. The filtrate contained some fulvic acid which was purified as previously described.

Treatment of product B. Product B yielded, by long-continued ethereal extraction, a pale, yellowish brown solid which was almost completely soluble in sodium bicarbonate solution. The unextracted part (after some weeks' extraction) was re-ground and the extraction continued with chloroform. After a few days, nothing further appeared to be extracted by this solvent, but this was due, not to removal of all the fulvic acid, but to the caking together of the solid in the thimble. The extraction was therefore discontinued and the residual solid treated with sodium bicarbonate *etc.*, as previously described. The presence of potassium hydrogen tartrate was noted in this residual solid, and a colourless specimen of this salt was obtained by repeated crystallisation from boiling water.

Recovery of dioxan. All dioxan used in the large scale work described above was purified by the method of Eigenberger [1931; see also Oxford, 1934] and was free from aldehydes and acetals. The final aqueous dioxan mother-liquors were combined and the greater part of the solvent was distilled off. The distillate was treated as crude, technical dioxan and submitted to the full process of purification.

The greater part of the dioxan used was recovered in this way in a pure state.

Yield of purified fulvic acid: 140 g. from 300 flasks, *i.e.* from 5250 g. glucose.

Section D. The colourless crystalline nitrogenous compound, M.P. *132–135°, from the mycelium of* P. Brefeldianum.

On p. 1108 it is stated that the material separating from the ethereal extract obtained during the first 2 or 3 days' extraction of the mycelium was kept separate from the material from later extractions. The weight of this material (by extraction of mycelium from 300 flasks) was 41·4 g. of which some 15 g. were insoluble in aqueous $NaHCO_3$. This latter material was repeatedly crystallised from dioxan (in which it is even more sparingly soluble than fulvic acid) and was finally obtained almost colourless but not crystalline by deposition from hot ethyl acetate solution. It melted at 132–135° with slight softening from about 129° onwards, the melting point remaining unchanged after a further crystallisation from dioxan. The melt set on cooling to a turbid glass. The substance contains neither sulphur nor phosphorus. (Found (Schoeller), C, 73·35, 73·24; H, 12·42, 12·29; N, 2·1 %; Methoxyl, nil. $C_{40}H_{79}O_5N$ requires C, 73·42; H, 12·18; N, 2·1 %.) The substance is of a waxy consistency and can be obtained crystalline only from dioxan, *e.g.* from hot aqueous dioxan it separates immediately in the form of tufts of curved, microscopically small, pointed hairs; but from hot anhydrous dioxan it separates first of all in tiny oily droplets, becoming partly crystalline in 24 hours and completely crystalline after several days in the form of radiating clusters of very small, straight needles, quite similar in shape to the crystals obtained when fulvic acid separates from alcohol. It separates in tiny droplets (in appearance not unlike yeast cells) from chloroform, acetone or ethyl acetate, but these do not become crystalline even on long standing. The material separating from these solvents can however be readily collected on a Büchner funnel and in bulk is indistinguishable from the crystalline form.

The substance is moderately readily soluble in cold alcohol, but quite insoluble in boiling water. It does not give the Molisch test for carbohydrates. It gives no coloration with ferric chloride in aqueous alcoholic solution. It is quite neutral, being insoluble in both dilute acids and alkalis, even on boiling. It gives no coloration with strong sulphuric acid and appears, in fact, to be a very stable and non-reactive substance. Further work is in progress on this substance and will be reported at a later date.

Section E. Fulvic acid and its derivatives.

Properties of fulvic acid. Fulvic acid is very sparingly soluble in the cold in all organic solvents, *e.g.* at 12°, even dioxan dissolves less than 1 % of the acid, which is not sufficient for an accurate determination of molecular weight by the cryoscopic method. It may be crystallised from boiling dioxan (15 parts), acetone or ethyl acetate (100–150 parts), ethyl alcohol (250–300 parts), toluene (very sparingly soluble even at B.P.), and from water when somewhat impure, pure fulvic acid being almost insoluble in boiling water. The appearance of the crystals obtained varies with the solvent used, the rate of cooling, the amount of water present and on other factors, *e.g.* from dioxan (with or without added water), it usually crystallises in lemon-yellow rods, sometimes curved, or in small rectangular prisms, or in parallelepipeds, sometimes with bluntly pointed ends; from acetone, in massive lemon-yellow prisms; from moist ethyl acetate in relatively large golden plates; from water in pale yellow plates, characteristically twinned; from absolute alcohol in clusters of very pale yellow, slender, pointed needles; from aqueous alcohol at 0° in slender, segmented, rectangular prisms; from toluene in very small, flat crystals of indefinite shape. From acetone or ethyl acetate it sometimes happens that massive yellow prisms are found side by side with much paler slender rods. In spite of this diversity of crystalline appearance, there can be no doubt of the essential homogeneity of the product prepared in quantity as previously described, since when regenerated from the recrystallised potassium salt, the product behaves similarly when recrystallised from the above solvents. Crystals of fulvic acid tenaciously retain many solvents, and air-dried, or even vacuum-dried, specimens do not always give results in accordance with the formula $C_{14}H_{12}O_8$. Drying at 138° in a stream of dry, oxygen-free nitrogen, or in a high vacuum at 100–110° is in many cases necessary to remove the last traces of solvent. The analytical results for various specimens of fulvic acid are summarised in Table III. Fulvic acid contains no methoxyl groups and no nitrogen.

Table III.

Source and treatment	% C	% H
1. From *P. griseo-fulvum*	54·43	4·10
Crystallised from H_2O. Dried to constant weight *in vacuo* at 100°	54·41	4·02
2. From *P. flexuosum*	54·24	4·01
Crystallised from dioxan. Dried to constant weight *in vacuo* at 110°	54·09	3·98
3. From *P. Brefeldianum*		
Crystallised from toluene		
(*a*) Dried *in vacuo* at ordinary temperatures	54·44	4·06
(*b*) Dried in N_2 at 138°	54·42	4·07
Theoretical for $C_{14}H_{12}O_8$	54·53	3·93

0·1134 g. of fulvic acid from *P. flexuosum*, dissolved in 13·57 g. dioxan, gave a depression in F.P. of 0·148°; hence, molecular weight = 268 (theory for $C_{14}H_{12}O_8 = 308$). This estimation is not very satisfactory because of the slight solubility of fulvic acid in cold dioxan but full confirmation of the formula assigned, *viz.* $C_{14}H_{12}O_8$, was obtained by the preparation and analysis of the trimethyl and triethyl derivatives, and the monoethyl ester (see later).

Pure fulvic acid, after crystallisation from any solvent, always begins to darken at about 195°, becomes gradually darker as the temperature is raised, begins to soften at about 236° and melts with vigorous effervescence to a deep brown liquid at about 246°, the actual softening and decomposition points varying a little with the rate of heating. Citromycetin ($C_{14}H_{10}O_7, 2H_2O$), which shows certain resemblances to fulvic acid, melts at 285° whilst a mixture of citromycetin and fulvic acid melted at 227°. The mixed melting-points of specimens of fulvic acid produced by all three moulds were as follows: product from *P. griseo-fulvum* (crystallised from ethyl acetate) + product from *P. flexuosum* (crystallised from dioxan), softens at 238°, melts with decomp. at 244°; product from *P. griseo-fulvum* + product from *P. Brefeldianum* (crystallised from dioxan), softening 236°, decomp. 243°; products from *P. flexuosum* and *P. Brefeldianum*, softening 235°, decomp. 245°. Further confirmation of the identity of all three specimens is afforded by the mixed M.P. of their trimethyl derivatives (see p. 1113).

Fulvic acid may be sublimed in a high vacuum at a bath temperature of 170°. The yellow sublimate melts at 242–243° (decomp.) but appears to have lost a molecule of water during the sublimation. (Found on different samples (Schoeller): C, 58·01, 57·63; H, 3·70, 3·48 %. Mol. wt. (in camphor), 329. $C_{14}H_{10}O_7$ requires C, 57·92; H, 3·47 %; Mol. wt. 290).

Fulvic acid titrates as a dibasic acid but the end-point is difficult to determine accurately because of the colour of the solution. 0·1902 g. from *P. Brefeldianum* dried to constant weight in N_2 at 138° dissolved in 10 ml. dioxan + 6 ml. water required 12·39 ml. *N*/10 NaOH for neutralisation to phenolphthalein; whence equivalent = 154. ($C_{14}H_{12}O_8$ titrating as a dibasic acid requires an equivalent of 154.)

Fulvic acid is optically inactive: 0·10 g. in 15 ml. dioxan in a 1 dm. tube gave a mean reading of only +0·02°. It is soluble with difficulty in aqueous sodium acetate giving a very pale yellow solution, but is readily soluble in sodium bicarbonate (with effervescence), carbonate or hydroxide to give yellow to orange solutions. With $FeCl_3$ fulvic acid gives (*a*) a wine-red colour in absolute alcoholic solution; (*b*) a deep green in aqueous alcohol, becoming olive brown on addition of more $FeCl_3$; (*c*) a stable green colour in aqueous dioxan. Citromycetin gives a dark emerald green colour under all these conditions. Unlike citromycetin, fulvic acid does not yield a hydrobromide with HBr in glacial acetic acid, nor is a hydriodide formed when it is dissolved in hot hydriodic acid of specific gravity 1·7, since an aqueous extract of the substance crystallising out on cooling gives no precipitate with silver nitrate.

Potassium salt of fulvic acid. This salt was prepared by the method used by Hetherington and Raistrick [1931, p. 222] for the corresponding salt of citromycetin. Fulvic acid (3 g.) was dissolved in boiling ethyl alcohol (750 ml.) and to the hot filtered solution was added an excess (90 ml.) of 5 % alcoholic potassium acetate solution. The potassium salt was precipitated immediately as a yellow jelly quickly crystallising to a mass of fine needles, which after standing overnight were collected, washed with alcohol, dried and recrystallised from boiling methyl alcohol, in which it is only very sparingly soluble.

The salt as prepared above was readily but not completely soluble in water and evidently contained traces of the free acid. (Found (Schoeller) on a sample dried to constant weight in a high vacuum at 80°, loss of weight (H_2O) 9·69 %; 9·42 %. $C_{14}H_{11}O_8K, 2H_2O$ requires 9·43 % H_2O. Found on dried material, C, 48·40; H, 3·60; K, 10·21 %. $C_{14}H_{11}O_8K$ requires C, 48·52; H, 3·20; K, 11·29 %.) Hence, as with citromycetin, the salt prepared by this method is essentially a monopotassium salt.

Ethyl fulvate. Various attempts to make methyl fulvate failed. These included the following: boiling the K salt with methyl iodide in dry methyl alcohol (no action); boiling the acid with 3 % methyl alcoholic HCl (mostly unchanged); boiling with saturated methyl alcoholic HCl (no crystalline product isolated). A beautifully crystalline ethyl ester was however obtained, though in small yield, by the following method. Fulvic acid (1 g.) was boiled with saturated ethyl alcoholic HCl (150 ml.) for 2½ hours. Most of the alcohol was then distilled off, and addition of water to the residue precipitated a brown amorphous solid from which nothing crystalline could be obtained. The aqueous mother-liquor from this amorphous solid deposited a considerable amount of yellow, crystalline material overnight in the cold room. This was collected, dried and extracted with a little boiling benzene. The residue, after many crystallisations from aqueous alcohol, yielded some 30 mg. of colourless, slender, silky needles; M.P. 230–234° (decomp.), after darkening from 200° onwards, but the effervescence is not so vigorous as with the parent substance.

(Found (duplicates by independent analysts): C, 57·11, 57·31; H, 4·86, 4·98; OEt, 13·88 %. $C_{14}H_{11}O_7.OC_2H_5$ requires C, 57·14; H, 4·80; OEt, 13·41 %.) Hence the substance is monoethyl fulvate. It gives a green coloration with ferric chloride in aqueous alcoholic solution. It dissolves immediately in aqueous sodium bicarbonate to a colourless solution, and addition of HCl then precipitates the unchanged ester. Its solution in glacial acetic acid (colourless) develops a yellow colour and a greenish blue fluorescence on addition of a few drops of concentrated HCl. Concentrated HBr however produces only a yellow colour and no fluorescence. Corresponding experiments with the parent acid gave neither colour nor fluorescence.

Trimethyl derivative of fulvic acid. Fulvic acid (0·8 g.) suspended in dry ether was treated with an ethereal solution of diazomethane prepared from nitrosomethylurethane (6 ml.). Evolution of N_2 was very slow and the acid did not appear to go into solution. The reaction mixture was kept overnight and the insoluble part was then collected. It consisted of almost colourless crystals (0·6 g.), which gave no reaction with ferric chloride in alcoholic solution, and was purified by two crystallisations from benzene (200 ml.) containing a little light petroleum, and then from dioxan (2·5 ml. per 100 mg.). From either solvent it formed colourless, microscopic crystals, M.P. 192°, with effervescence and some darkening. (Found on material dried to constant weight *in vacuo* over P_2O_5 (duplicates by independent analysts): C, 58·18, 58·32; H, 5·09, 5·21; OCH_3, 26·39, 27·02 %. $C_{14}H_9O_5(OCH_3)_3$ requires C, 58·26; H, 5·18; OCH_3, 26·59 %.)

The above trimethyl derivative was prepared by the same method from specimens of fulvic acid yielded by all three moulds, and the same compound was obtained in each case as the following melting points and mixed melting points show.

A. Derivative from fulvic acid from *P. griseo-fulvum* (crystallised from aqueous dioxan): M.P. 186–188°.

B. Derivative from fulvic acid from *P. flexuosum* (crystallised from benzene-light petroleum): M.P. 188–192°.

C. Derivative from fulvic acid from *P. Brefeldianum*, described above; M.P. 192°.

Mixture of A + C: M.P. 187–190°.

Mixture of B + C: M.P. 188°.

Like fulvic acid, this derivative is sparingly soluble in all solvents. It is not sufficiently soluble in cold dioxan to allow an accurate cryoscopic determination of its molecular weight. It is slightly soluble in boiling water giving a solution with a striking blue-violet fluorescence. It gives no coloration with ferric chloride and is slowly soluble in cold dilute alkali. Addition of a few drops of concentrated HCl to the colourless solution of the trimethyl derivative in glacial acetic acid produces a pale yellow colour and an intense blue fluorescence. Concentrated HBr gives a more intense yellow colour but no fluorescence.

The same product is obtained by methylation of fulvic acid in sodium bicarbonate solution with dimethyl sulphate.

Triethyl derivative of fulvic acid. Fulvic acid (0·8 g.) was treated with ethereal diazoethane prepared from nitrosoethylurethane (6·5 ml.). The reaction was vigorous and all the material soon dissolved. After standing overnight, a colourless substance (0·5 g.) had separated. This was collected and twice crystallised from benzene (50 ml.) and light petroleum (50–100 ml.). It formed colourless aggregates of microscopic crystals; M.P. 172–174° with effervescence to a red liquid which did not reset on cooling. (Found (duplicates by independent analysts): C, 61·04, 61·28; H, 6·31, 6·36; OEt, 33·6, 35·2 %. $C_{14}H_9O_5(OC_2H_5)_3$ requires C, 61·20; H, 6·17; OC_2H_5, 34·4 %.) 0·0781 g. in 5·41 g. dioxan depressed the F.P. of the latter by 0·180°. Hence mol. wt. = 377; $C_{20}H_{24}O_8$ requires mol. wt. 392.

The properties of the triethyl derivative are very similar to those of the trimethyl derivative, save that it is more soluble in certain solvents such as benzene and dioxan. It gives no colour with $FeCl_3$. It gives a yellow colour and a brilliant blue fluorescence with concentrated HCl and glacial acetic acid.

Diacetyl derivative of fulvic acid. To a solution of fulvic acid (6 g.) in glacial acetic acid (36 ml.) were added acetic anhydride (24 ml.) and anhydrous sodium acetate (7 g.), and the mixture was boiled for 20 minutes (oil bath at 140–150°); some darkening took place. It was then cooled and poured into ice-water, but nothing separated. Acidification with dilute HCl threw down a copious, pale yellow, sandy, crystalline precipitate which was filtered off immediately (5·4 g.). The product was purified by crystallisation from alcohol, then twice from chloroform-light petroleum, then from dioxan-light petroleum and finally from aqueous dioxan. It formed very pale yellow, minute, hexagonal prisms or square tablets which did not melt at 310°, but considerable darkening and shrinking occurred above 220°. It is almost insoluble in boiling benzene and carbon tetrachloride, sparingly soluble in boiling chloroform, moderately readily soluble in boiling ethyl alcohol or cold methyl alcohol, glacial acetic acid or dioxan. Its solution in aqueous dioxan or acetic acid has a marked blue fluorescence intensified by the addition of concentrated HCl. It is immediately soluble in aqueous $NaHCO_3$ or sodium acetate to yield almost colourless solutions with a marked blue fluorescence. It gives no colour with $FeCl_3$ in aqueous alcoholic solution. (Found (Schoeller): C, 57·77, 57·85; H, 3·89, 3·79 %. Mol. wt. (cryoscopic in dioxan), 319. $C_{18}H_{14}O_9$ (*i.e.* diacetyl derivative of $C_{14}H_{10}O_7$) requires C, 57·74; H, 3·77 %. Mol. wt. 374.)

Titration: 0·2305 g. in 35 ml. methyl alcohol + 10 ml. H_2O required about 9 ml. $N/10$ NaOH for the first transient end-point to phenolphthalein, but a permanent end-point appeared to have been reached at 12·2 ml. $N/10$ NaOH. This corresponds to an equivalent of 189 (theoretical for $C_{18}H_{14}O_9$ titrating as a dibasic acid = 187). The acetyl derivative is readily hydrolysed by cold dilute NaOH as was shown in the following way: 0·1529 g. was dissolved in 20·0 ml. $N/10$ NaOH, and the solution kept at room temperature for 3½ hours; the yellow colour became much intensified. Back-titration with $N/10$ H_2SO_4 then showed that 15·5 ml. $N/10$ NaOH had been used up, corresponding with an equivalent of 99 (theoretical for $C_{18}H_{14}O_9$ titrating as a tetrabasic acid, 94). Acidification of the titrated liquid then yielded 0·10 g. of almost pure fulvic acid (theoretical, 0·12 g.).

Acetyl estimation. 0·4418 g. was boiled for 6 hours with 50 ml. N H_2SO_4. 300 ml. H_2O were then added and the liquid distilled at atmospheric pressure until only 50 ml. remained. This was repeated seven times until a constant, very small titration was obtained for volatile acid in the distillate. A net amount of volatile acid equivalent to 21·8 ml. $N/10$ NaOH was produced in all, the theoretical for $C_{18}H_{14}O_9$ yielding $2CH_3.CO_2H$ being 23·6 ml. A parallel experiment showed that fulvic acid yielded no volatile acid at all under these conditions.

It will be noticed that the empirical formula for this acetyl compound $C_{18}H_{14}O_9$ corresponds to an empirical formula for the parent substance of $C_{14}H_{10}O_7$. The empirical formula we have assigned to fulvic acid, $C_{14}H_{12}O_8$, follows from the analysis of the trimethyl and triethyl derivatives, of the monoethyl ester and of the free acid dried to constant weight at 138° in nitrogen or at 110° in a high vacuum. On the other hand, fulvic acid on sublimation in a high vacuum at 170° gives analytical results agreeing well with the empirical formula $C_{14}H_{10}O_7$. Hence we believe that fulvic acid readily loses a molecule of water under certain conditions, *e.g.* acetylation or sublimation, and we hope to find the explanation for this fact as a result of experiments at present in progress on the molecular constitution of fulvic acid.

SUMMARY.

Penicillium griseo-fulvum Dierckx, *P. flexuosum* Dale and *P. Brefeldianum* Dodge when grown on a synthetic medium containing glucose, ammonium tartrate and mineral salts all give rise to a hitherto undescribed metabolic product for which the name fulvic acid is proposed. Fulvic acid, $C_{14}H_{12}O_8$, M.P. 246° (decomp.) is a crystalline yellow pigment. The following derivatives were prepared and are described: potassium salt, monoethyl ester, trimethyl, triethyl and diacetyl derivatives.

P. griseo-fulvum and *P. flexuosum* also produce 6-methylsalicylic acid.

Two different colourless crystalline compounds containing nitrogen have been isolated—one, M.P. 165° (decomp.), from the mycelium of *P. griseo-fulvum* and the other, M.P. 132–135°, from the mycelium of *P. Brefeldianum*.

CXL. STUDIES ON THE ANAEROBIC DECOMPOSITION OF PLANT MATERIALS.

III. COMPARISON OF THE COURSE OF DECOMPOSITION OF RICE STRAW UNDER ANAEROBIC, AEROBIC AND PARTIALLY AEROBIC CONDITIONS.

BY CADAMBI NARASIMHA ACHARYA.

From the Fermentation Department, Rothamsted Experimental Station, Harpenden, Herts.

(*Received April 1st, 1935.*)

THE experiments reported in this paper form a continuation of those already described [Acharya, 1935, 1, 2] and comprise a comparative study of the rate and course of decomposition of rice straw under anaerobic, aerobic and partially aerobic (*e.g.* water-logged) conditions.

The procedure and analytical details adopted were the same as those previously reported except for the modifications noted below. Ammonium carbonate equivalent to 1 % N on the straw, 0·5 g. K_2HPO_4, 0·05 g. $MgSO_4$, $7H_2O$ and 10 ml. of an extract from a rice soil were added to 20 g. portions of chaffed rice straw. The aerobic decomposition was carried out in open dishes, keeping the mass at a straw : water ratio of about 1 : 4 by additions of water from time to time. Water-logged conditions were obtained by having about an inch of water above the straw which was kept in beakers. Every few days the mass was stirred and fresh water added to replace evaporation losses. Decomposition under anaerobic conditions was carried out in stoppered bottles as already described [1935, 1, 2]. It was observed that abundant fungal growth accompanied decomposition under aerobic conditions and that even under water-logged conditions a thin fungal layer formed on the surface of the water when the mass was not stirred.

In addition to the above comparisons the effect of a regulated admission of air was tested by incubating samples in stoppered bottles and bubbling air through them at weekly intervals, after the accumulated gases had been tapped off for analysis. In one set of bottles a current of air was drawn for 5 minutes through the bottles just over the surface of the liquid; this is termed "mild aeration." In another set, air was bubbled through the liquid for 5 minutes so as to replace the dissolved gases by air and this is termed "strong aeration."

The results obtained are given in Table I. They show that the rate of decomposition is highest under aerobic conditions and lowest under anaerobic conditions, the partially aerobic (*e.g.* water-logged) systems occupying an intermediate position. At the end of 6 months the losses in ash-free insoluble dry matter are 65·0, 47·5 and 55·5 % for aerobic, anaerobic and water-logged fermentations respectively. The relative ease with which the cellulose and hemicellulose fractions of straw are attacked varies, however, in the different cases. Under anaerobic conditions, the hemicelluloses are the first to be attacked; at the end of one month 26·8 % of the amount originally present has been decomposed as against 9·8 % of the cellulose. At the end of the same period under aerobic conditions the loss of hemicelluloses is 62·4 % and of cellulose 56·2 %; the water-logged straw loses 38·0 % of hemicelluloses and 32·0 % of cellulose. The water-logged system thus resembles the aerobic system in the relative proportions of cellulose to hemicellulose destroyed, though the actual losses are much lower in the former case. The greater loss of cellulose in the early stages in these two systems, as compared with the anaerobic system, is probably due to the activity of cellulose-decomposing fungi.

The greatest loss of lignin occurs in the water-logged straw, whether determined on the material without any treatment or after a preliminary hydrolysis with 5 % H_2SO_4 [Norman and Jenkins, 1933, p. 826]; the losses are 39·6 % and 33·1 % of the initial value by these two methods. The corresponding losses under anaerobic conditions are 28·5 % and 28·5 %, and under aerobic conditions 33·5 % and 29·8 % respectively.

A striking difference between the three methods of fermentation lies in the protein content of the insoluble residue. In the aerobic system this rises from 2·88 g. per 100 g. straw at the start to 5·45 g. at the end of 6 months, whereas under anaerobic and partially aerobic conditions losses of this constituent are found. Of these two latter residues, the anaerobic contains less protein (2·01 g.) than the water-logged (2·69 g.); this difference is probably associated with the more intense reducing conditions present in the anaerobic system which help to bring more of the protein into solution.

The loss of added ammonia is most rapid under aerobic conditions, about 46 % of it being lost by volatilisation in a fortnight. The loss is less rapid from the water-logged straw, about 18 % being lost during the same period. The added ammonia is much better conserved under anaerobic conditions, the loss over a period of 6 months amounting to only 15 %; this no doubt is due to the closed nature of the system and the limited number of occasions on which the accumulated gases are let out for analysis.

The differences in the nature of the products obtained under aerobic and anaerobic conditions have been dealt with in a previous communication [1935, 1]. The formation of organic acids and the evolution of combustible gases characteristic of anaerobic decomposition are absent in the former case, where intermediate products if any are rapidly oxidised to CO_2. Water-logged conditions resemble the anaerobic system in the rapid accumulation of organic acids in the early stages, but these are decomposed much more rapidly than in the latter case.

The influence of partial aeration on anaerobic decomposition is shown in Tables I and II under the heads "mild aeration" and "strong aeration." The significance of these terms has been explained already.

With "mild aeration" the anaerobic conditions in the liquid portion are not appreciably disturbed as shown by the accumulation of organic acids and the evolution of methane and hydrogen. There is a marked increase in the amount of CO_2 evolved, presumably due to the admission of air, and a decrease in the amount of CH_4 formed. The amount of H_2 evolved shows a great increase as compared with anaerobic conditions. This difference, it is suggested, is associated with the oxidation-reduction potential of the system under these conditions.

The decomposition with "strong aeration" resembles that under aerobic conditions as shown by the small amount of organic acids, CH_4 and H_2 formed and the large amounts of CO_2 evolved (Table II). The high proportion of free nitrogen contained in the gases evolved in both aeration treatments is derived from the air passed through the bottles.

The nitrogen relationships under the different treatments are of special interest. It has already been noted that the amount of protein in the insoluble residue is lowest in the anaerobic system and highest in the aerobic system.

N_2 evolved	85	12,155	14,205

Whereas under anaerobic and water-logged conditions increasing amounts of protein dissolve with increasing periods of fermentation, in the aerobic system there is a continued accumulation of protein in the residue, due to the synthesis of insoluble microbial tissue.

The water-soluble protein-nitrogen is at a minimum under aerobic conditions (0·125 g. per 100 g. straw), as compared with anaerobic (0·207 g.) and water-logged systems (0·425 g.). The high value for soluble protein-nitrogen under water-logged conditions is noteworthy since most of it is synthesised from the ammonia originally added. It is an index of the great microbial activity under these conditions and is in marked contrast to the poor nitrogen immobilisation under anaerobic conditions.

The figures for nitrogen factor [Rege, 1927] and nitrogen equivalent [Richards and Norman, 1931] also show striking differences between the three sets of conditions. They are highest under aerobic conditions being 0·536 and 1·11 respectively, followed by water-logged conditions (0·395 and 0·961 respectively), while the anaerobic system shows the minimum values (0·069 and 0·169 respectively). Even "mild aeration" favours protein synthesis as shown by the jump of the nitrogen factor from 0·069 to 0·265, while "strong aeration" increases it to 0·330.

DISCUSSION.

The results indicate that partially aerated systems show the characteristics of both the aerobic and anaerobic types of decomposition of straw and that the degree of aeration decides which type predominates. Thus "mild aeration" resembles the anaerobic system because of the organic acids and methane formed, with the important difference that under suitable conditions a large amount of hydrogen is also liberated. More CO_2 is evolved than under anaerobic conditions. With "stronger aeration," conditions approach the aerobic system as shown by the small amount of organic acids, CH_4 and H_2 produced and the large amount of CO_2 evolved. Water-logged conditions occupy an intermediate position between the above two systems.

The water-logged system resembles the anaerobic system in some respects, *viz.* in the formation of organic acids, liberation of methane and formation of soluble protein, but in others it shows differences, *e.g.* in the relative losses of cellulose, hemicelluloses and lignin and in the synthesis of protein from ammonia. These differences could be explained by the presence of a wider variety of micro-organisms in the water-logged system able to attack cellulose and lignin. Moreover, the lower reducing power under water-logged conditions, as compared with the anaerobic system, permits an accumulation of proteins synthesised as a result of microbial activity. In these respects the water-logged system more closely resembles the aerobic system.

The admission of even limited amounts of air at weekly intervals alters the nitrogen relationships of the anaerobic system, as shown by the synthesis of protein from ammonia and by the rapid increase in the values for nitrogen factor and nitrogen equivalent.

SUMMARY.

1. The relative rates of decomposition of rice straw in decreasing order are: aerobic, water-logged and anaerobic fermentations. Cellulose and lignin are more easily attacked under water-logged conditions than under anaerobic conditions.

2. Partially aerobic conditions resemble anaerobic conditions in regard to the nature of the products obtained. Smaller amounts of organic acids and methane are, however, formed and there is an increase in the amount of CO_2 evolved. Under conditions of mild aeration much larger quantities of hydrogen are obtained than under anaerobic conditions.

3. The nitrogen factor and nitrogen equivalent decrease in the order: aerobic (0·536; 1·11), water-logged (0·395; 0·961) and anaerobic (0·069; 0·169), showing the degree of protein accumulation in the three cases. The protein formed under aerobic conditions is mostly insoluble in water, while under water-logged conditions it remains in solution.

4. In most respects the decomposition of rice straw under water-logged conditions gives results intermediate between aerobic and anaerobic decompositions.

The author's thanks are due to Sir E. J. Russell for placing the facilities of the Rothamsted Experimental Station at his disposal, to Mr E. H. Richards for guidance and to Dr S. H. Jenkins for helpful suggestions.

CXLI. STUDIES ON THE VITREOUS BODY. II.

BY WILLIAM STEWART DUKE-ELDER AND HUGH DAVSON.

*From the Department of Physiology and Biochemistry,
University College, London.*

(Received March 22nd, 1935.)

IN an earlier paper [Duke-Elder *et al.*, 1935] direct experiments were described showing that the vitreous body (henceforth called simply the vitreous) does not take up water *in vitro* under the influence of soaps and changed p_H. As the clinical picture of primary chronic glaucoma strongly suggests that a swelling of the vitreous is closely related to the raised intra-ocular pressure the work was continued with a view to showing whether such a change in volume of so dilute a gel can reasonably be expected on physico-chemical grounds.

So far two possible theories of the mechanism of volume increase have occurred to us depending on different conceptions of the mode of origin of the vitreous. First, if it is assumed that the vitreous is formed by a continuous process of swelling from an initial xerogel similar to the process of swelling of dry gelatin in water, then, considering it as at its swelling maximum at normal p_H, it seems possible that it could swell further if the p_H were altered in a direction favourable to increased hydration.

All previous experiments designed to show whether the vitreous swells have tacitly assumed the truth of the latter proposition. However, although the colloid chemical literature contains many studies on the swelling of gels in the presence of foreign substances, no one, it seems, has studied the influence of these substances on a gel already at its swelling maximum. The procedure in all cases has been to swell a quantity of the xerogel at one p_H, say, and then to take another lot of the xerogel and swell it at a new p_H and so on. On consideration it is by no means evident that a swollen gel will respond to a change in its environment to the same extent or in the same way as the dry xerogel, owing to the intervention of peptisation which is particularly to be expected when the micelles are already strongly hydrated.

If, on the other hand, the vitreous is formed by a sol to gel change another theory must be presented to show how it can swell[1]. In this case it is suggested that a minute fraction of the vitreous is peptised owing to the presence of some lyophilic substance; if, then, the procedure is reversed whereby the comparatively protein-rich fluid is converted into its gel form, the presence of the adsorbed hydrotropic substance enables the protein to orient more water than previously. The net result is an increase in volume. If this were to proceed over a number of years the effect would be to produce the pressure symptoms characteristic of chronic glaucoma. The process may be illustrated in a crude way by placing a lump of 10 % gelatin gel in a small volume of water. Addition of acid produces eventual peptisation; neutralisation of the acid converts the sol back into a gel of larger volume than before. (The objection that the increased pressure will expel fluid after the peptisation of a portion of the vitreous is overcome by postulating a unidirectional permeability of the surrounding membranes. This is not a further *ad hoc* assumption, as some such state must be the case or the vitreous would break down under the unbalanced stress.)

---

[1] Unpublished experiments of our own on gelatin clots together with theoretical considerations lead to the conclusion that a dilute clot, as opposed to a swollen gel, will not increase in volume directly when its environment is changed.

This paper is divided into three parts according as the experiments described throw light on the possibility of a gel at its swelling maximum swelling further on changing the p_H suitably (Part I), on the structure of the vitreous and hence its mode of origin (Part II), and on the possibility of peptising the residual protein (Part III).

Experimental.

Part I. Swelling of fibrin.

Pure fibrin, prepared by the combined methods of Fischer [1908] and Schuldenzucker [1928], was swollen at different p_H values in the acid range in a Schmidt apparatus [1931] which permits measurements of water uptake to within 0·002 ml. In Fig. 1 the water uptake per g. of dry fibrin is plotted against p_H. It is evident that by allowing fibrin to swell to its maximum at p_H 6 and then changing the medium to one of p_H 2 the conditions necessary to show whether a gel at its swelling maximum can take up further water by changing the p_H favourably will be achieved.

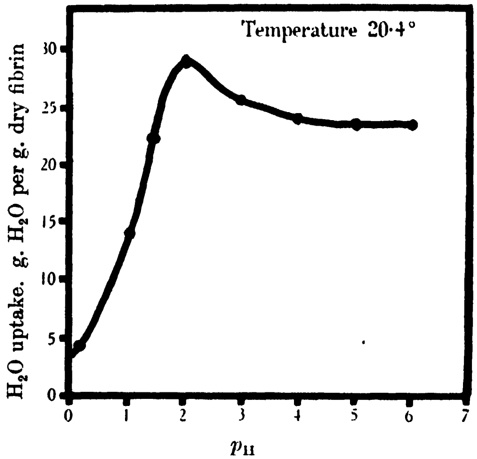

Fig. 1.

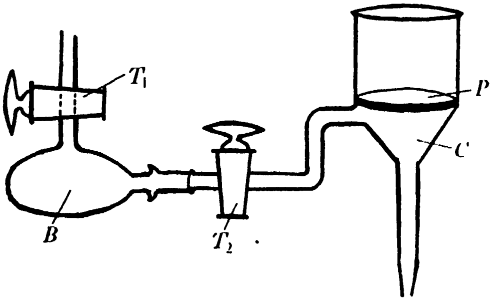

Fig. 2.

To this end the Schmidt apparatus was modified as in Fig. 2. A bulb *B* with a tap T_1 fits on the side-tube by a ground joint. With T_2 closed the bulb is filled with concentrated HCl and T_1 is closed. Fibrin is placed on the porous plate, *P*, and when the water uptake, as measured by the movement of a meniscus in the capillary in communication with the chamber, *C*, has reached its maximum the tap T_1 is opened allowing acid to diffuse in, thus lowering the p_H of the fluid in contact with the swollen fibrin.

In Fig. 3 the water uptake is plotted against time. For convenience the initial part of the curve is not shown and the scale of ordinates above 2·8 ml. is half of that below this value. Obviously the swollen fibrin adjusted itself to the changed p_H. If the acid had not diffused in, the water uptake would have reached a final value of 2·80 ml., whereas, owing to the changed acidity, it rose to a maximum of 3·18 ml.

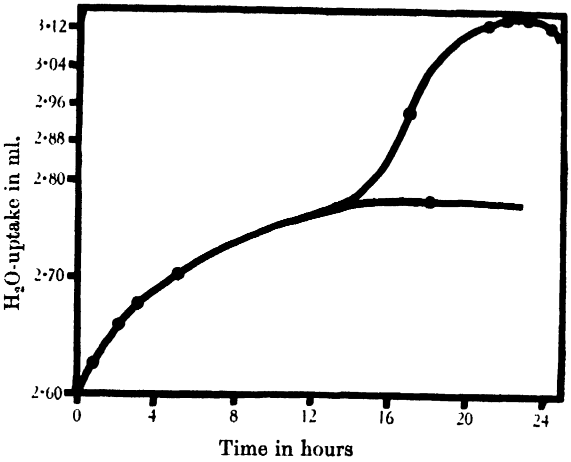

Fig. 3.

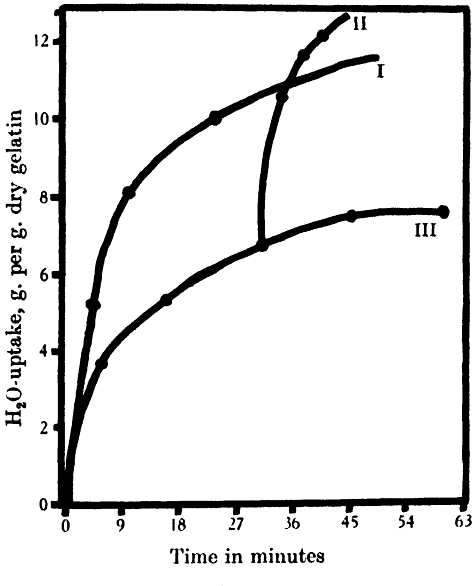

Fig. 4.

Swelling of gelatin. Gelatin was allowed to swell at p_H 4·8, the isoelectric point and hence the p_H at which swelling is minimum, and at p_H 1. Pieces of gelatin which had already swollen at p_H 4·8 were transferred to the solution of p_H 1 and their subsequent swelling followed.

Coignet's leaf gelatin was cut into approximately equal squares and after drying over conc. H_2SO_4 placed in a dish containing 2 l. of the solution in a room maintained at constant temperature (20·4°). At intervals pieces were removed, blotted with filter paper, and placed on weighed pieces of filter-paper which had been previously dried over H_2SO_4. The filter-paper and swollen gelatin were weighed and placed in a vacuum desiccator. After 24 hours drying was completed over H_2SO_4 and they were weighed again. The weight of H_2O taken up per g. of dry gelatin was plotted against time, Fig. 4.

Although a cruder technique than that of Jordan-Lloyd [1927] this has the advantage that the H_2O content of the swollen gel as it is in its final state is determined, whereas Jordan-Lloyd, by weighing the initial quantity of dry gelatin and then that of the wet gelatin remaining, is able to tell us nothing more than the change in weight of a piece of gelatin after placing it in a given medium. A medium very favourable to swelling dissolves a considerable portion of the gelatin so that by her technique the swelling of gelatin would appear to fall off with increasing acidity. This is definitely not the case.

In Fig. 4 I and II are the swelling curves of gelatin in solutions at p_H 1·1 and 4·8 respectively. The upper branch of curve II represents the change in the rate of swelling on transferring the gelatin from a medium of p_H 4·8 to one of p_H 1·1. It is at once evident that there is an immediate adjustment to the changed p_H.

Part II.

Goedbloed [1934, 1] described ultramicroscopic changes in the vitreous on treatment with KCNS solutions, which he interpreted as being due to an increased hydration of the micelles. If such were the case a change in the elastic properties of the vitreous on treatment with this substance would be expected. To test this two techniques were used, first the resistance of the treated vitreous to the emulsification of Hg by ultrasonic waves was compared with that of a control, and secondly the technique of Freundlich and Seifriz [1923] and Seifriz [1924] for the measurement of the elastic properties of gels, as modified by Robertson and Duke-Elder [1933, 1] to suit the peculiarities of the vitreous, was used.

Ultrasonic waves. When H_2O and Hg are submitted to ultrasonic waves, an emulsion of Hg in H_2O is immediately formed, the whole mixture taking on a dark grey colour [Wood and Loomis, 1927; Bull and Söllner, 1932]; if the H_2O is replaced by a jelly the elastic properties of the latter hinder the emulsification of the Hg so that after a given time there is a fairly well-defined boundary between the clear jelly and that into which Hg particles have penetrated. The height of this boundary gives a rough idea of the elasticity of the jelly.

Ox vitreous was placed in 1·0 *M*, 0·5 *M* and 0·14 *M* solutions of KCNS and in isotonic saline for 24 hours at 20°. The samples were transferred to test-tubes and 1 ml. of Hg added, and the tubes were held in succession over the vibrating column of oil above the quartz plate of the ultrasonic apparatus. The heights of the emulsified Hg columns were compared.

There was no detectable difference in the heights of the columns of the vitreous treated with KCNS and of those treated with normal saline, so that it is concluded no very gross change in the elastic properties of the vitreous are caused by KCNS.

Nickel particle technique. Vitreous is placed in a rectangular glass cell, 1 cm. edge, and a nickel particle about 50μ diameter is picked off a slide under the microscope and stabbed into the vitreous. The particle is focused and its extension due to an applied magnetic field measured by a micrometer eye-piece. Portions of vitreous treated with KCNS, K_2SO_4 and dilute HCl at p_H 3 were studied together with normal untreated vitreous. The results are shown in Figs. 5 and 6.

Curve 1, Fig. 5, is the typical extension-time curve for normal untreated vitreous, characterised by a rapid initial elastic displacement followed by a viscous creep approaching a fairly constant velocity.

Before describing the remaining curves we must say a few words in regard to the limitations of the technique and the results expected should hydration or dehydration of the colloid particles be achieved by the solutions mentioned. Firstly, a direct comparison of the absolute displacements of one given particle in different lots of vitreous in a given time and with a fixed field strength is difficult, as a particle of the size necessary for its recovery from the first vitreous is very irregular and its extension will depend on the direction of motion. Furthermore, as the vitreous is not stuck firmly to the cell walls there will be a certain amount of "give" which will vary with the quantity of vitreous in the cell and the depth of the particle in it. On the other hand the curve I, Fig. 5, is very typical and can be reproduced from vitreous to vitreous without difficulty. As far as the changes expected on treatment of the vitreous with the reagents mentioned are concerned, from the work of Leick [1904] and Kramer [1926] a decrease in elasticity is to be expected with K_2SO_4 and an increase with KCNS. This should be reflected in a diminution in the viscous creep, characterised by the upper part of the curve, in relation to the initial elastic displacement, in the case of K_2SO_4, and the reverse should hold for KCNS. (Once again no work has been done on the effect of such solutions on gels already formed; workers in this field have added the substance to be examined to the sol which was then allowed to set, and the elastic modulus measured.)

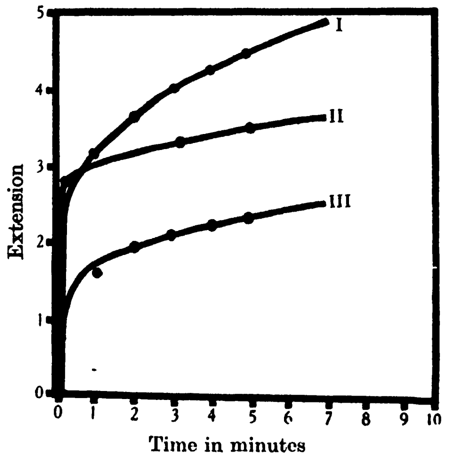

Fig. 5.

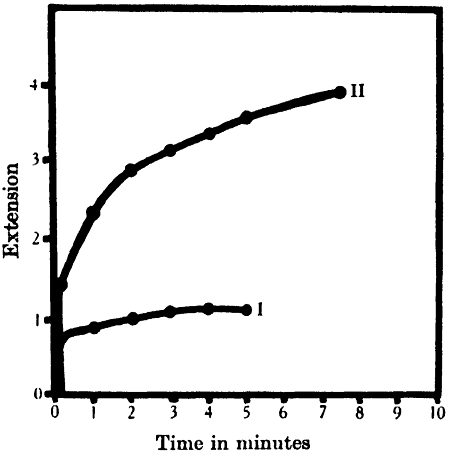

Fig. 6.

Curves II and III of Fig. 5 are those for vitreous treated with 0·5 *M* KCNS and K_2SO_4 respectively. They are representative of a number of curves determined similarly, but it should be mentioned that a few curves were obtained not conforming to these types; the reason for these irregularities, which were not observed in normal vitreous, will be brought out later. The displacements in the different curves are in no way comparable with one another as different particles were used. It is evident that 0·5 *M* K_2SO_4 has no appreciable effect on the extension-time curve of ox vitreous, whilst 0·5 *M* KCNS has the reverse effect to that expected on the supposition that it increases hydration, the extension subsequent to the first 10 secs. being very small compared with that during this time. The absence of effect by 0·5 *M* K_2SO_4 is very surprising as a considerable contraction in volume was observed. The curves for isotonic solutions of these salts (not shown) were in general similar to those for normal vitreous.

The curves obtained with vitreous treated with dilute HCl at p_H 3 (Fig. 6) throw a little light on the problem. Curve I was obtained by applying a small magnetic force; increasing the field with conditions otherwise the same gave curve II which is quite normal. It is evident that the viscosity of the medium has increased under the influence of the acidity, so that a limiting force has to be exerted to allow the creep to proceed. A similar phenomenon was observed with K_2SO_4 but not so regularly.

Baurmann [1924] showed that between p_H 3 and p_H 2 a precipitate fall in the volume of the vitreous occurs; this change is accompanied by the precipitation of the mucoprotein in the gel. If we assume that the volume change is due to the collapse of the vitreous structure, as opposed to a semi-reversible dehydration, then at p_H 3 we should expect the undermining of the vitreous structure to have already begun, and hence the changes in the elasticity could be put down to this cause. The decreased stability of the vitreous, which would tend to lower the elasticity, would at the same time increase the viscosity of the intermicellar fluid and the two effects would compensate each other to varying extents. If this is true, the irregularities in the shapes of the curves obtained by treating the vitreous with KCNS, K_2SO_4 and dilute HCl mentioned earlier are explained, as it is only to be expected that a body in a state of very unstable equilibrium will respond extravagantly to minute changes in its environment, thus prejudicing the reproducibility of results obtained on it.

In view of the results obtained on the extension-time curves, it was important to see whether the absolute values for the extension of a given particle varied greatly according as the vitreous was treated with K_2SO_4, KCNS or dilute HCl. The only way of achieving this end was to treat a large number of pieces of vitreous successively and analyse the results statistically.

Two cells were filled at the same time to the same height with normal and treated vitreous. A particle was placed in one, and its extension in a fixed magnetic field lasting for 5 secs. was measured. Immediately the particle was recovered and placed in the other cell, and its extension under the same conditions measured. This was repeated for 12 to 13 pairs and the results are tabulated in Table I.

Table I.

Solution	*d*	*n*	*s*	*t*	*P*
0·5 *M* KCNS	+4·34	13	2·56	3·3	<0·01
0·5 *M* K_2SO_4	−1·10	12	4·21	0·9	0·3–0·4
$1 \cdot 10^{-3}$ *M* HCl	−2·30	13	2·53	3·3	<0·01

In Table I *d* is the mean difference in extension for normal and treated vitreous; a positive value means that the treated vitreous gave a larger extension than its control. *n* is the number of pairs of determinations, *t* is the ratio of the mean difference to its standard error [Fisher, 1928], and *P* is the probability that such a value of *t* will occur by chance. It appears that in 0·5 *M* KCNS the extension is greater and in dilute HCl at p_H 3 less than the control whilst the difference with K_2SO_4 is insignificant. Here again the results are more in conformity with the supposition that the vitreous stability has been upset than that a reversible syneresis has occurred, or in the case of KCNS a reversible hydration. The relation of these results on the elasticity of the vitreous to its mode of origin will be dealt with in the discussion later.

As the volume decrease of the vitreous on treatment with dilute HCl appeared to be correlated with the precipitation of its mucoprotein [Goedbloed, 1934, 2] we decided to determine in what way the presence of a second protein influenced the stability of a protein clot.

Pure de-ashed gelatin was dissolved in phosphate buffer at p_H 7 to 10 % and 5 ml. lots were transferred to test-tubes. 2 ml. of a protein solution in phosphate buffer at the same p_H were added to one group and 2 ml. of the phosphate solution to another which served as controls. After equilibrating in a bath at 38° pairs were transferred to another at 20° and the course of setting followed by dropping in lead shot at intervals. When a shot failed to penetrate the surface the solution was considered to have set. As Fraas [1894] has shown that at room temperature complete equilibrium is only attained after 24 hours, the test-tubes were transferred after setting to the ice-chest overnight and the melting times of the clots determined by placing them in the bath at 38°. The results are shown in Table II; positive signs indicate degrees of increased stability of the clots as evidenced by a more rapid setting or a more protracted melting.

Table II.

Protein solution added	Change in stability	
	Setting time	Melting time
1 % ovalbumin	———	+
0·5 % agar-agar	———	+
2·0 % agar-agar	+ + +	+ + +
1·0 % serum globulin	+	−
0·75 % isinglass	———	+ +
1·5 % isinglass	———	+ +
2·0 % caseinogen	− −	− −

It is evident from Table II that a second protein, or in the case of agar-agar a carbohydrate, may enter into the intimate structure of a gelatin gel. Hitherto, in the vitreous, the residual protein has been considered as the determining factor in the degree of hydration of the vitreous. The results given in this paper lead to the view that the vitreous stability and hydration are bound up with the physical states not only of the residual protein but also of the mucoprotein and perhaps of the albumin and globulin.

Part III. Attempts at peptisation of the residual protein.

The vitreous was submitted to ultrasonic vibrations[1], as a class of gels, the thixotropic gels, are converted into their sol form by this treatment. No liquefaction of the vitreous was obtained in this manner. Solutions of KCNS of strengths varying from 0·5 *M* to a saturated solution, a variety of soaps, and thiourea, in the heat and the cold, were tried on the separated residual protein without any evidence of peptisation. Mörner's treatment [1894] by which the protein was heated with H_2O at 105° under pressure gave a clear solution, which, however, failed to set on cooling as described by him. Repeated attempts using this treatment failed to give a jelly, and it must be concluded that this vigorous treatment gave breakdown products.

DISCUSSION.

In accordance with the results of Part I, it is probable that if the vitreous were formed by a continuous process of swelling without the intervention of a sol stage, then the presence of soaps in the surrounding tissues would favour an increased volume of the vitreous (as suggested in the first paper of this series).

The results of Part II, however, in so far as they show that the effects of acid, KCNS and K_2SO_4 tend to lower the stability of the gel, point to the vitreous having been formed as a clot from an aqueous solution of the proteins, since gels formed by a swelling process alone exhibit a certain degree of reversibility in their hydration and dehydration phenomena. When, furthermore, the similarity in the elastic and ultramicroscopic properties of the vitreous and dilute plasma clots is considered [Robertson and Duke-Elder, 1933, 2] the balance of evidence points to the vitreous having been formed as a clot. (The histological study of embryonic vitreous development tells us very little about its physical mode of origin. In a preparation using Zenker's solution as a fixative streaks are seen emerging from the epithelium of the optic cup and later from the glial elements of the retina.) The experiments with gelatin clots show that it is likely that the mucoprotein and albumin and globulin of the vitreous enter intimately into the structure of this body.

---

[1] We are indebted to Prof. Freundlich and Dr Söllner for performing the experiments involving the use of ultrasonic waves described in this paper.

The unsuccessful attempts at peptising the residual protein described in Part III lend a certain support to the idea of a swelling origin of the vitreous, and militate against the theory that the raised intra-ocular pressure in glaucoma is brought about by a cyclical process of peptisation and clotting. Attention should be drawn here to the statement by Goedblocd [1934, 1] that KCNS in concentrations of 2·5 M and greater causes a complete solution of the vitreous. Such is not the case; we have observed repeatedly that, whilst at 2 M concentration and greater there is a decrease in the volume of the vitreous culminating at a concentration of 2·5 M in its shrinkage to a minute fraction of its original volume, the effect is not one of solution but one of dehydration as the residual protein is to be seen invariably floating on the top of the solution. We may add that the context of Goedbloed's statement leaves no doubt that it was his intention to convey the idea that the residual protein completely dissolved. The same author [1934, 1, 2] denies that the vitreous is a gel on the grounds that the phenomena associated with it are not reversible. There is no point in discussing the matter at length: we can only say here that his exclusion of the vitreous from the category of gels on this count simultaneously rules out practically all substances hitherto considered as belonging to this class.

SUMMARY.

The physico-chemical mode of origin of the vitreous body, the possibility of its swelling *in vivo*, and factors in its stability and structure are investigated.

The subsequent behaviour of swollen gels on altering the p_H is described.

The changes in the elastic properties of the vitreous after treatment with solutions of K_2SO_4, KCNS and dilute HCl are examined, leading to the conclusion that a decrease in stability, as opposed to reversible changes in hydration, is the consequence of these treatments.

The influence of proteins and agar-agar on the setting and stability of gelatin gels is studied.

It is concluded that the mucoprotein enters intimately into the vitreous structure and a possible mechanism of an increase in the volume of the vitreous based on a cyclical process of peptisation and clotting is suggested.

All attempts at peptising the vitreous or its isolated residual protein were without success.

We wish to thank Profs. Evans and Drummond for their valuable interest in this work, and the Medical Research Council for defraying the whole expenses of this research and for a personal grant to one of us (H. D.).

CXLII. THE REDUCTION POTENTIALS OF BACTERIAL SUSPENSIONS.

BY JOHN YUDKIN[1].

From the Colloid Science and the Biochemical Laboratories, Cambridge.

(*Received March 23rd, 1935.*)

A NUMBER of observations have been recorded on the reduction potentials of growing bacteria [Gillespie, 1920; Cannon *et al.*, 1926; Aubel and Aubertin, 1927; Aubel and Genevois, 1927; Hewitt, 1930, 1, 2, 3]. It was considered that, in this earlier work, the continuous changes occurring in the medium during the growth of the organisms complicated the problem to an extent which made it impossible to obtain a clear idea of the cause of the production of the potentials recorded. In order to simplify the system, the following work was carried out with washed suspensions instead of with growing organisms.

In a few cases measurements on washed cells have already been carried out. Thus, Aubel *et al.* [1928] have recorded the potentials of kidney, liver and muscle tissue, and Cannon *et al.* [1926] measured the potentials of washed yeast cells. These latter authors find a slow fall of potential, which becomes much more rapid after the addition of succinate. If methylene blue is added after these low values have been reached, the potential is brought up to the range characteristic of the dye until the dye is reduced. This reduction is very slow, and the potential correspondingly does not soon fall, in the absence of succinate, whereas in its presence this "poising" action of the dye is soon overcome and the potential rapidly resumes its negative values.

In none of this work has the actual cause of the potentials been made clear. It is conceivable that they are due to the cells themselves influencing the electrode. In this case, the increased negativity observed on the addition of metabolites might be due to some combination between the enzymes of the cell and the metabolites which is capable of affecting the electrode to a greater degree than the cells alone. On the other hand, the electrode potential may be due to substances formed by the cell enzymes, which substances are themselves capable of affecting the electrode. The work to be described was undertaken with a view to obtaining some clearer conception of the nature of the reduction potentials of bacterial cells, as recorded both by the electrode and by the use of redox indicators. No attempt has been made to study redox equilibria of any particular enzyme system as has been done for example by Lehmann [1929] for the succinate-fumarate system.

EXPERIMENTAL.

The bacteria used in this investigation were *Bact. coli* (Escherich), *Bact. alkaligenes* and *Cl. sporogenes*. Of these, the first is a facultative anaerobe, the second a strict aerobe, whilst the last is a strict anaerobe. They were all grown on a tryptic digest of caseinogen. *Bact. coli* and *Bact. alkaligenes* were grown in Roux bottles for 15–18 hours and *Cl. sporogenes* was grown for 2 days anaerobically. The cultures were centrifuged and washed twice by centrifuging in distilled water, and uniform suspensions were made in water.

---

Potentials measured at the electrode.

These were measured in an apparatus similar to that described by Green [1933] except that an extra side-tube was added to the reaction vessel by means of which solutions could be added to the fluid in contact with the electrode (Fig. 1). The nitrogen was freed from oxygen by passing over copper treated with palladium at a temperature of 380°. The potentials were measured at room temperature (which was observed at intervals) using a mirror galvanometer in series with which was a resistance of 50,000 ohms to minimise polarisation. Before and after the measurement of the reduction potential, a sample was taken for the determination of the p_H by the quinhydrone electrode. All the measurements of reduction potential are expressed as E_0' at p_H 7.

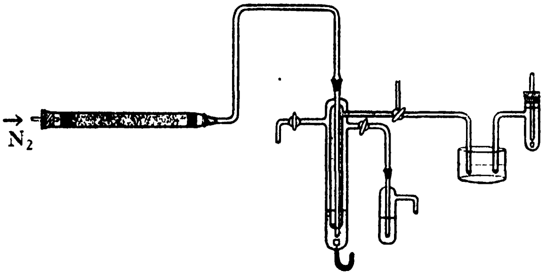

Fig. 1. Apparatus for measurement of reduction potentials.

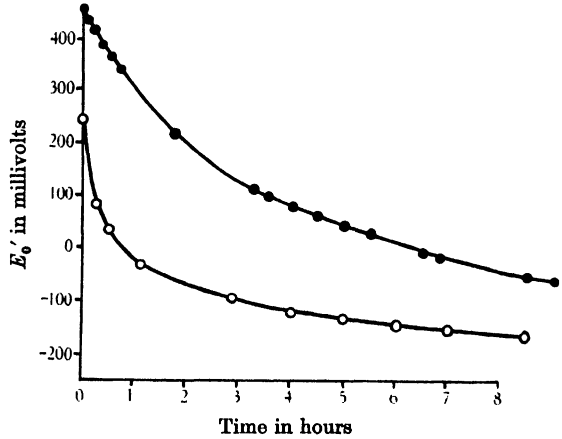

Fig. 2. *Bact. alkaligenes.* Electrode reduction potentials. •—• Fresh suspension. o—o Suspension 2 days old.

The potentials were determined of bacterial suspensions in the presence of an equal volume of $M/20$ phosphate buffer at p_H 7·0, with or without the addition of other substances. In the absence of these additional substances, a slow continuous fall of potential was observed, which continued as long as readings were taken. These in exceptional circumstances were extended over a period of 3 days and no constant value was obtained. The rate of fall of potential was slightly more rapid in the case of *Bact. alkaligenes* than with the other two species, particularly if the suspension had been kept 1 or 2 days in the ice-chest (Fig. 2).

The effect on the potential of adding certain substances was next observed. With *Bact. coli*, the presence of a small amount of $M/10$ sodium succinate solution did not change the rate of fall of potential. With one suspension of *Bact. coli*, a potential of $-0·25$ v. was reached after 10 hours both with and without the addition of succinate. If glucose or sodium formate was added, on the other hand, a rapid fall of potential occurred, which was complete after 15 mins. to 1 hour. Usually this was followed by a gradual rise of about 0·03 v. extending over about 1 hour. The lowest potentials recorded are given in Table I.

Table I. *Reduction potential* (E_0' *at* p_H *7·0 in volts*) *of washed suspensions of* Bact. coli *in the presence of:*

Glucose: $-0·38$, $-0·37$, $-0·35$, $< -0·33$, $-0·36$, $-0·36$, $-0·35$, $-0·37$
Formate: $-0·38$, $-0·40$, $-0·40$, $-0·38$, $-0·38$

The effect of the substrates on the potentials is shown more clearly by following the decrease before and after the substrates are added. This was effected by attaching to the extra side-arm of the reaction vessel a tube containing the substrate solution. It was arranged that the nitrogen passing through the bacterial suspension also passed through this solution, thus ensuring that this was free from oxygen when it was mixed with the bacteria. A typical result is shown in Fig. 3. It will be seen that there is an immediate rapid fall of potential on the addition of glucose. When the minimum potential value has been reached, the addition of formate causes a further slight fall. If formate is added first, the low potential recorded is not influenced by the addition of glucose. This method of observing the potential showed that the addition of succinate has little or no effect on the rate at which the potential falls. Addition of formate after the succinate caused a rapid fall to $-0·38$ to $-0·40$ v. The observed potential of a mixture therefore appears to be that of the most negative system present.

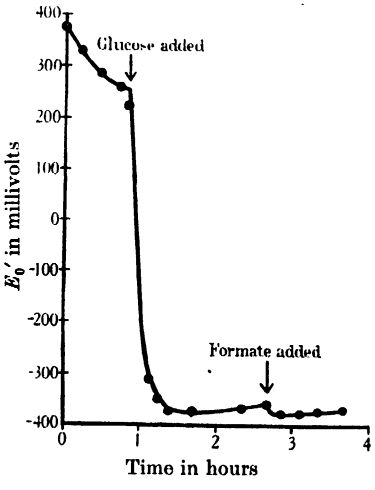

Fig. 3. *Bact. coli.* Electrode reduction potentials.

The effect of toluene on the reduction potential of *Bact. coli* in the presence of glucose was studied in order to see what part glucose dehydrogenase, which is inhibited by toluene, plays in the development of the reduction potential.

Experiment showed that the addition of toluene to the bacteria before the glucose resulted in a very slow fall in potential which, after 24 hours, had only reached 0·0 v. On the other hand, if the toluene was added from the side-tube to the mixture of bacteria and glucose which had been reacting for some time, the rate of fall and the final potential were exactly the same as in the absence of toluene. These results recall those in which methylene blue, although not reduced by toluene-treated bacteria in the presence of glucose, is reduced if the toluene is added after the glucose [Yudkin, 1934, 2]. This was explained as being due to the production of substances from the glucose which, unlike glucose itself, are able to reduce methylene blue in the presence of toluene-treated bacteria. In the case of the reduction potential also it appears that the actual potential is due to the action of the bacteria on the products rather than the initial action of the bacteria on glucose.

The above results were all obtained with *Bact. coli*. With *Bact. alkaligenes* similar results were recorded as far as the absence of effect of succinate is concerned. The effect of glucose is different with the two species of bacteria since the potential of suspensions of *Bact. alkaligenes* is affected comparatively little by this substance. Formate has a more marked effect (Fig. 4). A final value of the potential with this organism was difficult to obtain owing to the continuous, though gradually slowing, fall of potential. At the end of 6 hours, however, the fall is almost immeasurably small and approximate values of the potential for the different substrates can be obtained (Table II).

Table II. *Reduction potentials* (E_0' *at* p_H *7·0 in volts*) *of suspensions of* Bact. alkaligenes *after 6 hours.*

Bacteria alone or with succinate	−0·17
,, +glucose	−0·27
,, +formate	−0·30–0·32

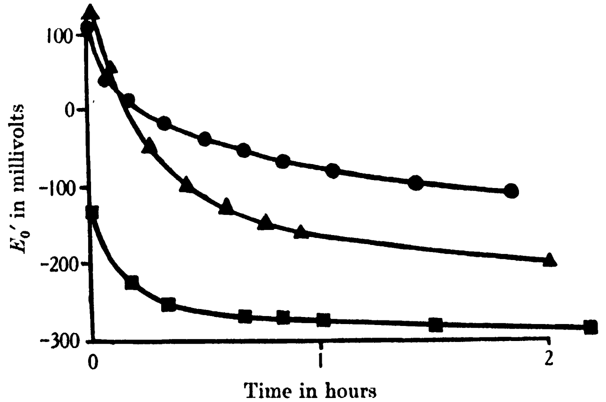

Fig. 4. *Bact. alkaligenes*. Electrode reduction potentials. ●—● Bacteria alone. ▲—▲ Bacteria+glucose. ■—■ Bacteria+formate.

Only a few measurements of reduction potential were made with *Cl. sporogenes*. The fall of potential was very slow indeed, the potential even after 24 hours being only about 0·0 v. The rate of fall and final potential were unaltered by the addition of alanine, which this organism can readily activate as hydrogen donator [Stickland, 1934].

Potentials measured by dye reduction.

In Table III is given a list of the indicators used, together with their potentials at p_H 7·0 for 50 % reduction.

Table III.

	Indicator	E_0' at p_H 7·0 50 % reduction		Indicator	E_0' at p_H 7·0 50 % reduction
1.	Cresolindophenol	+0·210	7.	Janus green	−0·252
2.	Cresyl blue	+0·031	8.	Phenosafranine	−0·256
3.	Methylene blue	+0·011	9.	Rosinduline	−0·281
4.	Indigo carmine	−0·125	10.	Neutral red	−0·340
5.	Nile blue	−0·150	11.	Benzylviologen	−0·359
6.	Cresyl violet	−0·173	12.	Methylviologen	−0·446

Dilute solution of these were placed in Thunberg tubes with the bacterial suspension and phosphate buffer p_H 7·0 and in some cases a solution of substrate. The tubes after evacuation were left at room temperature and observed after about 1 hour.

A suspension of *Bact. coli*, with or without succinate, reduced 1–8 completely, 9 partially and did not affect 10, 11 and 12. With glucose, 1–9 were reduced completely, 10 was doubtful, 11 partially reduced and 12 not affected. With formate, even 12 was slightly reduced. The reduction potentials as recorded by indicators are therefore:

	E_0' in volts
Bact. coli alone or with succinate	−0·27 to −0·30
,, +glucose	−0·32 to −0·37
,, +formate	−0·39 to −0·41

These figures agree fairly well with those given by electrode measurements (p. 1132).

The results with *Bact. alkaligenes* do not show this agreement between the electrical and colorimetric methods. Dyes 1–11 are all reduced by the bacteria alone or in the presence of succinate or glucose (E_0' −0·36 to 0·38). With formate, 12 is also definitely reduced (E_0' about −0·42). Similarly, *Cl. sporogenes* shows potentials by this method which differ greatly from those shown by the electrode. With or without alanine, 1–11 are rapidly reduced at p_H 7·0, indicating a potential of about −0·38 [*cf.* Stickland, 1934].

Potentials measured at the electrode in the presence of indicator.

Series of electrode measurements were made with *Bact. coli* and *Bact. alkaligenes* in the presence of dyes. The results depended on the range of potential of the dye used. If this was very positive, *i.e.* if the dye was rapidly and completely reduced, then the effect was small. For example, if methylene blue was added to *Bact. coli* in the presence of formate, a pause in the falling potential occurred whilst the dye was being reduced (*i.e.* in the region of 0·0 v.) but the subsequent rate of fall and final potential recorded were the same as when no dye was present. Again, if the dye was added from the side-tube after the potential had reached a low value, a slight rise occurred which lasted for a minute or two if the quantity of dye added was small, and then the potential rapidly returned to its previous low value. These results recall those of Cannon *et al.* [1926] which have already been referred to.

If a dye is chosen which is only partially reduced by the system, the potential recorded is approximately that which would be expected from the range of potential of the dye. For example, *Bact. coli* and glucose in the presence of benzylviologen give a reduction potential of −0·36 to −0·38 v. *Bact. alkaligenes* gives with benzylviologen the following reduction potentials measured electrically: alone, or with glucose −0·34 to −0·38 v.; with formate, −0·40 to −0·42 v. These values are those which would be expected from the amount of reduction of the dye used: that is, they agree with the values for the reduction potential obtained colorimetrically. The potentials recorded electrically in the presence and absence of these partially reduced dyes are, therefore, in agreement only in those cases where the electrical and colorimetric values are in agreement. This is shown in Table IV where the values obtained by the three methods outlined above are summarised.

Table IV. *Reduction potentials of bacterial suspensions* E_0' *in volts at* p_H 7·0.

		Potential measured		
Bacteria	Substrate	Colorimetrically	Electrometrically	Electrometrically in presence of partially reduced dye
Bact. coli	None	−0·27 to −0·30	< −0·25	—
	Succinate	−0·27 to −0·30	< −0·25	—
	Glucose	−0·32 to −0·37	−0·36 to −0·38	−0·36 to −0·38
	Formate	−0·39 to −0·41	−0·38 to −0·40	About −0·39
Bact. alkaligenes	None	−0·36 to −0·38	About −0·17	−0·34 to −0·38
	Succinate	−0·36 to −0·38	About −0·17	—
	Glucose	−0·36 to −0·38	About −0·27	−0·34 to −0·38
	Formate	About −0·42	−0·30 to −0·32	−0·40 to −0·42
Cl. sporogenes	None	About −0·38	About 0·0	—
	Alanine	About −0·38	About 0·0	—

The cause of the potential at the electrode.

The main problem was to decide whether the potentials were being caused by contact with the electrode of the bacteria, possibly with adsorbed reactants, or by contact with the electrode of the reactants themselves moving freely in the solution. A series of experiments to test this point was carried out with *Bact. coli*.

A bacteria-free filtrate of the mixture after the bacteria had acted on glucose for a long time was found to give a potential of about −0·20 v. which was almost certainly due to the glucose itself. However, it was found possible to obtain the low potentials recorded above in bacteria-free solutions by use of a thin collodion sac.

A small beaker with a well-fitting rubber stopper was used as reaction vessel. In the stopper were inserted two platinum electrodes, a tube through which the nitrogen bubbled into the solution, an exit tube for the nitrogen and a KCl-agar bridge making contact with the KCl half-element. Round one electrode was tied a collodion sac containing a mixture of buffer and substrate solution. In the beaker was placed the mixture containing bacterial suspension, buffer and substrate solution. Thus the electrode within the sac was in contact only with substances capable of diffusing through the sac.

It was found that if the sac was thin and not too wide, the final potentials recorded by the covered electrode were, within a few millivolts, the same as those recorded by the outside electrode. In one experiment with glucose for example a potential of −0·330 v. was recorded by the outside electrode and −0·327 v. by the covered electrode. Similar results were obtained with formate. It was necessary to leave the experiment for 6–8 hours before this agreement was obtained.

At the end of each experiment, the apparatus was dismantled carefully in order to observe whether the bacteria had passed into the sac through any small hole which had developed. In certain cases where this did occur it was very obvious, the liquid in the sac being quite milky and rapidly dripping out of the sac even when no visible hole existed.

DISCUSSION.

It seems fairly certain from the results given that the reduction potential of a bacterial suspension, as measured at an electrode, is produced by substances in solution in the suspension. The potentials recorded for suspensions in the absence of added substrate are probably due to substances exuding from the bacterial cells. This is supported by two observations; firstly, by the very slow and prolonged fall of potential, and secondly by the fact that older suspensions (of *Bact. alkaligenes*), in which presumably more of these substances have diffused out, show a more rapid fall of potential.

Of the substrates examined, two, namely glucose and formate, produce a potential more negative than the bacterial suspension alone. It may be inferred that the substances produced from other substrates, such as succinate, either have no effect at the electrode or have much less effect than the substances produced in the bacterial suspension itself. The equilibrium potential of the succinate-fumarate system is given as 0·00 v. at p_H 7·0 and 30° [Lehmann, 1929].

A possible explanation of the low potentials recorded in the presence of glucose and formate is that hydrogen is being produced, giving a partial pressure of $1-10^{-2}$ atmospheres. If this is correct then the reduction potential would be expected to depend on the rate at which the nitrogen was passed into the vessel since this would alter the amount of hydrogen left in the solution. This was found not to be the case. Also, a suspension capable of producing more hydrogen (*i.e.* containing a more active hydrogenlyase) might be expected to produce a more negative potential. The suspensions of *Bact. coli* as grown for this experiment contain no formic hydrogenlyase and very little glucose hydrogenlyase [Yudkin, 1932]. As has already been suggested [Yudkin, 1934, 1], it is conceivable that very small amounts of hydrogen are actually produced from formate in such suspensions but in quantities insufficient to be measured manometrically. These very small quantities might, however, be sufficient to affect the electrode. Suspensions of *Bact. coli* grown on glucose broth and hence containing active formic and glucose hydrogenlyases were prepared. The potentials of these suspensions in the presence of either glucose or formate did not, however, produce a more negative reduction potential than the other preparations.

The argument against hydrogen as the cause of the low potentials with glucose and formate in the case of *Bact. alkaligenes* is still stronger since in no circumstances is it possible to obtain measurable quantities of hydrogen by the action of this species on either glucose or formate.

We can also deduce from the experimental results that the substances responsible for the low potentials do not do so by virtue of being hydrogen donators in the presence of the bacteria. One might imagine that the activation of a substrate as a hydrogen donator involves a "loosening" of a hydrogen atom and that it is this which affects the electrode. But the results obtained with *Cl. sporogenes* in the presence of alanine show that this is not so.

We must, therefore, conclude that the potentials recorded by an electrode immersed in a bacterial suspension with or without added substrates are due to unknown substances either coming out of the bacterial cells or being produced from certain of the substrates (*e.g.* glucose and formate). That these substances affect the electrode at all and so give a measurable potential by no means indicates that a definite oxidation-reduction equilibrium is being measured. In fact, the slow and continuous fall of potential in the absence of glucose or formate and the ease with which all the systems are polarised suggest that the effect on the electrode of some of these substances at any rate is quite fortuitous and that the values obtained for the potential by electrical measurement gives very little knowledge of the state of the cells.

The above discussion was confined entirely to potentials measured at the electrode in the absence of dyes. We have seen that colorimetric measurements of the reduction potentials often give results differing widely from those obtained by such electrical measurements, although they agree with electrical measurements made in the presence of partially reduced dye. The differences may be explained along the following lines. It has been pointed out by Green *et al.* [1934] that the reduction of dyes by bacterial cells depends on the existence in the cells of positive (oxidising) and negative (reducing) systems. Whether or not a certain dye will be reduced does not depend on the actual potential of the cell. A small quantity of redox indicator will be completely oxidised, completely reduced or partially reduced depending on the relative rates of oxidation and reduction of the particular dye by the positive and negative systems. In the case of a dye which is partly reduced, we may perhaps speak of "reduction equilibrium" of the dye in question, where the rate of reduction of the dye by the negative systems is equal to the rate of its oxidation by the positive systems. In the presence of partially reduced dye, an electrode will naturally take up the potential value of this mixture of oxidised and reduced dye since both forms are active at the electrode. In other words, colorimetric measurements of the reduction potential will agree with electrode measurements in the presence of partially reduced indicator, and both are measuring the "reduction equilibrium" of the dye.

On the other hand, as shown above, the potentials recorded at the electrode in the absence of dye are due to the existence in the mixture of certain diffusible substances which are able to affect the electrode. These are quite fortuitous and have nothing to do with the oxidising and reducing mechanisms of the cells.

There is, therefore, no method by which the reduction potential of a cell, in the sense commonly used, may be measured. The author is of the opinion that the conception of the reduction potential of the living cell as an equilibrium exhibited by the whole cell has no great meaning. It appears much more likely that different parts of the cell in which the various systems are differently proportioned will have very different reducing intensities. The use of the term reduction potential, if justified at all at present in biology, must be restricted to reversible systems in true equilibrium such as reduced and oxidised cytochrome or succinic dehydrogenase in the presence of fumarate and succinate.

SUMMARY.

1. The reduction potentials of suspensions of *Bact. coli* and *Bact. alkaligenes* were measured (1) electrometrically, (2) colorimetrically by redox indicators, and (3) electrometrically in the presence of indicators. A few measurements were also made with *Cl. sporogenes*.

2. Both *Bact. coli* and *Bact. alkaligenes*, either alone or in the presence of succinate, show a slow continuous fall of potential at the electrode, which never

reaches a constant value. Glucose and formate induce more negative potentials, which in the case of *Bact. coli* soon reach minimum values.

3. These potentials have been shown to be due to electromotively active molecules capable of passing through a collodion sac and not to the bacteria themselves or bacteria *plus* adsorbed substances.

4. The reduction potentials recorded by indicators, although sometimes in fair agreement with the electrode values (*Bact. coli*), often bear no relation to the latter (*Bact. alkaligenes* and *Cl. sporogenes*). The electrode measurements in the presence of appropriate dyes give values agreeing with those indicated by the colorimetric study.

5. It is pointed out that the methods involving the use of these redox indicators merely measure the "reduction equilibrium" of the dyes used, that is, the point at which the rates of oxidation and reduction of the dye are the same. On the other hand, measurements of the electrode potential without an appropriate indicator give no information beyond the fact that there are certain (diffusible) substances in the solution which can affect the electrode. We have, in fact, no method whereby the true reduction potential of cells can be measured.

6. There is no correlation between the mode of life of the organism and the "reduction potential" measured by these methods. *Bact. coli* is a facultative anaerobe, *Bact. alkaligenes* a strict aerobe and *Cl. sporogenes* a strict anaerobe, but the reduction potentials show no correlative differences.

I desire to thank both Prof. E. K. Rideal for suggesting this investigation and Dr D. E. Green for helpful discussion during the course of this work.

CXLIII. THE DISTRIBUTION OF STEROLS IN HUMAN FAECES.

AN EXAMINATION OF ILEAL CONTENTS.

By JOHN ADDYMAN GARDNER, HUGH GAINSBOROUGH
AND RUTH MONA MURRAY.

From the Biochemical Department, St George's Hospital.

(*Received March 9th, 1935.*)

Long ago Flint [1862; 1868] observed that cholesterol undergoes a modification in the human intestine, and that it is found in the faeces as "stercorine." This substance, rediscovered by Bondzynski [1896] who gave it the name of "coprosterine," was more fully described by Bondzynski and v. Humnicki [1896]. The formula $C_{27}H_{48}O$ was ascribed to it and confirmed by the analysis of derivatives, and its discoverers regarded it as a dihydrocholesterol formed by bacterial reduction in the intestine. Support was lent to this hypothesis by the observation of Müller [1900] that in a patient kept for a long time on a milk diet, which presumably altered the intestinal flora, the sterol of the faeces was excreted as unchanged cholesterol. Later, Gardner [1921] isolated from human faeces, in addition to coprosterol, small quantities of β-cholestanol and cholesterol. These substances were found not only in the mixed faeces of a village community but also in the excreta of soldiers in training. Recently, Schoenheimer [1934] has perfected an improved method suitable for small quantities of material for the isolation of cholesterol from mixtures of β-cholestanol and coprosterol and has confirmed the presence of cholesterol in human faeces.

Fox and Gardner [1925] published the result of a long series of experiments on the cholesterol metabolism of breast-fed infants and found that the crystalline sterol of the faeces consisted only of cholesterol. At what stage of life the change of the faecal sterols, from the cholesterol of infant's faeces to the mixture of coprosterol, β-cholestanol and cholesterol characteristic of adult human faeces, takes place has yet to be determined.

Some evidence has accumulated as to the origin of the different forms of faecal sterol. The observation of Boehm [1911] that an isolated loop of intestine, accidentally produced in a woman under operation and left *in situ* for years, contained sterile material, the sterol content of which was solely β-cholestanol, suggests a secretion of this sterol through the wall of the intestine into its lumen. Beumer and Hepner [1929] found cholesterol in the colonic contents of a bile fistula dog fed on a lipoid-free diet and concluded that cholesterol was secreted by the large intestine. Schoenheimer and v. Behring [1930] examined the secretions of the isolated large intestines of a series of dogs. After suitable washing out of the secretions and sealing of the intestinal tube for a length of time, he finally obtained a cheesy material, similar to that obtained by Boehm, containing sterol of which 52 % was saturated, and showed it to be mainly β-cholestanol, the remainder being cholesterol. Sperry [1926–27] fed dogs which had had a bile fistula made, on a lipoid-free diet, and the unsaponifiable matter obtained from the faeces was afterwards closely examined by Schoenheimer and Sperry [1934]. They concluded that, despite a sterol-free diet and the total exclusion of bile from the intestine, coprosterol was the principal sterol excreted by their dogs: only 11 % of the total sterols excreted was unhydrogenated (probably cholesterol); β-cholestanol was also present. They considered that in such dogs coprosterol must be formed from cholesterol which is secreted into the intestine through the intestinal wall. It is to be noted that in Boehm's and Schoenheimer's experiments, where β-cholestanol appeared to be the predominant sterol, the intestinal contents were sterile.

The question arose as to how and where the faecal coprosterol was produced. It is to be remembered that coprosterol is not of the same stereoisomeric series as cholesterol, the direct hydrogenation product of which is β-cholestanol. So far the only explanation offered is that coprosterol is produced from cholesterol by bacterial action, and the only evidence available here is that of Müller mentioned above and that of Dam [1934] who thought he could show an increased formation of coprosterol in faecal putrefaction experiments in which cholesterol had been added, though the production of coprosterol here was only inferred from the solubility curve of the digitonide and the increase measured by Schoenheimer's method, which is possibly scarcely accurate enough to permit such conclusions to be drawn.

We feel by no means certain that the bacterial hydrogenation of cholesterol to produce coprosterol, if true, is the whole story. We have been amazed at the rapidity with which large quantities of coprosterol can be produced under certain circumstances. Dorée and Gardner [1908] made an extensive series of feeding experiments on a trained dog, using a number of different diets for long periods. It has been necessary to reinterpret the findings in that paper in the light of the greater knowledge of to-day, and we can safely conclude that the sterol matter isolated from the dog's faeces when the animal was fed on diets containing cholesterol in what might be considered normal amounts consisted of a mixture of cholesterol and β-cholestanol. Coprosterol was not isolated. However, when this same animal was fed on a diet of cooked sheep's brains, it excreted quantities of coprosterol. The actual quantity isolated in apparently pure condition was 1·2 g. per day, whereas approximately only 1 % of the total sterols isolated consisted of a mixture of cholesterol and β-cholestanol. Similar experiments by Ellis and Gardner [1909] with cats produced similar results, except that the cat, on a normal diet, produced coprosterol more easily than the dog. The contrast is very marked in the case of the herbivora [Dorée and Gardner, 1908] with which in no case could any trace of animal sterol be found in the faeces. It is curious that the normally fed dog should excrete cholesterol and β-cholestanol but no isolable coprosterol, and yet when fed on sheep's brains a mechanism should be available, of which there was no previous sign, which could produce such large quantities of coprosterol. If the mechanism is bacterial then why is there so little evidence of coprosterol formation with an ordinary diet? It is conceivable that on the brain diet a different intestinal flora appeared, but this explanation does not seem very likely, because the dog after feeding on sheep's brains showed a return to normal faecal sterol distribution on the withdrawal of that diet. In other words, if the reduction of cholesterol to coprosterol can be so extremely efficient in the brain-fed animal, why should the normally fed dog excrete so much cholesterol and β-cholestanol? At the same time (1908) it was shown that the total sterol excreted was much less than the sum of the total intake *plus* the biliary cholesterol, whence it was inferred that, as it seemed unlikely that cholesterol was destroyed in the gut, cholesterol was being absorbed in the alimentary canal. This has been confirmed, though coprosterol and β-cholestanol have been shown by Schoenheimer *et al.* [1930] not to be so absorbed from the intestine. We suggest that the mechanism of coprosterol formation shown by the dog and the cat protects the animals from the effects of over-absorption of cholesterol which can be so readily observed in the case of rabbits, where cholesterol is avidly taken up from the intestine, eventually producing a lipoid infiltration of the organs and tissues.

The question as to the site of coprosterol formation in man seemed to us easy of solution, but there have been many difficulties in obtaining uncontaminated ileal faeces from surgical cases. However, the opportunity finally presented itself of examining two cases in which ileostomy had been performed. In 1930 we had analysed some caecostomy faeces from a case of ulcerative colitis and obtained a clear-cut result, but as the faeces had already entered the colon we did not consider the unsupported result sufficiently significant. In this case 0·1 g. of crystalline material was obtained directly by crystallisation from the unsaponified matter of the ether extract and a further 0·12 g. after treating the residues with digitonin and subsequently splitting the digitonide in the usual way. The former portion melted at 146–147°, had $[\alpha]_D^{20°}$ −40·7° and was clearly cholesterol; the portion obtained by digitonin had melting point 142–143°, and $[\alpha]_D^{20°}$ −31·6° and was found to contain about 10 % of saturated sterol, probably β-cholestanol. No trace of coprosterol was isolated.

The ileal contents examined were from the following two cases:

M. C. Female, aet. 32. Ulcerative colitis. A caecostomy had been performed in August 1933 and, as only temporary benefit was obtained, a transverse ileostomy was made in July 1934 about 6 in. from the ileal termination.

L. H. Female, aet. 30. Ulcerative colitis. A caecostomy had been performed in May 1928; this was remade in November 1930, but as symptoms recurred later a transverse ileostomy was made in November 1933. This case unfortunately had a small ileo-caecal fistula, but it is unlikely that caecal contents could have flowed back into the ileum, hence the ileostomy discharge was considered to be uncontaminated ileal contents.

In both cases no grease of any kind was used to protect the skin of the abdomen: a kaolin paste was used for this purpose and great care was taken that no caecostomy discharges were included in the ileal excreta.

Exp. 1. Ileal faeces from M. C. were collected during the whole of May and June 1934. These were dried partly *in vacuo*, partly by heat, and as it was difficult to get rid of all the moisture the faeces were soaked in alcohol first cold, then warm. The alcoholic extracts were evaporated to dryness and the residue extracted with ether. The dried faeces were then exhaustively extracted with ether in a special Soxhlet apparatus without rubber connections, corks or taps. The two ether extracts were put together and made up to known volume. The solution was dark green and absorption bands indicated that this was due to chlorophyll. This extract after suitable concentration was hydrolysed with sodium ethoxide in alcoholic solution, the unsaponifiable matter extracted in the usual manner and this material crystallised from methyl alcohol. Successive crops of crystalline material, which very closely resembled cholesterol, were separated and 4·63 g. were obtained. The residual oil obtained from the mother liquors weighed 1·03 g.; this was precipitated by digitonin in the usual manner, and 0·13 g. of cream-coloured crystals was obtained by splitting the digitonide. The total crude sterol was altogether 4·76 g. This was brominated by the Windaus method and 4·67 g. of the dibromide were obtained, M.P. 112–113°. This was debrominated with zinc dust and acetic acid and after repeated crystallisation 1·77 g. of typical cholesterol crystals were obtained; M.P. 144–145°. This was again brominated, yielding a dibromide of M.P. 113–114°, and finally a sample of cholesterol was obtained (0·35 g.), of M.P. 146–147° and $[\alpha]_D^{19°}$ −36·8°. Further examination was made of the second crops of dibromide that were precipitated by water in both brominations. These substances after debromination were converted into the acetates and crystalline substances obtained, M.P. 117–118°, which on recrystallisation yielded pure cholesteryl acetate. Clearly some phytosterol was present but in quantity insufficient for isolation by the method suggested by Windaus [1906]. The mother-liquors were similarly examined with identical results.

Thus the great bulk of the original crude sterol consisted of cholesterol, but after much search only traces of phytosterol were detected and no β-cholestanol or coprosterol could be isolated.

Exp. 2. 115 g. of dried ileal faeces were obtained from L. H. These were extracted with ether, and the total ether extract consisted of a brown oil weighing 48 g. This, after saponification, yielded 40 g. of unsaponifiable material and it was then discovered that instructions in the ward had been disregarded and the patient had been given paraffinum liquidum by mouth. A digitonin estimation on an aliquot part of the ether extract showed that it contained 0·796 g. sterol in the whole specimen. The unsaponifiable matter was then dissolved in alcohol, precipitated with digitonin, left overnight, the separated digitonide filtered off and washed free from "paraffin" with ether. The digitonide so obtained was decomposed by the pyridine-ether method and the recovered sterol crystallised from methyl alcohol in faintly pink plates. The first crop consisted of 0·6 g. cholesterol, M.P. 144–145°, and this, recrystallised, yielded 0·46 g. of colourless crystalline cholesterol, M.P. 146–147°, with $[\alpha]_D^{18^\circ} -37{\cdot}7^\circ$. Further portions from this recrystallisation gave material with M.P. 143–144°. The second crop (0·07 g.), the third crop consisting of brownish crystals in oil, some further material obtained from some digitonide which had been finally separated from "paraffin" with great difficulty and all the residues from the first crop were mixed together, weighing 0·22 g. in all. This was brominated by Schoenheimer's method, the dibromide filtered off, digitonin in alcohol added and after 18 hours 0·028 g. of digitonide was deposited, and the filtrate yielded after a further 24 hours 0·036 g. of digitonide. These were separately decomposed by pyridine and ether, the first yielding 0·007 g., and the second 0·005 g. These were added together and crystallised from methyl alcohol, yielding plates which gave a strong Burchardt-Liebermann reaction. A solution of the whole material in chloroform was compared by means of this reaction with standard solutions of cholesterol and it was found that over 75 % of the material was cholesterol.

Evidently the bulk of the material in this case was cholesterol and no β-cholestanol or coprosterol could actually be isolated, though it was very likely that some traces of β-cholestanol were present.

Exp. 3. It was thought wise to repeat the analysis of further material from M. C., taking strict precautions as regards eliminating paraffin administration, and eliminating green vegetables and fruit from the diet in order to reduce the intake of phytosterols as far as possible. ·620 g. of dried ileal excreta, collected during November and December 1934, were thoroughly extracted with ether and 36·2 g. of ether-soluble matter obtained. The total sterol in this was estimated by digitonin in an aliquot part and amounted to 7·08 g. After saponification of the ether extract 6·6 g. of unsaponifiable matter were obtained and this was recrystallised from methyl alcohol. Crop I (5·015 g.) was further purified and crop I′ (3·22 g.) of pure cholesterol was thus obtained with M.P. 147°, $[\alpha]_D^{20^\circ} -35{\cdot}3^\circ$, and from the mother-liquors of this 1·29 g. sterol were obtained, M.P. 139–140°, $[\alpha]_D^{20^\circ} -37{\cdot}6^\circ$. The pure sample (crop I′) was brominated by the Windaus method and yielded an initial precipitate (A) of dibromide (3·8 g.), M.P. 112–113°, and a further crop (B), by adding water (1·25 g.). From A, after reduction, 1·6 g. of pure cholesterol were finally obtained, M.P. 148°, clearing at 150°, and the material from the mother-liquors was evaporated to dryness and benzoylated by the pyridine method, yielding a solid melting at 147°, clearing at 173°; a further sample from the mother-liquors melted at 146° and cleared at 168°. Neither of these benzoates on melting and cooling showed any play of colours. The material B yielded no crystalline matter after reduction and it was therefore all benzoylated as before and a sterol benzoate obtained melting at 146° and clearing at 171° without any play of colours. Crop II from the crystallisation of the crude unsaponifiable matter consisted of 0·65 g. of orange stained crystals. From this 0·49 g. of a benzoate was obtained melting at 141° and clearing at 167° without any blue flash but on cooling there was a quick play of colours. This effect was matched by a sample of cholesteryl benzoate to which 5 % of β-cholestanyl benzoate had been added. Small additional crops from this crystallisation showed the same behaviour. Crop III from the unsaponifiable matter consisted of 0·65 g. of orange crystals mixed with oily matter. Some of this was unfortunately lost but 0·15 g. of a benzoate was obtained, M.P. 129–133°, clearing at 168°, showing similar colour changes to the material from crop II but weaker.

This experiment amply confirms the previous findings that only cholesterol can be isolated but that traces of β-cholestanol can be detected.

It may be noted here that cholesteryl benzoate made from pure cholesterol does not show any trace of play of colours on melting and cooling, whereas addition of β-cholestanol benzoate to cholesterol benzoate in increasing proportions produces such phenomena on melting. This can be used for a rough indication of the amount of β-cholestanol in a sample of cholesterol by comparison with artificial standard mixtures.

It had occurred to us some years ago that the sterol distribution in human faeces might be affected by the presence or absence of bile. We collected the clay-coloured faeces of two cases of complete biliary obstruction and recovered the sterols therefrom. The analyses were not carried out to the ultimate fractions but it became clear that the bulk of the faecal sterols in these cases consisted of coprosterol as in normal subjects.

DISCUSSION.

It is quite clear from these three analyses of ileostomy excreta and one of caecostomy excreta that the sterol content is quite different from that of normal human faeces. From the former only cholesterol can be isolated and traces of β-cholestanol detected, whereas the latter contain sterol mainly as coprosterol, smaller quantities of β-cholestanol and traces of cholesterol. It follows that the production of coprosterol must occur in the colon. The earlier experiments of Dorée and Gardner showed that the dog on a normal diet excreted mainly cholesterol in its faeces and the cat cholesterol and coprosterol. We realise now that as the apparently pure cholesterol isolated in these cases yielded benzoates which showed marked colour changes on melting there must have also been some β-cholestanol present. The mechanism of coprosterol formation was easily brought into evidence by feeding the animals on a diet of sheep's brains, and it is difficult to understand how such an action can be due solely to bacterial hydrogenation for, if this were the case, there is no obvious reason why this action should remain latent in normally fed animals, in which little or no coprosterol is formed.

SUMMARY.

1. Coprosterol could not be isolated from intestinal contents discharged from either a terminal ileostomy or a caecostomy.

2. It follows that coprosterol formation must occur in the colon.

3. We think that the hypothesis that coprosterol formation results from the bacterial hydrogenation of cholesterol is insufficient.

We wish to express our thanks to our colleagues at St George's Hospital for allowing us access to these cases.

CXLIV. A STUDY OF THE ANTENATAL SECRETION OF THE HUMAN MAMMARY GLAND AND A COMPARISON BETWEEN THIS AND THE SECRETION OBTAINED DIRECTLY AFTER BIRTH.

By SIBYL TAITE WIDDOWS, MARGARET FRANCES LOWENFELD, MURIEL BOND, CECILIA SHISKIN and EFFIE ISABEL TAYLOR.

From the London (Royal Free Hospital) School of Medicine for Women.

(*Received February 4th, 1935.*)

In a fairly complete study already made by us on the composition of human milk obtained directly after parturition and during the later stages of lactation [Lowenfeld *et al.*, 1927; Widdows *et al.*, 1930; Widdows and Lowenfeld, 1933], certain facts of a rather unexpected nature with regard to its composition in the early stages after labour were reported.

It has been generally recognised that the secretory activity of the maternal mammary gland commences before the expulsion of the foetus. An opportunity was given us for the study of samples of antenatal secretions, and since as far as we could ascertain very little work had been done on this subject, it was decided to undertake an investigation, the results of which are recorded in the present paper.

Work has been done on the antenatal secretion of cows, and it should be emphasised that workers on this line have had the very great advantage of being able to study in the same animal the progressive effects of pregnancy on the composition of the secretion. In particular, the work of Houdet [1894], and later Eckles and Palmer [1916], Woodman and Hammond [1922; 1923], and Asdell [1925] is interesting in view of certain results obtained by us.

Woodman and Hammond, working with heifers, analysed the secretion at 15, 22 and 28 weeks' gestation, the secretion between these stages being removed at intervals but not analysed, while Asdell removed and analysed the secretion at intervals from the 4th week of gestation up to parturition (total number of weeks of gestation being 41), first taking samples biweekly and afterwards weekly. Woodman, Hammond and Asdell all arrived at very much the same conclusion.

Up to the 15th week they obtained a serous secretion containing all the constituents found in milk, but with only traces of fat, and with small amounts of lactose, caseinogen, globulin and albumin, the globulin predominating over the caseinogen and albumin. About halfway through pregnancy the character of the secretion changed and it became thick, viscid and honey-like, with a high content of solid, chiefly protein. The protein consisted almost entirely of globulin, no caseinogen at all being found by Woodman and Hammond, and only a very small amount by Asdell. Traces of lactose were present and a very small amount of fat, and, in fact, Woodman and Hammond looked upon the secretion as a very concentrated solution of globulin. At about the 28th to the 30th week this viscid secretion gave place to a milk-like fluid in relatively large quantity which contained appreciable percentages of the normal constituents of colostrum. When the cow is milked up to parturition, as shown by Asdell, the colostrum milk closely follows the composition of the prepartum fluid which has been approximating to true milk.

If the viscid secretion is not removed, then the transition to the colostral phase appears to be more gradual, and it is only at the time of parturition that the secretion assumes the character of normal colostrum with a high percentage of globulin.

These workers concluded that during the early months of pregnancy the secretory activity of the gland is present but is feeble. At about halfway through pregnancy, which appears to correspond to a definite stage in the development of the gland, the normal activity of the cells, which results in the production of the caseinogen, lactose and fat, seems to be inhibited. If the viscid secretion at this stage is removed, the normal activity of the gland is gradually resumed in the same way as frequent milking stimulates activity during normal lactation.

Outside the limits of normal lactation, globulin seems a characteristic constituent of the mammary secretion, the protein of the secretion at a certain stage consisting practically entirely of globulin.

A tentative suggestion is put forward by Asdell, as a result of this study, that the globulin is present in the mammary ducts as a result of the change from growth to secretion on the part of the mammary cells. If the mammary secretion is removed at this stage, and continually removed as pregnancy proceeds, the proportion of globulin rapidly decreases, while if the secretion is allowed to remain in the gland, the globulin percentage remains high up to the time of parturition, and in the colostrum milk immediately after it, and only acquires the percentage found in ordinary milk as the result of continuous removal of the milk after parturition.

Eccles and Palmer in their work on cows, concluded that when cows are milked up to the time of parturition, the colostrum milk follows closely the composition of the milk given before birth. As the cow approached parturition, these workers found a marked increment of the heat-coagulable proteins which reached their maximum in the first milk obtained after birth. They concluded from these results that the high content of heat-coagulable proteins was the chief, if not the only real effect of parturition on the milk. This does not seem to accord with Asdell's later work, and although these workers only milked continuously for a month before birth, and they were dealing with cows and not heifers, one would have expected a month's continuous milking to have reduced and not increased the heat coagulable-proteins. The secretion during labour was not investigated by these workers. In our work such a complete investigation as the above was not possible. The secretion investigated was that which could be obtained (*a*) once or twice from the same woman during the 2 months before parturition, but (*b*) more often single scanty samples obtained from different women during this period. In view of the results of Woodman, Hammond and Asdell, on cows, it was thought that although the period of study of the antenatal secretion would be more limited in our case, such an investigation would be interesting. It was hoped that similar and comparative results would be obtained for the last 2 months of pregnancy, so that what was experimentally proved in the case of cows for the very early secretion might be inferred to be true of women, where the difficulties of obtaining this secretion make experimental work on such samples impossible.

In this paper it will be seen that to a certain extent our results are comparable, but that there are certain points not in accord and which at present lack explanation.

Czerny and Keller [1925] point out that for the analysis of the secretions of the mammary gland before parturition, there are only the incomplete analyses of Clemm [1845], whose figures are referred to by Engel [1911][1]. The figures obtained from the table in Engel's paper are the results of six analyses from the secretion of one woman. The figures obtained from such a method of investigation taken in conjunction with the probably less accurate methods of investigation available at this early date afford little material for comparison.

METHODS AND OBSERVATIONS.

The material for our work has been obtained from cases both primiparae and multiparae in the Maternity Department of the St Pancras Hospital and from the Shoreditch Carnegie Welfare Settlement.

In only a few cases has it been possible to deal with the same woman throughout the antenatal course, but the secretions from a large number of different cases have been studied, extending over a period from 2 months to the day of delivery. It is felt that to a large extent individual differences may be eliminated in this way and some generalisations may be drawn.

Cases investigated—total number 53.

1. Cases where specimens were obtained only before labour:
   (*a*) 26 cases where a single specimen was obtained;
   (*b*) one case where two specimens were obtained.
2. Cases where specimens were obtained both before and after labour:
   (*a*) 16 cases (including 4 cases in labour) from whom a single specimen was obtained before labour;
   (*b*) 10 cases from whom more than one specimen was obtained before labour, giving in all 34 specimens distributed as follows:

6 cases gave 2 specimens
1 case gave 3 ,,
1 ,, 4 ,,
1 ,, 5 ,,
1 ,, 10 ,,

3. These cases gave a total number of 78 specimens examined before labour.

The chemical constituents estimated were protein, ash, sugar, calcium, phosphorus and chlorine.

The methods employed in the estimations were those recorded in our earlier papers on milk [Lowenfeld *et al.*, 1927; Widdows *et al.*, 1930].

A. *Physical properties of the secretions studied.*

An examination of the mammary secretion before and after labour shows marked differences in its physical properties.

1. *Volume.* In the case of multiparae, after the first day after parturition the volume of the fluid obtained was found to vary from 10 to 30 ml., and in one woman (J.) investigated on the second day the volume obtained was as much as 90 ml. In the case of primiparae, the volumes were found to vary considerably, and sometimes for the first few days after birth were noticeably small.

---

[1] So far it has not been possible to obtain a paper by Guiraud [1897] in which all the early work on colostrum up to 1897 is collected including the figures of Clemm.

With very few exceptions, large volumes were not found to be obtainable before labour. Of the 64 women investigated, 9 specimens had a volume under 2 ml., 39 between 2 and 3 ml., 10 between 4 and 6 ml., and 6 between 6·5 and 7·5 ml. Occasionally an exception occurred—for instance, a multipara (H.) gave a volume of 22·5 ml. 2 weeks before labour, and another, a primipara (Ha.) gave, 5 weeks before labour, a volume of 38 ml. In two other cases a volume of 11 ml. has been obtained.

This great difference with regard to volume naturally suggests that the early secretion may merely be a concentrated form of later milk, and upon the elucidation of this point the interest of an investigation of the antenatal secretion depends. If the relative values of the different constituents of the gland are found to be approximately similar on both sides of the line of labour, then we are dealing with a physical change only, and the type of secretory activity is identical before and after labour.

A glance at the tables given below for sugar and calcium, compared with those for protein and ash, shows immediately that this is not the case. Each of the calcium and the sugar curves from 30 days before to 10 days after labour shows a fairly steep rise, settling down later to a more or less even value. In contrast with these curves, the protein values of the antenatal secretions never fall below 2·69 %, with an average of 8·9 %, and from these high values the curve declines steadily during the 10 days after parturition to 1·5 %, above which its value never rises (as shown in our paper on later milk [Widdows *et al.*, 1930]). It is clear therefore that the differences that occur between the fluid obtained from the mammary gland before and after labour must be due to a difference in the secretory activity of the gland and not merely to the variation of the water content in an otherwise standard fluid. For instance, one example (F.), 4 days after parturition gave a protein value of 1·62 % and at the same time 0·042 % CaO, 6·43 % sugar, and 0·28 % ash. The antenatal secretion 9 days before birth gave a protein value of 9·14 %, which on the assumption that there is merely a variation in the water content of the secretion should have given for CaO 0·238 %, for sugar 36·27 %, and for ash 1·57 %, whereas the percentages actually found were 0·0443 % CaO, 4·72 % sugar, and 0·56 % ash.

In view of the results obtained by Woodman, Hammond and Asdell on heifers and cows, it is possible that the explanation lies in the fact that the fluid before parturition in women is not removed from the breast.

2. *Colour and viscosity.* It is well known that the general physical properties of colostrum and early milk are different from those of later milk, and attention has been drawn to this point in our paper on early milk [Lowenfeld *et al.*, 1927]. The antenatal secretion seems to fall into three classes:

(1) A beige-coloured watery secretion, with fat globules sometimes separate from the watery fluid.

(2) An opalescent milky-looking fluid, much more viscid than the fluid described in (1).

(3) A secretion creamy and thick, sometimes very yellow, very viscid and sometimes appearing almost gelatinous.

The larger number of antenatal secretions examined belong to classes (2) and (3), and of these by far the larger number belong to class (2). Both these solutions coagulate on heating.

Engel [1911] in a paper on the biochemistry of cows' colostrum, in a short paragraph on the antenatal secretion, points out that Houdet [1894] had found similarly in cows two types of secretion, a viscid and a more fluid form, but he had not been able to say at what stages in the pregnancy these two different types were produced.

Woodman, Hammond and Asdell, on the other hand, as shown above, associate the three degrees of viscosity with distinct periods of lactation, the very viscid (class 3) corresponding to the secretion obtained halfway through pregnancy.

All our samples fall within the last 2 months of pregnancy. It is therefore possible that the viscosities obtained by us may be very much less than would be shown by the secretion if we could obtain a specimen at about 5 months before birth. All three different types of secretion as regards viscosity, both in multiparae and primiparae, appear during the last 2 months of pregnancy, and at all times, varying from the day before to 2 months before birth. At present it does not seem possible to correlate these three types of secretion either with the stage of gestation or with a condition depending on the number of children borne. Some correlation seems, however, to be indicated between the chemical findings and the physical condition. This point will be referred to in connection with the different constituents of the secretion studied.

B. *Chemical results.*

Protein. Protein analyses were made on specimens from 48 women, 8 women giving specimens on more than one day, 35 giving one specimen only, and 5 giving specimens in labour or on the day of labour.

Table I. *Protein (g. per 100 ml.).*

P = primiparae, M = multiparae, L = lowest, H = highest.

	Before birth						
	Weeks 8, 7, 6, 5	Weeks 4–3	Day 21–15	Day 14–8	Day 7–2	Day before labour	In labour
P	L 2·69 H 8·97	L 4·54 H 17·5	L 6·06 H 8·64	L 5·90 H 11·09	L 4·12 H 13·46	L 5·49 H 6·43	L 9·864 H 17·34
M	L 5·36 H 11·99	L 5·17 H 10·32	L 5·74 H 16·0	L 3·94 H 9·14	L 3·89 H 12·26	L 4·24 H 19·4	L 10·87 H 12·31
Average values P + M (bracketed figures = no. of samples analysed).	8·40 (15)	9·28 (8)	9·18 (7)	7·54 (8)	8·16 (16)	8·385 (11)	12·598 (4)

	After birth							
Days ...	1st	2nd	3rd	4th	5th	6th	7th	8th
P	L 4·58 H 14·1	L 2·25 H 8·34	L 1·36 H 8·47	L 1·23 H 3·66	L 1·27 H 2·34	L 1·26 H 1·76	L 1·29 H 1·96	L 0·855 H 1·94

Average values P + M (bracketed figures = no. of samples analysed).	7·864 (11)	4·599 (17)	2·80 (27)	1·895 (25)	1·704 (20)	1·575 (20)	1·55 (13)	1·55 (23)

The figures for the percentage of protein of the antenatal secretion are compared with those of the protein of the milk obtained from 40 women during the 10 days after labour. 156 samples of the postnatal milk were analysed. The comparison is not made with later milk, as the comparison between the milk during the early and later days of lactation has already been recorded [Widdows *et al.*, 1930].

In our earlier work [Lowenfeld *et al.*, 1927], it was suggested that a significant difference was to be found in the protein values of the early days of lactation between multiparae and primiparae.

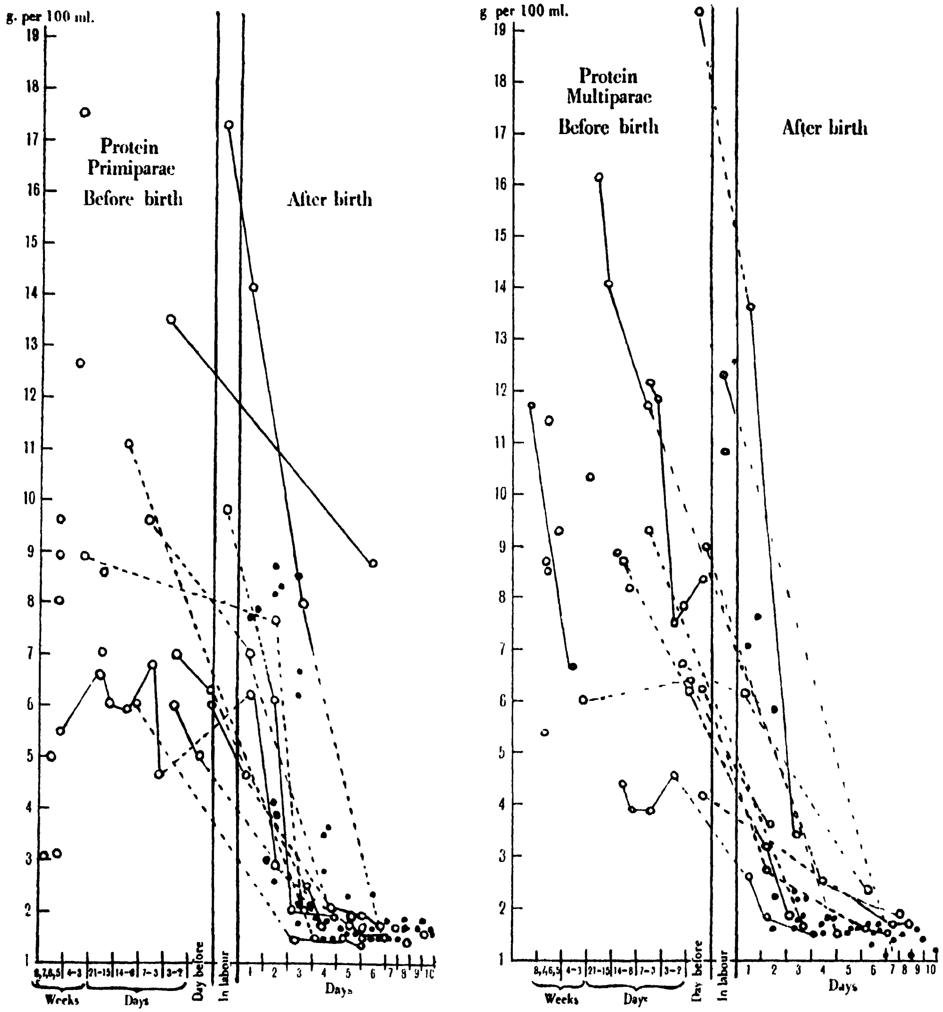

Fig. 1*a*. Fig. 1*b*.

Fig. 1. ● Represent percentages where no antenatal specimens were obtained. For clearness here percentages from same woman at different periods are not connected. o Represents percentages where both ante- and post-natal specimens were obtained. These are joined where more than one specimen from same woman was available, the connecting line being broken during periods when there were no specimens.

If the post-labour curves in the figures be considered, this suggestion that on the whole the milk of the primiparae tends to give much higher protein values than that of the multiparae on the 1st day after labour is reasonably borne out. It will be noticed that not only on the 1st day do the protein values tend to be higher, but even on the 3rd day after labour there are several values in the case of the primiparae over 6 %, whereas there are none in the case of the multiparae. On the other hand, when the values for the antenatal milk are considered, very little reliable difference can be observed between the two series of curves. This may be due (*a*) to the absence of antenatal figures in so many of the primiparae mothers who give protein values of above 5 % on the 1st to the 5th day after labour and (*b*) to the fact that the cases represented in the multiparae table show a greater number in whom it was possible to make a series of consistent observations throughout the ante- and post-natal periods.

These differences have arisen out of practical circumstances in the cases studied. In our early work the postnatal cases were obtained largely from the wards of the Obstetric Unit of the Royal Free Hospital, and as is always the case with wards of this nature, there is a heavy preponderance of primiparae in their admissions. On the other hand, the antenatal cases were studied in connection with the St Pancras Hospital, where the larger proportion of cases admitted, either as in- or out-patients of the maternity department, are multiparae, whether married or single. To decide definitely whether, as first suggested, there is any real difference between the antenatal protein values of the primiparae and the multiparae will only be possible when a large number of primiparae can be studied throughout pregnancy.

From a study of the graphs of the cases so far examined, the following facts can be ascertained.

(1) In all cases, without exception, the protein value for the antenatal secretion is higher than it is in that obtained after labour. In the secretion actually obtained in labour, in the few cases examined, the value is very high, in one case reaching the astonishing value of 17·2.

(2) The protein value for both multiparae and primiparae falls steeply during the first days after lactation, the fall, as far as our figures show being very much steeper in the case of multiparae than in that of primiparae. In the case of multiparae with a single exception, all samples were below 3 % by the 3rd day, while in the primiparae they did not reach this level till the 6th day. With only one exception, by the 3rd day all values obtained were below 2·5 % for multiparae but values above 3 % were still found on the 4th day in the case of the primiparae.

(3) One of the characteristic features obtained from a study of the curves shown equally in primiparae and multiparae, is the very great degree of variation in the protein values found in specimens of the antenatal secretion. No explanation has been found for these differences. Clemm seems to have found a similar variation in his antenatal protein results, as with the same woman on two different occasions 4 weeks before birth, he gives the percentages 2·9814 and 6·9033 respectively.

(4) The protein values appear to fall to a certain extent into two groups related to a line drawn across the curves in the neighbourhood of the value 7 %. Approximately half of the specimens examined appear to fall into a group with percentages above this level, and half below.

This tendency to fall into a group of high or low values is borne out in other constituents, but we have not as yet any suggestion to make as to the possible factors responsible for this.

Houdet [1894] in the case of cows showed that the viscid secretion gave a very high protein percentage and the more liquid secretion a low percentage. In our results practically all the very high protein percentages, those over 10 %, both in the case of the primiparae and the multiparae, are obtained from secretions class (3) which were very viscid, while the low percentages, those below 6 %, were obtained from very watery thin secretions class (1). The percentages varying from 6 to 10 % were obtained from the creamy and viscid class (2).

There are, however, exceptions to the above generalisations. For instance, in one case a secretion creamy and viscid (class 2) gave a protein percentage of 12·6 %, and another of the same consistency 12·3 %—the latter was, however, a specimen taken in labour which, as indicated by results obtained in these cases, always seems to raise the protein value. In one or two cases where the secretion was rather viscid, low protein values were obtained—*viz.* about 6 %.

A point of interest which so far we have had no opportunity of investigating, but which we hope to investigate in the future, is the type of the protein in both the antenatal and postnatal secretions.

The protein in the colostrum of cows has been investigated by, among others, Sebelien [1885], Emmerling [1888], Engel [1911], Winterstein and Strickler [1906], Southerst [1902], and Tiemann [1898] and in the antenatal secretion by Woodman and Hammond [1922; 1923], and Asdell [1925]; in human colostrum by Camerer and Söldner [1896], Birk [1910], Meigs and Marsh [1913; 1914], Pfaundler [1915], and Lowenfeld *et al.* [1927], and in the antenatal secretion by Clemm, but only so far as total protein is concerned. Czerny and Keller [1925] sum up the results on both human and cows' colostrum by stating that the "insoluble" globulin was 2–4 times, and the total "insoluble" protein 10–30 times, more concentrated than in milk.

Woodman and Hammond and Asdell show that in the case of the cow the high percentage of protein is due largely to the globulin produced at about the 5th month of pregnancy, which does not disappear from the gland until the milk is regularly removed after parturition, although the secretion of all the constituents of true milk has been taking place for some weeks.

We have noticed that all specimens of the antenatal secretion give a very deep orange colour with concentrated nitric acid, and the same colour is given by specimens on the 1st and 2nd days after parturition. From the 2nd day onwards only a very pale yellow colour is given by the milk analysed. This characteristic, combined with the fact that the secretion gives a very heavy precipitate with dilute acid, and coagulates easily on heating, may possibly be due to a high globulin content.

It is thought that it is the phenyl group in the protein which gives the deep colour with nitric acid, and from the table given by Lloyd [1926, p. 46] it will be seen that globulin contains a high percentage of the constituents containing this group. If the colour reaction with nitric acid is due to the preponderance of globulin in the antenatal secretion as well as that immediately after birth, it would seem that there is a very quick diminution of this protein with the withdrawal of the secretion after birth, as the deep orange colour disappears so rapidly.

A breast that has not had a period of lactation does not secrete as readily as one that has already done so, and it is unlikely that there will be any leakage of the secretion before parturition. From a comparison with the work on cows, it seems probable that the secretory activity of the gland in the case of the primiparae would not be as advanced as in many cases of the multiparae where stimulation to increased secretory activity would be induced by leakage. One would thus expect in the majority of cases of primiparae to find a high percentage of globulin as compared with cases of multiparae, and a smaller proportion of the constituents of normal milk both before and for a longer time after birth.

The type of protein occurring in the antenatal secretion and that immediately after birth is a point that requires investigation, but the great difficulty in attacking this problem lies in the inability to obtain sufficient of the secretion for analysis.

Sugar. The antenatal secretion was examined for sugar in 67 samples from 43 women. The number of cases whose secretion was examined on more than one day was 10, on one day only 30 and in labour 3. Between the 1st and 10th days after labour, 244 samples were analysed. In contrast to the ash and protein, as seen in the table and by the graph, the percentage of sugar is low before labour and rises very rapidly during the first days after labour. A low percentage before labour was to be expected from our earlier work [Widdows *et al.*, 1930], where it was shown that the sugar percentage was at its lowest in early milk, but had risen by the end of the 1st month to an average of a little over 7 %, from which there was little material alteration throughout the whole subsequent course of lactation. There seems to be no significant difference in the sugar values of the primiparae and multiparae. The lowest value obtained before labour was 1·1 % and the highest 4·72 %, but the usual value was between 2·5 and 3·9 %. On the 3rd day after labour, the average value in the case of both primiparae and multiparae had risen to over 6 %. In the three cases examined during labour, in the two primiparae there was a very low sugar percentage, while in that of the multipara it was high, slightly higher than the average for the six samples taken the day before labour. Whether there is really any significant difference here can only be determined by the analysis of a great many more samples, but as the difficulty of obtaining

such samples is evident, the authors felt it was of interest to record these results.

There is, however, this point to notice, that in the case of the multipara G. the sample analysed was taken about 7 hours before the birth of the child, while in the case of both of the primiparae, the sample was taken at an earlier stage in labour. One, W., was taken at the beginning of labour where the labour lasted 2 days, and the other J. was taken between 16–17 hours before the birth of the child. Whether in the case of the multipara the value of the sugar percentage was lower at the beginning of labour, and at the time of taking was beginning to rise as it always does directly after labour, or whether there is really a difference between the primiparae and multiparae can only be decided by further work. In no case yet have we been able to make a consecutive series of analyses beginning a few days before and continued through labour to a few days after labour. Only from such analyses could any definite conclusions be drawn.

On considering the highest and lowest values in the average of percentage for sugar for the different periods, in Table II it will be seen that the primiparae and multiparae seem to divide themselves into two groups as in the case of protein and ash, (1) those starting with a percentage of sugar before labour of 2 % and rising during the second week after labour to 6 %; (2) those starting before labour with a percentage of about 3·8 % and rising in the same period after labour to 8 %. The quicker rise to a higher figure after labour is more manifest in the groups starting with higher sugar before labour.

On examining the different classes of fluid, it was found that the percentage of sugar for the very viscid class 3 (20), the opalescent and viscid milky fluid class 2 (43), the watery secretion class 1 (14) gave respectively average values of 2·717, 3·45 and 3·585 g. Although the highest individual value 5·02 % was found among the less viscid type class 2, yet in the case of the watery secretion the values, except in one case, were all well over 3 % and in some cases over 4 %, the lowest being 2·79 %. In the other types of secretion there were many values between 2 and 3 %.

Ash. The antenatal secretion of 50 women has been examined for ash. A sample on more than one day was obtained from 9 women and on one day only from 36 women. Five samples were obtained during labour.

There is no significant difference to be observed between the multiparae and the primiparae.

The ash percentage is consistently high throughout the antenatal period. Out of 74 samples analysed, only in two instances did it fall below 0·3 %. The majority of cases give a percentage between 0·5 and 0·68, except in two samples from one particular patient on two consecutive days when the percentage obtained was 0·8. In the five cases in labour the percentage is over 0·6.

After labour there is a steady decline in the percentage of the ash from over 0·5 % on the 1st day to between 0·2 and 0·3 % after the 1st week.

The specimens from both the primiparae and the multiparae seem to fall into two groups:

(1) Those starting in the antenatal period at 0·5 % and declining gradually to 0·16 % 10 days after labour.

(2) Those starting about 0·68 % and gradually declining in the same period of time to about 0·34 %.

The graphs for ash and protein run almost parallel. The graphs show rather irregular figures before labour, falling gradually but persistently after labour to a more or less constant level.

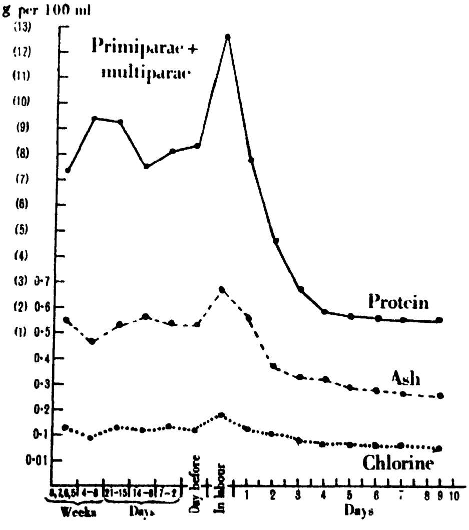

Fig. 2.

As regards the relation of the ash content to the physical properties of the secretion, in the case of cows, Houdet, according to Engel [1911], found that in the viscid secretion there were only traces of salts and in the more fluid about 0·36 %.

In the case of the human secretion, a study of our figures does not seem to show any striking connection between the three classes of fluid and the ash values found. In the very viscid fluids (20) class 3, there was only one example giving a low ash 0·3 %, in the less viscid secretion (46) class 2 and the watery secretion (15) class 1 both high and low values occurred, the high values largely preponderating in both. The averages for the three types respectively were 0·586, 0·518 and 0·49 %. The high or low values do not seem to occur at any definite time during the antenatal period, both high and low values are found at all times from 8 weeks before and up to the day of birth, although at all periods the high values largely predominate.

Calcium. Calcium has been investigated in the antenatal secretion of 49 women, in 36 cases on one day only, 9 on more than one day and 4 in labour, 74 samples in all having been analysed. The results so obtained are compared with those obtained from the secretion during the 10 days immediately after labour, of which 215 examples were examined.

On the whole the percentage of calcium in the antenatal secretion is low, although occasionally a high value is obtained. In the few specimens obtained during labour, the average shows a decrease in the percentage at this time, rising immediately after labour and continuing to rise gradually during the next 10 days.

It has been shown already [Widdows *et al.*, 1930] that the calcium value rises gradually to a maximum during the first 4 months after birth, and then falls very slowly during the 5th to the 7th months, and more rapidly from the 7th to the 10th months.

We have in our earlier work on two occasions [Lowenfeld *et al.* 1927; Widdows *et al.*, 1930] in agreement with other workers [Hunaeus, 1909; Bahrt and Edelstein, 1910] emphasised the fact that the differences between individuals in the calcium content of the milk are much greater than the variations from day to day in any one individual.

This makes the interpretation of results difficult where only a few samples of the secretion can be obtained, and where it is not possible in the same women to obtain samples for the few days consecutively before and after the period in question, as for example, in the cases of samples obtained from women in labour.

From Table IV it will be seen that in the primiparae the average percentage of calcium oxide the day before labour is 0·0366, during labour 0·0305, and on the 2nd day after labour 0·0376. Only three samples were obtained during labour, two from the same woman gave low calcium oxide values of 0·0254 and 0·0264 %, whilst the one from the other gave higher values of 0·0396 %. Four samples were obtained on the day before labour but from different women from those in labour. One gave a high value for the calcium oxide 0·0548 %, higher than the highest value during labour, 0·0396 %, and the others the low values of 0·0272, 0·033 and 0·0311 %. The lowest value before labour, 0·0272 %, is also higher than either of the low values 0·0254 and 0·0264 % during labour.

In the case of the multiparae, where the secretion was examined in the case of only two women during labour, the percentage of calcium oxide in one sample was 0·0258 g., and in the other 0·0234 g. both low values, but in the seven samples the day before birth the highest percentage of calcium oxide in one sample was 0·041 g. and the lowest 0·0224 g. Here also the highest value before labour, 0·041 g., is higher than the highest value during labour, 0·0258 g., on the other hand, the lowest value before labour, 0·0224 g., is lower than that of the lowest value, 0·0234 g., during labour. Again, these values were not those of samples taken from the same women as those whose samples were taken in labour, and the value 0·0224 g. was the only one out of seven lower than the value in labour, 0·0234 g.

In these circumstances, the average values are probably a better criterion of the relative changes occurring throughout the ante- and post-natal periods studied.

From our work on milk in the early and later days of lactation it was realised that some women throughout lactation had consistently a higher calcium value for their milk than others, and it was therefore not surprising to find that this was also the case in the antenatal secretion. For instance, in one case M. where in the antenatal period 10 days before birth four samples were taken, the calcium oxide percentage varied between 0·027 g. and 0·025 g., in the postnatal period the value gradually rose to 0·0388 g., whereas in another case R., where

$\frac{\text{Calcium oxide}}{\text{Phosphorus pentoxide}}$ ratio.

1·4	1·32	1·59	1·45	1·23	1·01	0·99	1·36
(3)	(3)	(13)	(14)	(9)	(10)	(12)	(21)

Average ratio for first 7 days = 1·27.

three samples were obtained, one a month, one 3 weeks and one 4 days before birth, the values were over 0·04 %, and they remained high after birth, rising on the 4th day after labour to 0·048 %.

From these average values, it is concluded (*a*) that the calcium percentage in the secretion before birth rarely rises to much over 0·03, and in many cases is much less, and (*b*) that it is at its lowest value during labour and steadily rises after labour towards its maximum.

There does not appear to be any difference in the calcium values in the cases of the primiparae and the multiparae.

Phosphorus. The antenatal mammary secretions of 27 women were examined for phosphorus, and 34 samples were analysed, of which 23 represented single specimens from 23 different women and 11 were samples from 4 women, one providing 4, one 3, and two 2 samples on different days. 132 samples of milk from the 1st to the 10th day after birth were analysed, and the results compared with those obtained from the antenatal secretion.

The percentage of phosphorus in the secretion is very low throughout the antenatal period studied, but begins to rise immediately after labour. It has been previously shown that the maximum value for the phosphorus pentoxide percentage is not realised till the end of the 4th month after parturition. Before birth, the highest percentage of phosphorus pentoxide, except in one case of a multipara giving 0·029, is only just over 0·02, and in many cases the percentage is much lower.

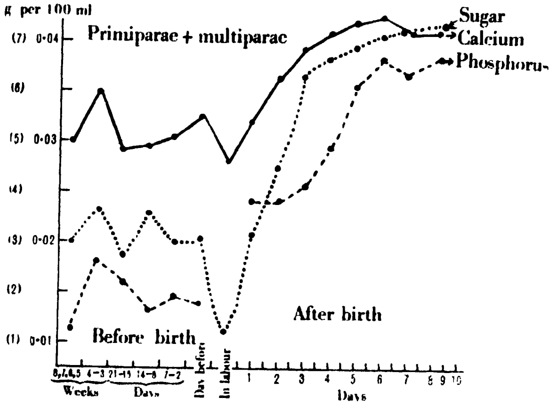

Fig. 3.

Ca/P ratio. On examining the graphs for calcium oxide and phosphorus pentoxide at the different stages both before and after labour, it will be seen that they follow each other very closely, the phosphorus values being at a much lower level before birth than those of the calcium. In the case of the calcium oxide the average percentage before parturition is over 0·03 or approximating to it, the highest value for each period being over 0·04, while, as stated above, in only one case does the value rise to 0·029 in the case of the phosphorus pentoxide. After birth too the average value for the calcium oxide percentage has risen to over 0·04 on the 4th day, while in the case of the phosphorus pentoxide, on the 10th day the value is still lower than that of the calcium.

Schlossmann [1904] thought that a high protein value was associated with a high phosphorus value, but our work does not seem to support this view. Our protein values are highest before and just after birth, while our phosphorus values are low during all these periods.

In our work on later milk it was shown that the percentage of calcium oxide in milk throughout lactation was usually greater than that of phosphorus pentoxide, and that the average ratio of these percentages did not show a great variation. The average ratios during the periods 1–2 weeks, 1 month, 2–4 months and 5–10 months were 1·35, 1·34, 1·42, 1·25 respectively. The individual variations however were shown to be greater, varying from 0·81 to 2. McCollum *et al.* [1921] had pointed out the importance of this ratio, and in our paper [Widdows *et al.*, 1930] this ratio was discussed and an explanation suggested.

In the case of the antenatal secretion this ratio was also examined and as the percentage of phosphorus pentoxide before birth relative to that of calcium oxide was considerably lower than it is after birth, this ratio necessarily has a higher value. The average value for the ratio for the whole period from 8 weeks to the day before birth is 2·46 and for the different periods considered the average ratio varied from 1·5 to 3·21. The average value for the first 7 days after birth is 1·27.

One would expect the ratio of calcium to phosphorus in the antenatal secretion to be different from, and more variable than, that in the milk after birth, partly on account of the fact that the secretion has no practical value as a food for the infant at that time, and also because the proportions of the calcium and the phosphorus present must depend on several factors. These factors are:

(1) The demand of the foetus for these elements at the stage of gestation under consideration.

(2) The necessity of a supply of these elements (which are constituents of normal milk) to the secretion gradually developing to form the fluid which is the perfect food for the newborn infant.

(3) The capacity of the blood supply of the mother to provide all the calcium and phosphorus required both for the foetus and the secretion without drawing unduly on her own reserves.

Since in our work we have only been able to study the composition of the secretion during the last 2 months before parturition, it will here only be possible to consider that period.

Bar [1907] had made an exhaustive study of the nutrition of the foetus during normal pregnancy. In this work he has shown that the need of the foetus for both phosphorus and calcium is usually very small during the first part of gestation but increases enormously during the last 2 months. During this latter period the foetus demands from the maternal organism 0·58 g. of phosphorus in the form of the pentoxide and 0·638 g. of calcium in the form of the oxide per day, while from the 4th to the 6th month only 0·046 g. of phosphorus pentoxide and 0·083 g. of calcium oxide are required per day. There is, therefore, a heavy drain on the mother by the foetus at this period for these two elements, so that the secretion developing to form the normal milk will only, one may suppose, obtain its necessary supply after the needs of the foetus are satisfied.

Both in the case of phosphorus and calcium there is a large retention towards the end of the pregnancy as shown by the decreased urinary output of these elements, although in the case of phosphorus Bar states that the proportion of organic phosphorus in the urine may be very slightly increased.

Since our ratio of calcium oxide to phosphorus pentoxide in the mammary secretion is higher before than it is after parturition, it is probable that there is more calcium relatively to phosphorus available for the secretion from the parent organism before than there is after birth.

Bar points out, from his work on dogs, that during gestation the mother can remove from the food the phosphorus elements necessary for the development of the foetus, and, provided the ration is sufficient, does not draw on her own capital of phosphorus.

He has also shown that phosphorus assimilation follows closely that of nitrogen. At the beginning of gestation there is a retention of both above the needs of the foetus, followed by a period of excretion probably due to the saturation of the organism by these elements. During the last weeks there is a very active retention to meet the heavy demands of the foetus.

In the case of nitrogen, throughout the whole of pregnancy, its assimilation seems to be good so that Bar remarks that in women in good health free to regulate their own diet it is common to observe a retention of nitrogen above that required for the foetus, its appendages, and the development of the uterus and the breasts, and that the nitrogen retained goes to increase the nitrogen capital of the mother. Consequently pregnancy appears to be a period of gain of nitrogen to the maternal organism. This would account for the high nitrogen content of the mammary secretion both before and after parturition which has been emphasised in the preceding pages.

Bar showed also that although the assimilation of phosphorus follows the same course as that of nitrogen, its retention is by no means as good, and that there may be a gain of nitrogen where at the same time there is a loss of phosphorus.

Towards the end of its intra-uterine life, the demand of the foetus for phosphorus is greater than it is for nitrogen, but, in spite of this, in the ration absorbed the proportion of phosphorus may be small—further in the case of women Bar has observed that the utilisation of the absorbed phosphorus ration has been frankly mediocre. This he points out may be due among other things to the phosphorus being present largely in the inorganic form owing to an excess of mineral bases, and thus passing into the state where it is of no value for building up the tissues of the foetus.

It is evident from Bar's work that the parent organism will often have as much as it can do to supply the foetus at the end of gestation with its necessary phosphorus, and that therefore there can only be a small amount available for the mammary secretion that is forming. The fact that the phosphorus percentage in this secretion is low both before and immediately after parturition has perhaps here an explanation, especially as the women whose secretions were examined all came from the poorer classes where the food ration is likely to be poor in phosphorus.

In the case of the calcium Bar has shown that four-fifths of the calcium which the foetus contains at full term is acquired during the last 2 months of gestation. During the early part of pregnancy he has also shown that there is mobilisation of calcium, though this is not required by the foetus at that time. This is eliminated largely by the faeces and the urine, but at the end of gestation, when the needs of the foetus become intense, this elimination suddenly diminishes.

It appears from Bar's work that there is always calcium available during pregnancy, more than sufficient for the needs of the foetus, some always being derived from the maternal organism. It is therefore not surprising that the antenatal mammary secretion, as we have found, contains a larger percentage of calcium relative to that of the phosphorus than is found in the milk secreted normally after birth.

From a study of the calcium in blood of pregnant women, it has been shown by de Wesselow [1922] and Widdows [1923] that, in spite of the heavy demands made by the foetus during the last 2 months before birth, the blood tends to maintain a fairly constant value for calcium oxide, tending to decrease during the 8th and 9th months and to rise again immediately after parturition. Among other workers, Bar [1907] and Lamers [1912] found the blood calcium higher in pregnant than in non-pregnant women, Kehrer [1920] found it definitely low in pregnant women, and Jansen [1918, 1, 2] found it little altered. The above discrepancies may be in part accounted for by the fact that de Wesselow and Widdows analysed the serum and the other workers the whole blood.

In the case of the whole blood the calcium is not distributed evenly between the plasma and the corpuscles and so, unless the proportion of the corpuscles to plasma is ascertained, the true value for the calcium is not obtained. De Wesselow [1922] found also that in the case of phosphorus there was a tendency for its value to fall during the last 2 months of gestation, rising after parturition and during lactation to a figure definitely above that of the non-lactating female.

These facts bear out and we think explain the reasons for the calcium value of the antenatal mammary secretion being high relatively to the phosphorus before parturition.

Chlorine. No record has been given in any previous papers of our results on the percentage of chlorine either in early or late milk, although estimations have been made during these periods.

The method of estimation for the chlorine was that of Patterson [1928]. Our results on the whole agree with those of Sissons and Denis [1921] who have made a fairly comprehensive study of this element in postnatal milk. Our average for 80 samples taken from different women at all stages of lactation from 2 weeks to 42 weeks after birth is 32·1 mg. per 100 ml. of milk. The average given by Sissons and Denis is 38·1. These investigators found that in normal women after the 1st week of lactation there was a relatively narrow range of variation from 30 to 50 mg. of chlorine per 100 ml. of milk. We have found that the range in our cases was from 20 to 50 mg., that 25 % of our cases varied from 30 to 50 mg. and 48·75 % from 20 to 30 mg. Out of the 80 samples analysed we had only 10 over 50 mg. per ml. Sissons and Denis found that specimens of milk in which the chlorine concentration was over 50 mg. per ml. were from mothers who were giving an inadequate amount of milk for the growth of the infant. Our 10 cases where the percentage of chlorine was over 50 mg. per 100 ml. and not exceeding 58 mg. do not seem to support this contention, as in all cases, except one, the supply of milk was plentiful and the child was doing well. this one case, as well as in one additional case where the content of chlorine was 72 mg. per 100 ml., it is true the supply of milk was scanty, but as, in both cases, artificial feeding had been adopted and the child was doing well, it is not possible to say whether these cases support the findings of Sissons and Denis.

It may be that where the milk is insufficient for the nourishment of the child the chlorine percentage may be high, but it does not seem that a content of chlorine over 50 mg. per 100 ml. is necessarily accompanied by a scanty supply of milk and an ill-nourished child.

We found, as did Sissons and Denis, extreme variations in the chlorine contents of specimens of milk collected from women in the same period of lactation. In the 4th week of lactation there was a variation from 23·9 mg. per 100 ml. to 52·2 mg. per 100 ml. and specimens with high and low contents were found to occur at all stages of lactation. In one case, a 4-week specimen gave 23·9 mg. per 100 ml. chlorine, and in another 52·2 mg. per 100 ml., while two 19-week specimens gave respectively 29·7 mg. and 42·2 mg. per 100 ml. It was noticed that only during the last weeks of lactation, with one exception, did the value even fall below 20 mg. per 100 ml.

There is a tendency for a high concentration of chlorine during the 1st week after birth. Sissons and Denis found that it varied from 158 mg. to 42 mg. per 100 ml. Our average variation, examined between the 1st and 7th days after parturition, was from 118 mg. to 51 mg. per 100 ml. for 243 specimens, and the average value for the 8th, 9th and 10th days from 69 samples was 43·6 mg. per 100 ml. Our percentages during this period varied from 233 mg. to 20 mg., one sample giving a value of 16·9 mg.

Sixty-three samples of antenatal secretion have been investigated for their chlorine contents. The percentage of chlorine is strikingly higher throughout the whole antenatal period examined, and seems to run parallel with that of the protein and ash.

The average given by the 63 samples is 118 mg. per 100 ml., the same as the average value found for the 1st day after labour. The range of values is from 276 mg. to 45 mg. per 100 ml. In the whole 63 samples there are only three, including one of a primipara in the 3rd to 4th week before birth giving 23·6 mg., which give a value for chlorine less than 50 mg. per 100 ml., and 57 % of the samples analysed gave over 100 mg. per 100 ml. Since the value for the percentage of chlorine is high immediately after birth, it was to be expected from analogy with the protein and ash values that the chlorine value before birth would also be high, and, as shown, this expectation was realised since both the average and individual values in the antenatal secretion are considerably above those found in the early postnatal milk.

Three specimens from women in labour were investigated and show a much higher chlorine value than the average for the day before or the day after birth. In the case of the primipara the value 200 mg. per 100 ml. in labour is above the values for all the three samples taken the day previous to birth, and in the case of the two multiparae the higher value is above the values for all the seven samples taken the day before birth, while the lower one is higher than five, equal to one and lower than one. The women giving the samples in labour are none of them women from whom samples had been obtained the day before birth.

The same extreme variations were noticed in the chlorine content of specimens of the antenatal secretion collected from different women at the same period of lactation as had already been noted in the cases during later lactation. There seems no significant difference between the results obtained from primiparae and multiparae.

The values for the chlorine in the antenatal period, as already noticed, are always high, but the highest values do not necessarily correspond to the highest ash values.

The curve for chlorine follows that of the protein and the ash, but a study of the figures for chlorine does not show any striking relationship between the viscosity of the secretion and the chlorine value. Both high and low values occur in all three classes of the secretion. Where, however, several samples of the secretion from the same woman were taken at different stages during the antenatal period, it was noticed that, if the ash value varied, the increase or decrease coincided with a corresponding variation in the chlorine value. In one case, for instance, where the value of the ash rose from 0·44 to 0·52 %, the chlorine value rose from 45 mg. to 48 mg. per 100 ml.

The average values for the very viscid (21) class 3, the less viscid (40) class 2, and the watery (14) class 1 secretions are respectively 0·106, 0·1158 and 0·1307 g. per 100 ml., the watery secretion showing the highest average. It has not been possible so far to estimate the alkali metals and magnesium, and it may be that the chlorine percentages are related to these elements.

SUMMARY.

1. A total of 78 specimens from 53 women of the antenatal secretion for periods from 2 months before parturition up to the time of labour and in labour were analysed. The constituents studied were protein, sugar, ash, calcium, phosphorus and chlorine.

2. The results have been compared with work on postnatal milk during the first 10 days after labour and also with similar work on cows.

3. In all cases results suggested from our previous work as to the probable composition of the antenatal secretion have been obtained, suggestions have been made to account for certain experimental facts, but there are points for which at present no explanation can be offered.

4. A comparison of the relative proportions of the main ingredients of the fluid secreted by the mammary gland before and after parturition shows that a true difference in secretory activity is involved and not merely a difference in concentration.

5. A study of the physical properties of the antenatal secretions shows them to fall into three classes: (1) a beige watery fluid, (2) an opalescent more viscid fluid and (3) a very viscid cream to bright yellow fluid. All three forms were found during the last 2 months of pregnancy and could not be correlated either with absence or presence of previous lactation or, as in the case of cows, with the period of pregnancy.

6. In all cases the protein value for the antenatal secretion is higher than for that obtained after labour, and these values tend to fall into two groups with a mean value of 7 %.

The protein values of the secretion for the first few days of lactation are higher in the primiparae than in the multiparae. There appears to be a definite relationship between the viscosity of the secretion and the percentage of contained protein.

7. In the case of the sugar low values are obtained before labour, the mean value lying between 2·5 and 3·9 %.

In sugar content, as with protein, the samples tend to fall into two groups, 2 % rising to 6 % and 3·8 % rising to 8 %.

A definite relation exists between the viscosity of the secretion and the sugar percentage.

8. The percentage of ash in the antenatal secretion is always high, and in the five cases examined in labour the percentage was over 6 %. As in the case of protein irregular figures are shown before labour, falling steadily and persistently after labour to a more or less constant level.

9. In the case of calcium, while the fact that very considerable differences exist between the averages for individual women obscures the interpretation of the figures, yet from the average values the conclusion may be drawn that the percentage of calcium oxide is lowest during labour, rarely rising above 0·03 before labour, and steadily rising to a maximum after labour.

10. The phosphorus percentages in the antenatal period are very low, the highest percentage (P_2O_5) being only just over 0·028. The curves for phosphorus follow very closely those for calcium.

The calcium/phosphorus ratio before parturition is higher than that obtained after parturition. This is consistent with the work of Bar on the needs of the developing foetus for this element.

11. The percentage of chlorine is consistently very strikingly higher in the antenatal than in the postnatal period. There appears to be no clear relationship between the viscosity of the fluid and the percentage of chlorine present.

The curves run parallel for chlorine, protein, and ash.

In conclusion we have to express our thanks to Dr Harding and Sister Griffin at the St Pancras Hospital and Dr Macgregor at the Shoreditch Carnegie Welfare Settlement for facilities for obtaining the material for the above investigation. We wish to thank Prof. Winifred Cullis for valuable criticism and advice, and the Medical Research Council and the Waller Research Fund for grants towards the expenses of the work.

CXLV. IRRADIATION OF FATS.

I. A STANDARDISED METHOD OF USE OF ULTRA-VIOLET LIGHT.

By LESLIE HERBERT LAMPITT, NORMAN DARBY SYLVESTER AND PHILIP BILHAM.

(*From the Lyons Laboratories.*)

(*Received March 14th, 1935.*)

During the last few years an increasing amount of work on oxidative changes in fats has been recorded, and one of the causative factors of this type of change, namely light, has received some attention. Unfortunately however very little effort has been made to study the activity of light from a quantitative standpoint. Two examples only are of sufficient importance to be noted.

Rogers and Taylor [1926] investigated the effect of light on the oxidation of linseed oil under various conditions, using a quartz mercury lamp as the source of illumination. Their statements with regard to the light energy absorbed are however based on calculations and not on direct measurements.

Read and Bailey [1933] examined the effect of ultraviolet light from a quartz mercury lamp on the development of rancidity in crackers and in shortening fats. The incident energy was measured by means of a fluorescent photometer, but no attempt was made to obtain an accurate estimate of the total light energy. Quantitative estimates of the oxidative changes were not made.

Investigations of such actions, in order to be of definite use, necessitate standard methods of evaluating the changes by chemical tests, correlation of the results obtained with observations of taste and smell if desired and a defined technique whereby figures representative of the energy of the light acting on the sample under examination can be obtained.

The work described herein deals with one of these requisites, namely the standardisation of the method of irradiation, and certain results of experiments on butter fat are recorded as examples of the applicability of the method.

Obviously it is of importance to differentiate between the total light and that which is absorbed, but no work has yet been carried out by the present authors to attempt to indicate their respective values. A complete standardisation of the conditions would involve the measurement of intensity at all wave-lengths emanating from the source of irradiation. It was found however when the absorption spectrum of butter fat in ether was determined spectroscopically (Plate III, fig. 1) that no selective absorption could be observed except that in the region 5000–4300 Å., which is due to the pigment of the butter fat, whilst the absorption spectrum (Plate III, fig. 2) of an ethereal solution of butter fat which had been irradiated until colourless showed the absence of the above band. There was however in both cases general absorption throughout the ultra-violet region of the spectrum, and it seems unnecessary therefore to exclude any wavelengths emitted by the arc in the measurement of the light intensity incident on the fat.

The statement by Gortner [1929] and attributed by him to Holm (no other reference has been found) that the greatest effect occurs when the light has a wave-length of approximately 3600 Å., is not upheld by these absorption spectra, since there is no predominating absorption at this wave-length.

It appeared therefore that the control of the total light energy of the source of irradiation was sufficient for the purposes of the present investigation.

The possibility of the occurrence of changes in distribution of the light energy emitted from an ageing lamp was not investigated, in view of the definite statement by Coblentz *et al.* [1926] that such changes do not occur. In the present experiments lamps have been used which have previously been burned for about 100 hours. It will be seen that the method of irradiation described makes allowance for any small changes which may occur in the quantity of light emitted from the lamp.

EXPERIMENTAL.

(*a*) *Electrical equipment.*

After several abortive attempts to obtain standard and reproducible experimental conditions, the lay-out of apparatus shown in Fig. 1 was finally evolved.

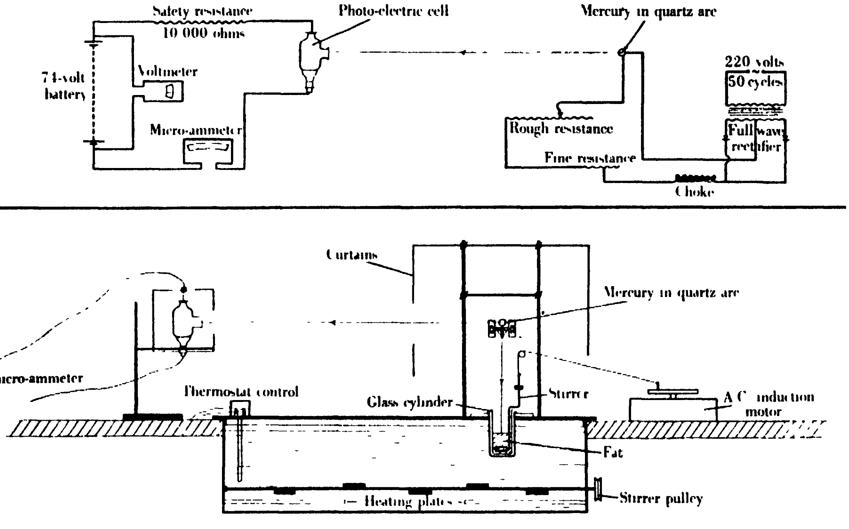

Fig. 1.

The fat to be irradiated was contained in a cylindrical glass vessel which fitted into a metal holder, supported from the cover of a thermostatically controlled water-bath. The mercury quartz arc lamp (Kelvin, Bottomley and Baird) was clamped in a fixed position, the centre of the arc being vertically above the tube containing the fat.

A measure of the light intensity of the lamp was obtained by means of a photo-electric cell (U.N.G. 7 type G.E.C.) having an activated sodium cathode in a glass bulb with a quartz window. A constant potential of 74 v. was applied to the cell from accumulators[1], and the photo-current was measured by means of a micro-ammeter.

The current for the lamp was supplied by a rectifier from the A.C. mains. Two variable resistances were placed in series with the lamp, and the major

---

[1] In earlier experiments the cell potential was applied from the A.C. mains through a rectifier; difficulties due to fluctuation of the mains potential however made this method impracticable.

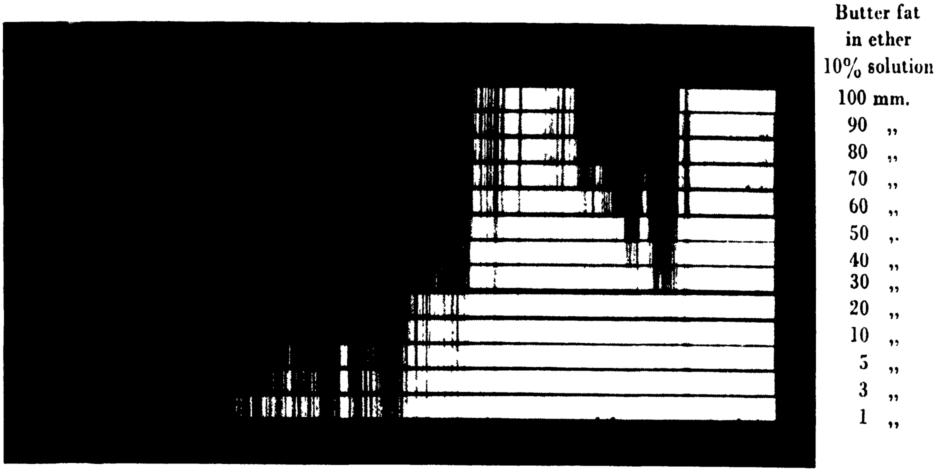

Fig. 1. Absorption spectrum of fresh butter fat in ether.

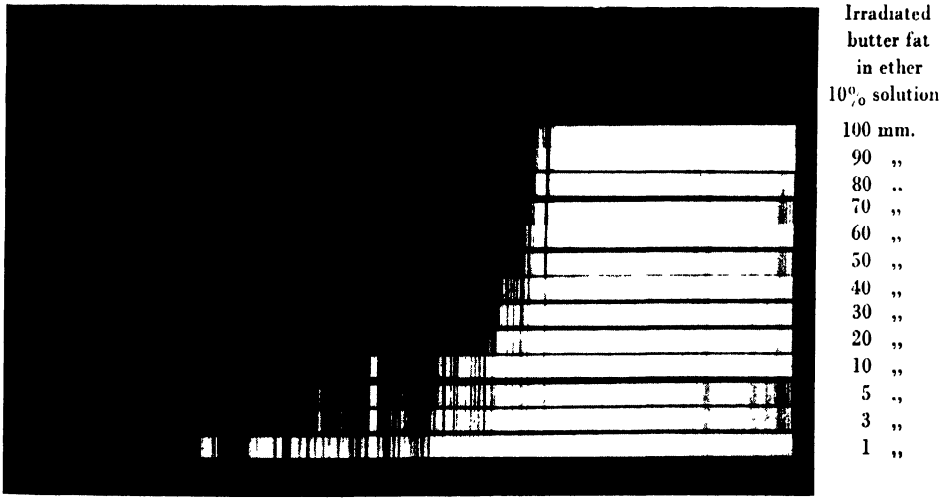

Fig 2. Absorption spectrum of irradiated butter fat in ether.

alterations in intensity were effected by means of the "rough" resistance, the light from the lamp being approximately adjusted to any required intensity (as indicated by the micro-ammeter reading), accurate adjustments being made with the "fine" resistance.

During the progress of irradiation it was necessary to make periodic adjustments to the fine resistance in order to restore the micro-ammeter reading to the required magnitude. These corrections were necessitated by fluctuations in the A.C. voltage, and they were required at all times of the day and night. Fortunately the major fluctuations occurred at fairly definite times and could be anticipated.

The fat was stirred with an up-and-down motion by means of a glass rod stirrer, shown in Fig. 2, which was designed so that the obstruction of the light would be at a minimum. The stirrer was guided by movement through a vertical glass tube, and was actuated by an A.C. induction motor, the speed of which varied between 63 and 68 revolutions per minute.

Irradiation experiments could then be carried out at any fixed light intensity which was indicated by the micro-ammeter reading, and the effect of slight variations in the A.C. supply, as well as that due to ageing of the lamp, were corrected by periodic adjustments to the resistance.

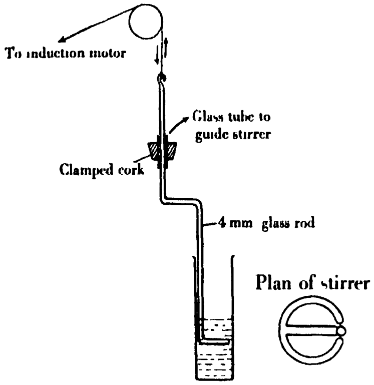

Fig. 2. Glass stirrer used in irradiation apparatus.

(b) Measurement of the light intensity in absolute units.

In order that the micro-ammeter readings obtained with the cell in the remote position might be related to the actual light energy falling on the surface of the fat, it was necessary to determine a conversion factor. The cell responded only to a limited wave-band and therefore the standardisation of the cell against a standard of radiation was made through the medium of a thermopile.

Calibration of the thermopile. The thermopile was used, without its collecting funnel, in conjunction with a micro-ammeter. The calibration of this combination was made with a carbon lamp, standardised by the National Physical Laboratory and used, under the conditions specified in their certificate, as the source of radiation. The response obtained was 0·155 micro-amp. for an incident radiation of $5{\cdot}864 \times 10^3$ ergs per second per cm.^{2} A reading of 1·0 micro-amp. would therefore be equivalent to $3{\cdot}78 \times 10^4$ ergs per second per cm.^{2} radiation on the surface of the thermopile.

This figure was roughly checked by the use of a Leslie cube. The intensity of the radiation R on a spherical wave front from the black face of the cube is given by the formula:

$$R = \frac{\sigma (T^4 - t^4) \times E \times A}{2\pi r^2} \text{ ergs per second per cm.}^2,$$

where σ = Stefan's constant $= 5{\cdot}72 \times 10^{-5}$,
T = temperature of cube = 95°,
t = temperature of air = 19·5°,
E = efficiency of radiation from cube = 0·9 [Poynting and Thomson, 1919],
A = area of black face = 20·5 cm. × 20·5 cm.,
r = radius of spherical wave front = 50 cm.

When the values were as stated above the response given by the thermopile was 0·34 micro-amp. It may be calculated from these figures that the incident radiation for a response of 1·0 micro-amp. would have been 4·45 × 10^4 ergs per second per cm.^{2}

This figure is subject to some inaccuracy, due to departure from the inverse square law, owing to the extended surface of the source as compared with its distance from the thermopile. It served as a check on the first figure which has been used in all subsequent calculations.

The conversion factor can be determined in two ways:

1. *The standardisation of the cell against the calibrated thermopile and the measurement of the ratio of the micro-ammeter reading to a hypothetical reading which would be obtained if the cell occupied the position of the irradiated fat.*

The comparison of the responses of the calibrated thermopile and the cell to the light of the arc was carried out by rapidly substituting one instrument for the other when the arc was burning steadily, the surface of the thermopile occupying the same position as the outer surface of the quartz window of the cell. The responses obtained were 3·04 micro-amps. and 1·01 micro-amps. for cell and thermopile respectively and therefore the radiation from the arc which would give a reading of 1·0 micro-amp. when incident on the window of the cell would be 1·25 × 10^4 ergs per second per cm.^{2}

The ratio of the actual to the hypothetical micro-ammeter readings was determined by direct experiment. When the outer surface of the cell window occupied the same position as the fat surface, the light was so intense that the cell would have given a current far in excess of its normal working range and not proportional to the light intensity. To avoid this error the incident light was reduced by a non-selective filter consisting of a tube on each end of which was tightly stretched and soldered fine mesh wire gauze. Two such filters were used having transmissions of 6·25 and 12·2 %, which factors, combined with the responses, gave values of 8·0 and 7·65 for the ratio. The mean value of 7·8 has been taken.

Using the figures obtained in the above experiments, it is possible to calculate the energy per second incident on the fat surface of area 9·2 cm.^{2} when a reading of 1·0 micro-amp. is given by the cell in the remote position. The result is *0·090 ×* 10^7 *ergs per second.*

2. *The measurement of the energy at the fat surface with the calibrated thermopile and the correlation of this with the response of the cell in the remote position.*

When the cell in the remote position was giving a response of 3·9 micro-amps., the thermopile was placed so that its surface occupied the same plane as that normally occupied by the fat and gave a response of 8·6 micro-amps. The light energy per second incident on the surface of the fat when the cell is giving a reading of 1·0 micro-amp. in the remote position can be calculated from the previous calibration of the thermopile. The result is *0·077 ×* 10^7 *ergs per second.*

Since neither method can be considered the more accurate, the mean of the two results, *viz. 0·084 ×* 10^7 *ergs per second,* has been used for calculating the total incident light energy in the irradiation experiments to be described.

(c) *Standard procedure.*

The following are the summarised conditions of standard experiments:

Distance, centre of arc to surface of fat	25·5 cm.
Area of fat surface exposed	9·2 cm.^{2}
Weight of fat	50 g.
Depth of fat	6·0 cm.
Distance of photo-electric cell from arc	91·5 cm.

Under these conditions the effects of the irradiation of the butter fat were reproducible, and the chemical determinations satisfactory, even when duplicate experiments were carried out after an interval of as much as 14 days.

Results obtained using the standard irradiation apparatus.

The experiments, the results of which are given in subsequent tables, were carried out on pure butter fat, prepared from best quality Australian unsalted butter. The fat was separated after melting the butter at a low temperature, filtered twice through filter-paper and stored in vacuum jars in the dark.

A point of interest is concerned with the amount of fat taken. Since the extent of oxidation of the fat is not proportional to the time of irradiation, it follows that if, for example, 25 g. of butter fat were taken, the oxidation would not be twice that observed in the normal experiment using 50 g. of fat. It was decided however to carry out experiments in which the weight of fat was reduced to 25 g., the period of irradiation being also reduced to one-half. The other experimental conditions such as area of fat exposed, distance from the lamp, temperature and intensity of the incident light were the same for both experiments.

The results obtained are given in Table I.

Table I.

Time of irradiation	15 hours	30 hours
Weight of fat	25 g.	50 g.
Issoglio value	41·3	41·4

The above results were confirmed by duplicate experiments. It appears that the oxidative changes in the fat are not appreciably affected by a variation in the amount of fat taken, provided that the time of irradiation is proportionately altered. It is obvious that the depth of the fat is an important factor, and that the above conclusion will not be true when the depth of the fat is so decreased that an appreciable proportion of the active light is transmitted by the fat without exercising any photochemical effect.

Irradiations were made under various conditions of time, temperature and light intensity. The other experimental conditions were those which have already been described.

Table II. *Effect of light intensity.*

Time of irradiation constant at 20 hours. Temperature 40°.

Micro-ammeter reading	—	1·5	2·0	3·0	3·5	4·0
Watt-secs.	Nil	9,000	12,000	18,000	21,000	24,000
Peroxide value	1·3	3·8 3·7	4·3	6·2 5·8	8·6	12·5 13·9
Issoglio value	2·1	1·95 2·05	6·0	13·3 12·1	15·6	20·7 19·6
Kreis test	Neg.	4 4	10	35	70	100 100

Table III. *Effect of time.*

Light intensity constant at 2·75 watts per cm.^{2} (micro-ammeter reading 3·0). Temperature 40°.

Irradiation time	Nil	10 hrs.	20 hrs.	30 hrs.	40 hrs.	50 hrs.	70 hrs.
Watt-secs.	Nil	9,000	18,000	27,000	36,000	45,000	63,000
Peroxide value	0·8	3·5 3·1	5·2 4·9	32·0 26·5	45·5 47·5	68	120
Issoglio value	1·9	2·7 2·4	10·2 10·5	32·0 31·0	—	—	116
Kreis test	Neg.	5 5	18 20	200 200	650	1300	2650

Table IV. *Effect of time.*

Light intensity constant at 2·75 watts per cm.^{2} (micro-ammeter reading 3·0).
Temperature 60°.

Irradiation time	Nil	10 hrs.	20 hrs.	25 hrs.	30 hrs.	40 hrs.	50 hrs.
Watt-secs.	Nil	9000	18,000	22,500	27,000	36,000	45,000
Peroxide value	0·8	2·4	8·0 8·6	23·5 23·0	39·0 46·5	78	117
Issoglio value	1·9	3·4	19·0 19·8	30·0 30·5	47·0 46·0	83	—
Kreis test	Neg.	4	50 50	170	650	2000	4000

In the above tables where two sets of figures occur in one column, they represent the results of duplicate irradiations carried out in some cases after an interval of 2 weeks. The duplication of the results is seen to be satisfactory.

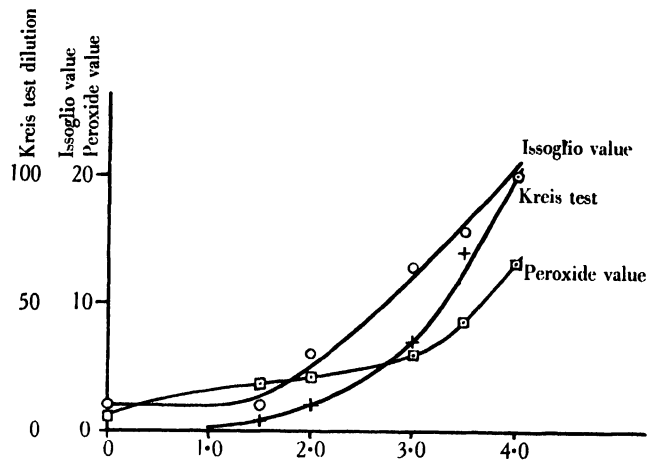

Fig. 3. Effect of light intensity.

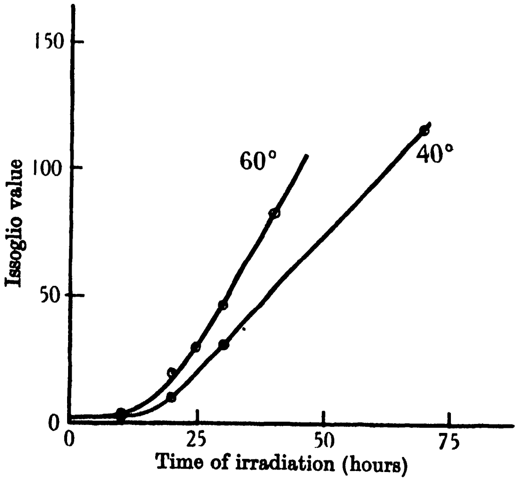

Fig. 4. Effect of time and temperature on Issoglio value.

Peroxide values, and Issoglio values are both expressed as mg. O_2 per 100 g. fat, and the Kreis test is expressed as the first dilution (in light petroleum) at which a positive test is not obtained. The methods of analysis will form the subject of a separate paper.

The results are shown graphically in Figs. 3, 4, 5 and 6.

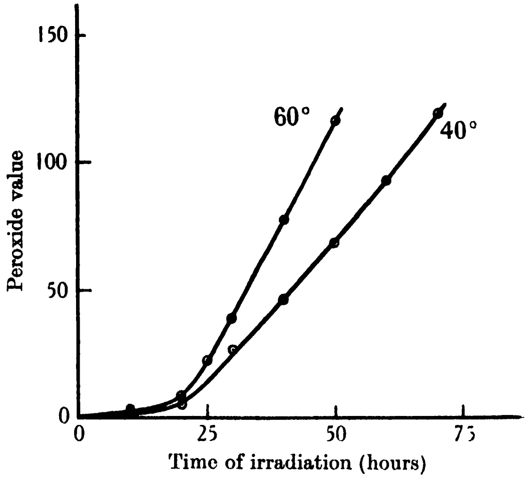

Fig. 5. Effect of time and temperature on peroxide value.

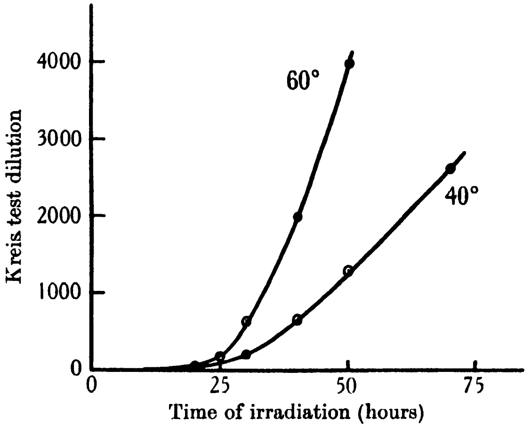

Fig. 6. Effect of time and temperature on Kreis test.

Discussion.

The utility of such an apparatus as has been described is obviously not restricted to the type of experiment described in this paper, and this method of irradiation has, for example, been used by the authors in an investigation on the development of tallowiness in milk. Moreover, it could be applied to determinations of the induction period of a fat with a view to assessing its potential keeping properties, and such factors as the addition of pro- and anti-oxidants, variations in methods of fat processing *etc.* could be examined with regard to their effects on the susceptibility of the fat to oxidative deterioration. Such determinations can be made with the certainty that the experimental conditions can be reproduced and the results confirmed.

The results which have been given on the irradiation of butter fat have been included principally to illustrate the utility of the technique which has been described, and they are not presented as a definite contribution to the subject of oxidative changes in fats.

A consideration of the figures will show, however, that although the three determinations increase concurrently, and in a similar manner, there is not a strict parallelism between any two of them.

The effect of temperature is clearly demonstrated and has an effect on the magnitude of all the determinations. It is seen further that any relationship which might exist, say, between the Kreis test and the Issoglio value is changed by temperature. Lea [1931] has made a similar observation with regard to the Kreis test and peroxide value and the present results afford confirmation of his assertion.

SUMMARY.

1. An irradiation technique has been worked out suitable for experiments on oils and other liquids, such that good reproducibility of results can be obtained.
2. A method has been indicated whereby measurements made in a position other than that of the sample have been correlated with the intensity, in absolute units, of the light incident on the fat.
3. Butter fat has been irradiated under standardised and reproducible conditions. The oxidative changes have been measured by chemical tests, and an approximate determination of the incident light energy has been made.

The authors wish to thank Messrs J. Lyons and Co., Ltd., in whose laboratories this work was conducted, for permission to publish this paper.

CXLVI. THE BEHAVIOUR OF PATHOLOGICAL SERA IN THE ULTRACENTRIFUGE.

By ARTHUR SPROUL McFARLANE[1].

From the Institute of Physical Chemistry, Upsala, Sweden.

(*Received April 1st, 1935.*)

In a previous paper [McFarlane, 1935, 1] we have described the results of the examination of horse serum albumin and globulin in the ultracentrifuge, both separately and in the form of mixtures of the two. It was shown that these two proteins behave ideally in dilute mixtures of the two, but in concentrated mixtures their general behaviour is abnormal. In particular, each molecular fraction is present in abnormal concentration, there being always more of the lighter ("albumin") fraction present than corresponds to the albumin added and correspondingly less of the heavier ("globulin") fraction. It is believed that there exists in mixtures of serum albumin and globulin a form of molecular dimensional equilibrium the exact nature of which has still to be discovered. In the course of this work a modified optical system for the ultracentrifuge has been developed which enables protein solutions as highly concentrated as untreated serum to be examined.

In a second paper [McFarlane, 1935, 2] we have described the application of this system in the analysis of the serum proteins of the normal cow, horse and man. Since it is clearly a matter of great interest to know the molecular dimensional distribution of the protein in untreated serum it was our aim to examine these sera as far as possible without dilution. In the case of human serum, however, it is necessary to dilute slightly in order to avoid a form of distortion in the photographs, the nature and cause of which is discussed. It has been shown that this slight dilution of a normal human serum does not affect the results, whereas dilution of all sera with more than 2–3 vols. of 1 % sodium chloride causes an alteration in the concentration of the fractions which is in exact agreement with the facts relating to artificial mixtures of albumin and globulin. We have found that the sera of all three species are constituted in a similar manner of three molecular fractions, two of which correspond approximately in sedimentation constants (with due allowance for the effect of protein concentration) to purified horse serum albumin and globulin. The chemical nature of the third fraction, of molecular weight slightly greater than albumin, is obscure and it is not proved that the substance is capable of an independent existence. It appears from the examination of sera from a series of normal healthy persons of various ages and of both sexes that the concentration ratios of the three fractions vary only within narrow limits in the presence of large variations in the concentration of total protein. The concentration of the globulin fraction in the series is (10 ± 5) % of the total protein.

In the present paper there are presented in detail the results of the examination of a series of pathological sera, chosen more or less at random, and obtained mostly from the general hospital in Upsala[1]. We wish to emphasise the general nature of the investigation. There has been repeatedly in the course of these experiments a strong temptation to interrupt the series in order to pursue in greater detail the investigation of one or two particularly interesting sera. We resisted this because it was believed that a more useful purpose could be served at the moment by collecting a series of results which would give an impression—however superficial—of the field as a whole. This is our justification for omitting to proceed with several more detailed investigations which logical consideration will at once suggest to the reader might have been done on certain sera. We need hardly say that it is planned to investigate many of these individual problems in the immediate future.

---

[1] Beit Memorial Research Fellow.

In the two previous papers [1935, 1, 2] there will be found a complete description of the general technique employed in this work. We will only draw attention here to one important fact, *viz.* that all calculations of protein concentration are based on the apparent baseline of the sedimentation diagram. As a result the only method of detecting the presence of any polydisperse, and presumably denatured, protein is by comparing the protein refraction increment of the serum, as measured with the refractometer, with the total refraction increment from the area of the sedimentation curve. We have, therefore, in most cases, dialysed a portion of the serum at constant volume against 1 % sodium chloride and measured the refractive indices of solution and dialysate using the difference prism of the Pulfrich refractometer and the sodium D line. In certain cases of nephritis the serum was characteristically turbid owing to suspended lipoid matter and considerable difficulty was experienced in detecting any transmitted beam in the refractometer. Centrifuging for an hour or more at 3000 r.p.m. in a standard laboratory centrifuge failed to produce any detectable reduction in the degree of turbidity. The effect of this turbidity in the centrifuge-cell as seen from the camera is to give rise to a green coloration due to the selective scattering of the lower wave-lengths in the mercury spectrum. It is interesting to record in these cases that as the ultracentrifuge accelerated a band of clear serum appeared at the bottom of the cell and the green coloration invariably disappeared into the region of the meniscus within 10–15 minutes from starting, and before the rotor had attained a speed of 25,000 r.p.m.

The conditions of the various experiments have been made more comparable by employing as far as possible centrifuge-cells 2·0 mm. in thickness and by using centrifugal forces uniformly in the region of 250,000 times gravity.

Each experiment is recorded under the initials of the donor of the serum and the clinical diagnosis of the condition. In the form of an appendix there is given a series of notes on each case, those features in the history being stressed which might have a connection with the state of the serum proteins.

In accordance with previous practice we shall refer to the fractions in a serum as A and G which correspond in sedimentation constants to purified horse serum albumin and globulin, and to other fractions as X, Y, Z, in order of increasing sedimentation constant.

In order to determine whether two fractions correspond in sedimentation constants it is necessary to take into consideration the concentration in which the fractions are present. This should be possible in the case of the lightest fractions with considerable accuracy since the boundary is sedimenting in a medium which is free of other proteins. In the case of the heavier fractions however, this is not so, and it is not possible with the data at present available to effect more than an approximate comparison of the sedimentation constants of corresponding *X* or *G* fractions. In order to facilitate the identification of *A* fractions we have constructed the graph in Fig. 1 by plotting the values already found for the *A* boundary sedimentation constants of normal human sera, and shown in Table XVII of a previous paper [1935, 2], against the refraction increments $(n_1 - n_0)$ of the same fractions. We shall have occasion to refer to it in the description of the following experiments.

---

[1] I am greatly indebted for facilities to obtain pathological sera to Profs. G. Bergmark, G. Nyström, and Axel Westman of Kungl. Akademiska Sjukhuset, and to Dr O. Bratt of Epidemisjukhuset, Upsala.

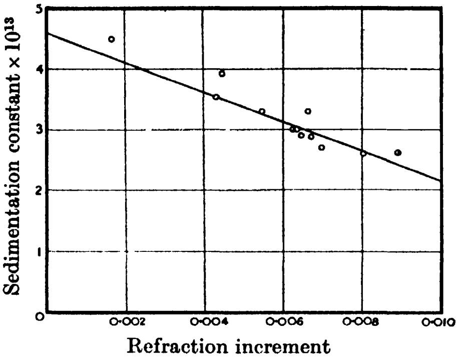

Fig. 1. Showing the relationship between the refraction increments and sedimentation constants of the *A* fractions of normal human sera. Data taken from Table XVII of earlier paper [1935, 2].

In the preceding paper [1935, 2] we have calculated the concentrations of the protein fractions in g./100 ml. from the specific refraction increment (α) values of the albumins and globulins described in the literature. In this work we shall calculate only the total protein concentrations using the values α (total horse serum) = 0·00184, and α (total human serum) = 0·00202, both for the sodium *D* line.

Before describing the experiments with pathological human sera there will be given some results obtained with two samples of antidiphtheritic horse serum kindly supplied by Messrs Burroughs and Wellcome, Beckenham, Kent.

Exp. 1. Antidiphtheritic horse serum.

Serum 1, containing 200 units of antitoxin, was examined undiluted in a cell 2·00 mm. in thickness, and excellent scale photographs were obtained with the scale 1·0 cm. from the centre of the cell. When allowance is made for the refractive index of the quartz cell plate this distance corresponds to an optical distance of 0·78 cm. The experimental conditions and results are shown in Table I, and Fig. 2 *a* shows the curve of an exposure taken 83 minutes after reaching full speed. The distance separating the two boundaries is small, but owing to the small amount of boundary spreading in this concentrated mixture, it is sufficient to give a symmetrical graphical delineation of both boundary curves. The sedimentation constant of the *G* fraction is unusually low. Owing to the high concentration of this fraction, however, and to the fact that the *G* molecules are sedimenting in a dense and viscous medium of *A* molecules, the effect of which is not taken into account in the $S_{W,20}$ figure, the value of the constant is not inconsistent with the fraction having a molecular weight the same as that of horse serum globulin. We can find no evidence of an X fraction such as is present in normal horse serum, but this may be present in low concentration and not detectable because of the overlapping of the two boundaries.

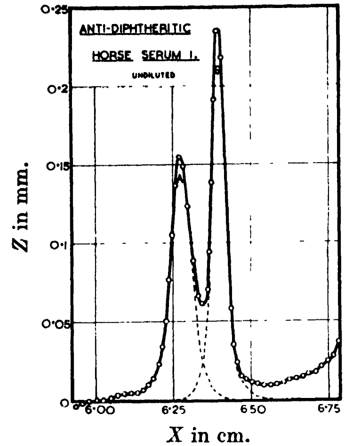

Fig. 2a

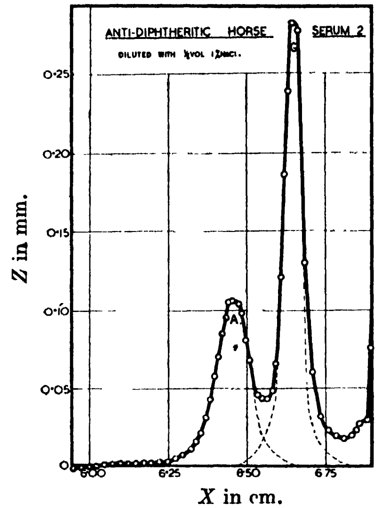

Fig. 2b.

Table I. *Results obtained in the examination of two antidiphtheritic horse sera.*

		Serum 1. Undiluted	Serum 2. Undiluted	Serum 2. Diluted with ½ vol. 1 % NaCl
Cell thickness (mm.)		2·00	1·50	2·00
Optical scale distance (cm.)		0·78	1·12	1·69
Temperature inside cell at time of first exposure		36·3°	33·9°	33·4°
Temperature inside cell at time of last exposure		38·6°	36·1°	35·0°
Approximate duration of run (hours)		2½	2½	2
Mean centrifugal force used (times gravity)		245,000	255,000	250,000
Total $n_1 - n_0$, by refractometric measurement on the serum and its dialysate; $\lambda = 589\ m\mu$		0·0204	0·0177	0·0118
Corresponding total protein concentration (g./100 ml.)		11·1	9·62	6·41
Total $n_1 - n_0$, corrected to $\lambda = 366\ m\mu$		0·0220	0·0191	0·0127
Average $S_{W,20} \cdot 10^{13}$	A fraction	2·97	3·00	3·86
	G fraction	3·71	3·86	5·11
Average $n_1 - n_0$, calculated from sedimentation diagram, $\lambda = 366\ m\mu$	A fraction	0·0102	0·0090	0·0052
	G fraction	0·0109	0·0089	0·0073
	Total	0·0211	0·0179	0·0125
Difference between measured and calculated total $n_1 - n_0$ expressed as a percentage of the former		-4 %	-6 %	-2 %
Proportion of total calculated $n_1 - n_0$ due to G fraction		52 %	50 %	58 %
Spreading coefficient of A boundary (cm.²/sec. × 10⁷)		0·4	0·3	3·8

From our experiences with normal sera we are of opinion that only very small amounts of X fraction, if any, can be present. The value of the spreading coefficient of the A boundary is in favour of this fraction being homogeneous.

Serum 2, containing 1200 units of antitoxin, was also examined without treatment of any kind and gave rise to sedimentation diagrams very similar to those of serum 1. The results of this experiment are shown in Table I and it will be seen that they are generally similar to the results of the previous experiment. In particular, it is noteworthy that there is no increase in the proportion of *G* fraction which might correspond to the increased antitoxic value of serum 2. We have also examined the same serum after slight dilution with 1 % sodium chloride. Fig. 2 *b* shows the curve of an exposure from this experiment taken 81 minutes after reaching full speed. It will be seen from this and from the results in Table I that there has occurred a considerable increase in the concentration of the *G* fraction, and a proportionate decrease in that of the *A* fraction. The extent of separation of the two boundaries has not been greatly affected by the dilution although the sedimentation constants of both the *A* and *G* fractions are quite markedly increased. There is also a substantial increase in the degree of spreading at the *A* boundary.

In all three experiments there is very close agreement between the measured and calculated total protein refraction increment values. This is probably accidental since with very short scale distances the experimental error is increased considerably.

Exp. 2. Serum from A.J. (ovarian carcinoma).

This serum from an advanced case of malignancy was examined first without any treatment and then after dilution. Large quantities of pleural exudate were also available which resembled the serum closely in colour and general appearance. A sample of this was examined also without treatment of any kind. The results of all three experiments are collected in Table II, and Fig. 3 *a* shows the curve of an exposure in the first experiment taken 112½ minutes after reaching full speed. Comparison of this curve with that on Fig. 14 of the previous paper [1935, 2] showing a typical normal human serum, shows that gross changes have taken place.

In this malignant serum three fractions are present which we have labelled *A*, *G* and *X*. The sedimentation constant of the lightest fraction, *viz.* 2·32, is considerably lower than the corresponding value for the *A* fraction of a normal human serum obtained from Fig. 1, *viz.* 3·4. The difference between these values is much greater than could be explained by any experimental error. The value for the *A* fraction in Table II is indeed lower than any value for an *A* fraction recorded in Table XVII of the previous paper irrespective of concentration. The evidence that we are dealing with a substance of lower molecular weight than serum albumin seems therefore to be quite definite. It is to be noted however from Table II that the sedimentation constants of the *X* and *G* fractions in this serum are unusually low, and also that the sedimentation constants of the three fractions bear approximately the same ratios to each other as do those of the *A*, *G* and *X* fractions in normal human sera. These facts suggest either that all the fractions have abnormally low molecular weights or else that some common factor is acting on normal *A*, *G* and *X* fractions to make them sediment abnormally slowly.

There is no evidence in the large number of experiments carried out by Svedberg and collaborators on purified proteins of the existence of any such obscure influence. We have noted, however, that in their experiments a better degree of agreement is to be found between the values for the sedimentation constant of a particular protein than we have obtained between values for the *A* fraction of normal human sera (*cf.* Fig. 1). In whole serum it is possible that some factor, perhaps electrochemical in nature, or some substance, possibly lipoid, by influencing the molecular shape or charge, or the viscosity at the surface of the particles, may cause a change in the sedimentation constant without altering the molecular weight. These possibilities cannot be excluded so long as we are examining a solution of relatively undefined composition. So long as they exist an element of doubt attaches to our method of identifying the serum fractions, particularly in cases where all the fractions have abnormal sedimentation constants. It cannot therefore be said without further investigation whether any or all of the fractions in the serum of A.J. differ in molecular weight from the *A*, *G* and *X* fractions of normal sera. As a matter of convenience we have labelled these fractions meantime as *A*, *G* and *X*.

The proportions of both *X* and *G* fractions in this serum are abnormally high. This is perhaps best brought out by comparing the average proportion of *A* fractions in normal human serum, 66 %, with the proportion in this case,

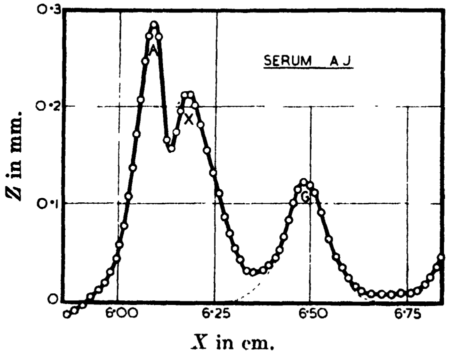

Fig. 3*a*.

Spreading coefficient of *A* boundary (cm.²/sec. 10⁷)		—	21·3	16·1

42·5 %. It is not possible to effect a symmetrical graphical separation of the overlapping *A* and *X* curves in this serum for reasons discussed in the previous paper, so that the *A* and *X* concentration values given are not exact. The combined $A+X$ value is exact, and in our graphical estimation of the *A* and *X* concentrations in the present case we have given the benefit of the doubt to the *A* fraction. The value for the *A* fraction can therefore be regarded as an upper limit to the true value. Similarly, the true *X* value is not less than the one given. Also, owing to the extent of overlapping of the *A* and *X* boundaries we cannot estimate the spreading coefficient of the *A* boundary.

In the second experiment the serum was diluted with 4 volumes of 1 % sodium chloride. The sedimentation rates of both boundaries are markedly increased. The degree of *A* boundary spreading is also much increased and definite signs of a separation of the lighter fraction into *A* and *X* fractions cannot consequently be seen. The curves of the more slowly sedimenting boundary are however all unsymmetrical in a manner suggesting the presence of two fractions in concentrations not differing greatly from each other. The heterogeneity of the fraction is confirmed by the general dimensions of the curve and the extremely high value of the spreading coefficient, *viz.* 21×10^{-7} cm.^{2}/sec. In Table IV of a previous paper [1935, 1, p. 423] we have shown the spreading coefficient values for a boundary of recrystallised horse serum albumin (sedimenting under standardised centrifuge conditions) plotted against the protein refraction increment of the solution. From this curve we find that a sedimenting protein boundary, assumed to be homogeneous, of the same protein concentration as the *A* boundary in this experiment has a spreading coefficient of approximately $6{\cdot}0 \times 10^{-7}$ cm.^{2}/sec.

Table II also shows that there has been a definite increase in the proportion of the total protein refractivity due to the *G* fraction on diluting the serum.

In the third experiment we examined the untreated pleural exudate. Fig 3 *b* shows the curve of an exposure taken 83 minutes after reaching full speed. The results of this experiment are also shown in Table II. It happened that the total protein concentration in the pleural exudate was almost an exact mean between the corresponding values in the two preceding experiments. Table II shows that the sedimentation constants of the two fractions in the pleural exudate are also roughly a mean between the values in the former experiments. From this we deduce that the protein fractions in the pleural exudate have approximately the same mean molecular dimensions as the corresponding protein fractions in the serum.

From Fig. 3 *b* it will be seen that the *A* curve does not show any obvious signs of dividing into two components, but it does not have the perfect symmetry which has characterised the homogeneous proteins in our earlier experiments [1935, 1]. Once again, the view that we are concerned with a mixed fraction, the heterogeneous nature of which is obscured by the increased spreading of the boundaries, is confirmed by the general dimensions of the curve and by the high value of the spreading coefficient, *viz.* 16×10^{-7} cm.^{2}/sec. The value for a purified albumin boundary of corresponding protein concentration is $1{\cdot}6 \times 10^{-7}$ cm.^{2}/sec. The proportion of *G* fraction in the pleural exudate is in agreement with the other results and all conform with the view that the fluid is a passive transudate of whole serum which has undergone simple dilution in passing from the blood into the pleural cavity.

Exp. 3. Oxalate plasma from K.H.B. (acute phthisis).

In this case we obtained oxalate plasma and no preliminary dialysis was carried out. The plasma did not keep well over the period of the experiments but gave rise to a small deposit of fibrin. The amount of protein thus removed from the solution was not sufficient to affect materially the results obtained. In the first experiment we examined the undiluted plasma and obtained curves showing marked distortion of the A and X curves. The G curve was symmetrical, however, and from the area of this curve we find:

Calculated $n_1 - n_0$ of G fraction in undiluted plasma $= 0{\cdot}00318$.

The plasma was then examined after dilution with one-third its volume of 1 % sodium chloride. Fig. 4 *a* shows the curve of an exposure taken 98½ minutes after reaching full speed, and the general results of the experiment are recorded in Table III.

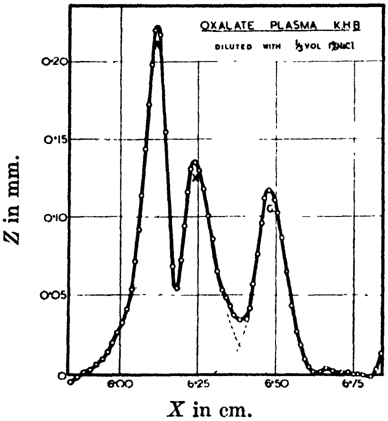

Fig. 4*a*.

Proportion of total $n_1 - n_0$ due to X fraction		30 %	—	—

A comparison of the curve with that of Fig. 3 *a* shows a close general similarity to exist between the two. The sedimentation constant of the lightest fraction, 2·79, is considerably lower than the value 3·5 for a normal *A* fraction in corresponding concentration (*cf.* Fig. 1). As in the previous experiment however the $S_{W,20}$ values for all the fractions are unusually low and bear approximately the same ratios to each other as do the values for the fractions of normal sera. We conclude that this plasma also represents a case in which it cannot be said without further investigation whether the fractions are identical with the fractions of normal sera.

The calculated value of $n_1 - n_0$ for the *G* fraction is interesting. If this value is corrected for the dilution we find:

Calculated $n_1 - n_0$ of *G* fraction in original plasma based on proportion found after dilution ... ... 0·00432

We conclude that unlike the state of affairs in a normal human serum the effect of even slight dilution of a pathological serum is to produce a change in the concentration ratio of the fractions which is apparent as an increase in the absolute concentration of the *G* fraction. We have studied the effect of dilution further in this case by examining the plasma after dilution with an equal volume, and with twice its volume, of 1 % sodium chloride. The results of these experiments are collected in Table III and call for little comment. It is apparent that the proportion of the *G* fraction increases steadily on dilution. We cannot say whether there is at the same time any change in the ratio of the *A* and *X* fractions because the two do not separate sufficiently in the more dilute solutions. Fig. 4 *b* shows the curve of an exposure taken 97½ minutes after reaching full speed in the experiment with plasma diluted with an equal volume of 1 % sodium chloride. The dual nature of the lighter boundary is rather obvious but we cannot resolve the curve graphically. In the final experiment the *A* curve has only one peak but it is unsymmetrical, with a squat appearance (*i.e.* a high ratio of breadth at the base to height) and an abnormally high spreading coefficient, *viz.* 9×10^{-7} cm.^{2}/sec.

Exp. 4. Sera from B.I.L. and J.O.D. (scarlatina).

The object of this experiment was to examine the serum protein changes associated with the development of immunity. Sera from two patients in the early stages of scarlet fever were obtained and examined in the centrifuge. It was planned to obtain serum again from both patients in the later stages of the disease but owing to unforeseen circumstances this was only possible in one of the cases. This particular case (B.I.L.) was a child of four years and the first specimen of serum had a rather low total protein concentration. This fact induced us to examine the serum in the untreated state and curves were obtained which showed only slight distortion of the *A* and *X* curves. Fig. 5 *a* shows one of these curves obtained from a photograph taken 73 minutes after reaching full speed and the results are shown in Table IV.

The serum from the second case had a normal protein concentration and was therefore examined after slight dilution with 1 % sodium chloride. The results are also shown in Table IV. The sedimentation constant of the *A* fraction in the case of B.I.L.'s serum, 2·28, is again lower than the corresponding value for a normal *A* fraction obtained from Fig. 1, 2·9. Unlike the results in the earlier experiments the $S_{W,20}$ value for the *G* fraction in this case does not appear to be abnormally low. It is possible in this serum that the fraction we have labelled *X* is really an *A* fraction and that our *A* fraction is a new molecular type of lower molecular weight than serum albumin. The evidence however is inconclusive. The fractions of J.O.D.'s serum correspond satisfactorily in sedimentation constants with the fractions of normal human sera. The proportions of G fraction in both sera fall within the limits of the formula (10 ± 5) % which we have found to hold for normal sera.

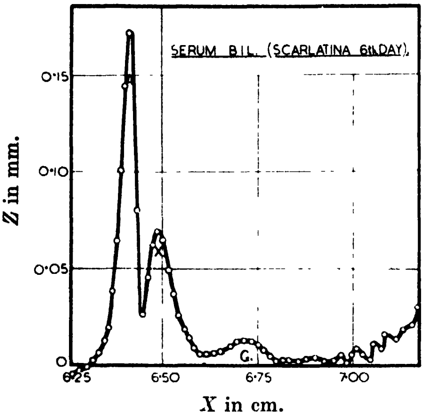

Fig. 5a.

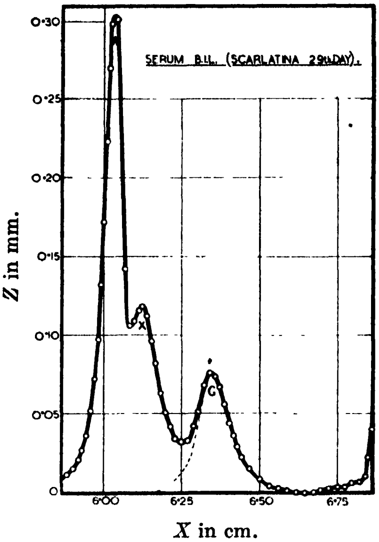

Fig. 5b.

Table IV. *Results obtained in the investigation of sera from two cases of scarlatina.*

	Serum B.I.L. (6th day of disease). Undiluted	Serum B.I.L. (29th day of disease). Diluted 5 to 2 vols. 1 % NaCl	Serum J.O.D. (8th day of disease). Diluted 5 to 2 vols. 1 % NaCl

G fraction	0·00102	0·0026	0·0014
X fraction	0·0046	0·0021	0·0024
Total	0·0126	0·0107	0·0105
Calculated total $n_1 - n_0$ of original serum	0·0126	0·0150	0·0147
Proportion of total $n_1 - n_0$ due to G fraction	8·1 %	24 %	13 %
Proportion of total $n_1 - n_0$ due to X fraction	36·5 %	19·5 %	23 %
Spreading coefficient of A boundary (cm.²/sec. 10⁷)	0·4	1·6	0·3

The serum of J.O.D. was dialysed at constant volume and the total protein refraction increment from refractometric measurements on serum and dialysate was found to be 0·0157 ($\lambda = 589\,m\mu$), giving 0·0169 ($\lambda = 366\,m\mu$). The percentage discrepancy between measured and calculated $n_1 - n_0$ is therefore in this experiment − 13 %.

When the undiluted serum from B.I.L. was examined 23 days later we obtained curves showing marked distortion at the A and X boundaries. These curves however showed symmetrical *G* boundary curves which gave the following value:

Calculated $n_1 - n_0$ of *G* fraction in undiluted serum (B.I.L.) ... ... 0·00336

The serum was re-examined after diluting 5 vols. of serum with 2 vols. of 1 % sodium chloride. Fig. 5 *b* shows the curve from an exposure taken 86½ minutes after reaching full speed and the general results are shown in Table IV. The distortion of the *A* and *X* boundaries has disappeared and there is obviously an increased proportion of *G* fraction present. In the period of 23 days during which immunity to scarlatina developed the total serum protein concentration has increased by 19 % of its original value.

The proportion of *G* fraction in the undiluted serum is $\frac{0{\cdot}00336 \times 100}{0{\cdot}0150} = 22{\cdot}4\ \%$.

The effect of slight dilution on the proportion of *G* fraction is not therefore very significant in this case. The large increase in the proportion of *G* fraction—from 8·1 to 22·4 %—would appear to be associated with the development of immunity to the disease.

Exp. 5. Serum from A.B. (myeloma).

This patient first came to our notice some months before the scale projection system for examining undiluted sera had been worked out. The patient's urine contained typical Bence Jones protein and we attempted an ultracentrifugal analysis of the serum in the hope of finding some evidence of the presence in it of a substance of lower molecular weight than albumin. An investigation of the urinary protein is reported in a subsequent paper. For the serum investigation we had no choice at the time but to dilute the serum, and a dilution of 2 vols. of serum with 3 vols. of Ringer's solution was found satisfactory. The curves show no evidence of the presence of an unusual molecule, but the proportion of *G* fraction is high, even for a diluted serum. The patient was lost sight of for eight months when she returned to hospital with a spontaneous fracture of the femur and obviously in the terminal stages of the disease. During this interval there had been continuous excretion of Bence Jones protein in the

urine. We were able to obtain another specimen of serum and this was examined by the scale projection method after diluting 5 vols. of the serum with 2 vols. of 1 % sodium chloride. The diagrams again show no signs of a new molecule, the $S_{W,20}$ values for the fractions corresponding well with the values for the fractions of normal sera. The results of the two experiments are shown in Table V. The lower proportion of *G* fraction in the second experiment is probably due in part to the higher total protein concentration in which the serum was examined. In both experiments the degree of spreading at the *A* boundary appears to be unusually high. This feature will be discussed more fully later.

Exp. 6. Serum from G.L.E. (myeloma).

The results of this experiment form an interesting comparison with those of the previous one. Almost at the same time as we obtained the first specimen of serum from A.B. another clinically characteristic case of myeloma (ordinarily a comparatively rare disease) was discovered, but this case had very little protein in the urine and that present did not give the characteristic reactions of Bence Jones protein. We found the total protein concentration of the serum to be unusually high (10·9 g./100 ml.) and could only obtain satisfactory sedimentation diagrams at the time by diluting the serum with twice its volume of Ringer solution. The disease terminated fatally shortly afterwards and the *post mortem* examination confirmed the diagnosis of myeloma. The presence of Bence Jones protein in the urine however was never definitely established. We preserved a specimen of the serum in the refrigerator for some months until it was possible to undertake an examination with the scale projection system. It was then found that dilution with at least an equal volume of 1 % sodium chloride was still required to avoid completely distortion of the *A* and *X* curves.

We show in Table VI the results of the two experiments. Fig. 6 *a* shows the curve of an exposure taken 43½ minutes after reaching full speed in the experiment with the serum diluted with an equal volume of 1 % sodium chloride, and Fig. 6 *b* is from an exposure taken 26½ minutes later in the same experiment. The results show that there are present four molecular fractions in the serum, two of which correspond in sedimentation constants to the *A* and *G* fractions of normal sera. The heaviest fraction, which we have labelled *Z*, is not of much significance since it represents a very small proportion of the total protein. The remaining fraction, which we have called *Y*, is of great interest since it is clearly quite different from the *X* fraction of normal sera and of the pathological sera already described. The sedimentation constant is much higher than that of any *X* fraction in comparable circumstances which we have found and is also unusual in lying nearer to the value for the *G* fraction in the same experiment. This is also seen in Figs. 6 *a* and 6 *b* in which the separation of the *A* and *Y* peaks is greater than of the *Y* and *G* peaks and also greater than that of the *A* and *X* peaks in any of the curves previously obtained.. It is also interesting to note that the *A* curve is quite symmetrical, indicating the absence of any *X* fraction. We regard this experiment as definite evidence, to be supported by data from later experiments, that there may exist in pathological sera fractions of molecular weight not ordinarily present in normal sera.

Increasing the dilution of the serum from 1 : 1 to 1 : 2 appears to have little, if any, effect on the proportion of the *G* fraction. It appears, however, that the *Y* and *A* fractions exist in a form of concentration equilibrium just as we have shown the *G* and *A* fractions to exist in normal sera. It is not possible to examine the serum satisfactorily at a greater dilution than 1 : 2 because it will be appreciated that with three major diffusion boundaries to be accommodated in a short depth of centrifuge-cell marked overlapping must occur between them. At dilutions greater than 1 : 2 this overlapping makes graphical resolution of the component curves impossible.

Exp. 7. Sera from K.M., C.P. and J.A.F. (malignant disease).

Although we have classed these three sera together under the heading of malignant disease the clinical conditions of the patients from whom they were obtained differed considerably. The first patient (K.M.) was in an extreme state of jaundice due to obstruction of the bile duct, and the serum was highly coloured with bile pigment. The second (C.P.) was emaciated and had an advanced ulcerative condition in the rectum. The third patient had a tumour in the epigastrium, but the liver was not palpable, and the general condition was not so advanced as in the other two. Further clinical details of these cases will be found in the appendix.

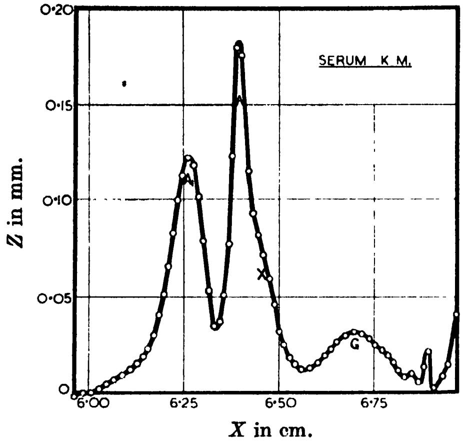

Fig. 7*a*.

Boundary spreading coefficient of lightest fraction (cm.²/sec. × 10^7)		4·3	3·5	0·7

All three sera were diluted slightly with 1 % sodium chloride before examination in the centrifuge. The results are collected in Table VII. Fig. 7 *a* shows the curve of an exposure taken 79 minutes after reaching full speed in the first experiment (K.M.), and the curve of Fig. 7 *b* is from an exposure taken 81 minutes after reaching full speed in the second experiment (C.P.). If we consider first the results for sera C.P. and J.A.F. it will be seen that both contain three molecular fractions which correspond in sedimentation constants with the *A*, *G* and *X* fractions of normal sera. The proportion of *G* fraction in the case of J.A.F. is just above our limit for a normal serum, and in the case of C.P. there is definitely an abnormally high proportion of this fraction. The other results call for no comment.

In the serum of K.M. there are present four definite molecular types. The lightest and heaviest fractions separate well and give rise to symmetrical curves. The two intermediate fractions do not separate completely, resembling the *A* and *X* fractions of normal sera in this respect. Also, if the curve of the lightest fraction is temporarily disregarded the diagram which remains resembles very closely the diagram which we have obtained with some diluted normal sera, with the exception that the proportion of *G* fraction is greater than usual.

The $S_{W,20}$ value for the lightest fraction (which we have called A_1), 2·57, is much lower than the value for a normal *A* fraction in corresponding concentration, 3·9 (*cf.* Fig. 1). It is not possible to compare the $S_{W,20}$ value for the *A* fraction in Table VII with the value for a normal *A* fraction in corresponding concentration because the *A* protein is sedimenting in a medium of A_1 molecules. The effect of the A_1 molecules will be to reduce the sedimentation velocity of the *A* molecules. The $S_{W,20}$ value for a normal *A* fraction in a concentration equal to the sum of the *A* and A_1 fractions in this serum is 3·3 (*cf.* Fig. 1). Earlier results obtained for albumin and globulin mixtures [1935, 1] show that globulin sediments more slowly in pure solution than in a solution of the same total protein concentration but containing quantities of albumin. The value of 3·42 for the *A* fraction of this serum therefore appears to be in keeping with the view that the fraction is a normal *A* fraction sedimenting in the presence of lighter A_1 molecules. The $S_{W,20}$ values for the *X* and *G* fractions also support the view that the serum of K.M. has the qualitative constitution of a normal serum with the addition of a new molecular species sedimenting more slowly than the others. The spreading coefficient of the A_1 boundary, $4{\cdot}3 \times 10^{-7}$ cm.^{2}/sec., is consistent with the view that the fraction represents a homogeneous protein of lower molecular weight than serum albumin.

Exp. 8. Sera from G.N. and K.L. (pneumonia).

In this experiment also we are comparing the sera from patients showing marked differences in their clinical conditions. The first (G.N.) was a young man who showed all the signs of a fulminating type of pneumonia and died shortly after the serum was taken. The *post mortem* examination revealed septic infarcts in both lungs secondary to thrombo-phlebitis of the iliac vein. The other (K.L.) was from a woman of 78 years with a long history of pulmonary trouble, who was dying from croupous pneumonia with empyema.

The serum from G.N. was first dialysed at constant volume and the value of $n_1 - n_0$ obtained from refractometric measurements.

Total $n_1 - n_0$ of undiluted serum (G.N.), by refractometer ($\lambda = 589\,m\mu$) ...	0·0122
Total $n_1 - n_0$ of undiluted serum corrected to $\lambda = 366\,m\mu$	0·0132
Corresponding total protein concentration	6·04 g./100 ml.

Owing to the low concentration of total protein the serum was centrifuged without dilution. The results are shown in Table VIII and Fig. 8 shows the curve of an exposure taken 96 minutes after reaching full speed. It will be seen that three fractions are present, each of the two heavier fractions in greater concentration than the lightest one. This very severe alteration in the composition of the normal serum must have taken place inside three weeks, between the onset of the disease and the taking of the blood and was probably produced in a much shorter time.

A consideration of the $S_{W,20}$ values for the fractions shows that these are all unusually low but bear approximately the same ratio to each other as do the corresponding values for normal serum protein fractions. Once again we cannot be certain whether the fractions in this serum have abnormal molecular weights

or whether a common influence is causing normal *A*, *G* and *X* fractions to sediment unusually slowly. The discrepancy ("% difference") between measured and calculated total $n_1 - n_0$ in this experiment is $-9{\cdot}1$ %.

The serum of K.L. was first examined undiluted and the curves showed distortion at the *A* and *X* boundaries. The serum was then diluted with one-third its volume and with an equal volume of 1 % sodium chloride, and the results of the two experiments are reported in Table VIII. No curves are reproduced since these show no significant points of difference from the curves of a normal serum. The results in Table VIII show that the *A* fraction of this serum sediments rather more slowly than a normal *A* fraction, while the *G* and *X* fractions correspond approximately in $S_{W,20}$ values with the *G* and *X* fractions of normal sera. It is interesting to find that the serum changes should be so small in this case of low-grade pulmonary and pleural infection, while on the other hand in the acute and rapidly fatal septic pneumonia the changes should be so radical.

Exp. 9. Sera from A.K. and E.K.L. (phthisis).

Both sera in this experiment were from elderly men with histories of pulmonary tuberculosis. A.K. was probably in a more advanced stage of the disease than E.K.L. and had been treated by induced pneumothorax. The results in Table IX show that both sera have approximately the same qualitative protein constitution as normal sera, but contain an abnormally high proportion of *G* fraction. This is especially marked in the case of A.K. A curve from this serum is shown in Fig. 9. It is from an exposure taken 85 minutes after reaching full speed. Many observers [quoted by Sato, 1933] have found a high proportion of globulin in the serum in tuberculosis using precipitation methods of analysis.

Spreading coefficient of *A* boundary (cm.²/sec. × 10^7)		1·7	0·4

Exp. 10. Sera from P.P. and M.L. (nephritis).

Both the patients P.P. and M.L. had histories of chronic albuminuria. In the case of M.L. the undiluted serum gave distorted *A* and *X* curves. From the area of the symmetrical *G* curve we obtain the values

$n_1 - n_0$ of *G* fraction in undiluted serum (M.L.)	0·00094
Proportion of total $n_1 - n_0$ due to *G* fraction in undiluted serum	7·1 %

The sera were then examined after dilution with sodium chloride and the results are shown in Table X. No curves are reproduced since they show no unusual features. From Table X it will be seen that the $S_{W,20}$ value for the *A* fraction of P.P.'s serum, 2·98, is lower than the value for a normal *A* fraction in corresponding concentration, 3·5 (*cf.* Fig. 1). The other fractions of both sera appear to correspond in sedimentation constants to the fractions of normal sera. Serum M.L. appears to be normal in every respect. In serum P.P. the proportion of *G* fraction is higher than we have found in any normal sera. The other features are normal.

Exp. 11. Sera from K.A.B. (congenital syphilis), H.A.A. (metastatic tumour of bone), and A.S.L. (pneumonia).

These sera are grouped together arbitrarily. The patients had no symptoms in common with exception that both H.A.A. and A.S.L. were excreting protein in the urine. The results for the serum of K.A.B. show that fractions corresponding in sedimentation constants to the *A*, *G* and *X* fractions of normal sera are present, but the proportion of *G* fraction is abnormally high. The results for the sera from H.A.A. and A.S.L. show an unusual feature. The curve in Fig. 10 *a* was obtained from an exposure in the first experiment (H.A.A.) taken 93½ minutes after reaching full speed, and that in Fig. 10 *b* is from an exposure in the second experiment (A.S.L.) taken 76½ minutes after reaching full speed. In Fig. 10 *a* the

This suggestion is confirmed by the unusually high value of the boundary spreading coefficient, $5{\cdot}03 \times 10^{-7}$ cm.^{2}/sec. We cannot resolve the combined curves graphically. For this reason the $n_1 - n_0$ value given for the A fraction in Table XI represents the value for the combined A and X fractions. A similar phenomenon appears in the serum of A.S.L. The curve (Fig. 10 *b*) is practically symmetrical and no evidence of an X peak is seen. On the other hand the general dimensions of the curve are not in keeping with a homogeneous boundary of the same protein concentration but closely resemble those for a strongly diluted human serum [*cf.* 1935, 2, Fig. 16]. The boundary spreading coefficient is again high. The impression which we have from this curve is that A and X fractions are present in the serum in concentrations which do not differ greatly from each other. We may also note the abnormally high proportion of G fraction in H.A.A.'s serum.

Exp. 12. Sera from K.J.K. (chronic nephritis) and L.E. (albuminuria of pregnancy).

The patient K.J.K. had been passing large amounts of protein in the urine for at least a year. In the patient L.E. proteinuria commenced suddenly about a month before parturition, when twins were born. During this period excessive amounts of protein were passed in the urine. Both specimens of serum were turbid in appearance and behaved in the centrifuge cell as we have described earlier in this paper for sera containing quantities of suspended lipoids. An examination of the urinary proteins will be described in a subsequent paper.

Fig. 11 *a* shows the curve of an exposure taken 65 minutes after reaching full speed in the experiment with serum, slightly diluted, from K.J.K. The complete absence of any signs of an X fraction and the marked dissymmetry of the A curve are to be noted. It occurred to us at this point that some of the unusual features of this serum might be due to the presence of quantities of urea or other waste substances in the serum. We therefore dialysed the serum (with slight incidental dilution) against changes of 1 % sodium chloride until equilibrium was obtained and re-examined the diluted serum in the centrifuge. The results of both experiments are shown in Table XII and demonstrate that no significant change has resulted from the dialysis. The general shapes of the curves for the dialysed serum are the same as those for the undialysed serum. If urea, or other dialysable substances, in serum have any effect on the serum proteins we conclude that this is irreversible.

Fig. 11 *b* shows the curve from a photograph taken 61 minutes after reaching full speed in the experiment on the serum of L.E. Once again, there are no obvious signs of an X fraction, but the general dimensions of the A curve resemble those of the boundary curve of a homogeneous protein in considerably more dilute solution. The boundary spreading coefficients in all three experiments (*cf.* Table XII) are much higher than correspond with the concentrations of the protein fractions. The large percentage discrepancies between measured and calculated total protein refraction increments also support the view that significant amounts of grossly polydisperse protein are present in both sera. It is to be noted however that the refractometric measurements of $n_1 - n_0$ include the refraction effects of the suspended lipoids which are not included in the values of $n_1 - n_0$ obtained from the centrifugal diagrams. This may introduce a significant error. The above facts, in conjunction with the dissymmetry of the A curve in Fig. 11 *a*, suggest that at least for the serum of K.J.K. the most probable explanation of the absence of any X fraction is the one suggested above—that all or a large part of the protein in the lighter fraction is polydisperse.

DISCUSSION.

The more important results from the foregoing experiments are collected together in Table XIII. In a comparison of these results with the results characteristic of normal human sera the following points from the data in Table XVII of the previous paper [1935, 2] are important:

Maximum proportion of *G* fraction recorded in a normal serum (total $n_1 - n_0$ of sera greater than 0·00600) = 13 %.

Maximum spreading coefficient recorded for the *A* boundary of a normal serum ($n_1 - n_0$ of *A* fractions greater than 0·00500) = $1 \cdot 9 . 10^{-7}$ cm.^{2}/sec.

Table XIII. *Collected results for pathological human sera.*

* Combined values for A and X fractions. † Value for lightest (A_1) fraction.

There is also shown in Table XIII for each serum the value for the sedimentation constant of a normal A fraction of the same concentration as the A fraction in the serum (*cf.* Fig. 1). It will be seen that the agreement between the $S_{W,20}$ values for normal and pathological A fractions is good in some cases and very poor in others. The agreement is particularly bad in the cases of A.J., B.I.L., K.M. (A_1 fraction) and G.N. In one of these sera (K.M.) the evidence for the presence of a new molecular fraction is conclusive since four fractions are present altogether. In the other three it is possible that the fractions which we have labelled A are really of lower molecular weight than the A fractions of normal sera. It is to be noted that in these three cases also we have found abnormally high proportions of X fraction. It is possible in these cases that the fractions which we have labelled X are really A fractions and the fractions labelled A are substances of lower molecular weight. It is seen in Table XIII that the general agreement of the $S_{W,20}$ values for the lightest fractions among themselves is not as good as the agreement in the case of the A fractions of normal sera. The latter in turn do not agree to within the full experimental accuracy of the method. These facts suggest that in pathological sera, and to a lesser extent in normal sera, a variable factor of which we have no precise knowledge influences the sedimentation of the proteins. This factor does not affect the sedimentation of purified proteins in solutions of defined inorganic composition. Alternatively, there may exist in normal and pathological sera a great many A, X and G fractions of different molecular weights. To decide between these views it is necessary to carry out further investigations of the effect of the physical and chemical conditions which hold in normal and pathological sera on the sedimentation constants of the fractions. We have obtained however in the results for two sera (G.L.E. and K.M.) conclusive evidence that fractions of molecular weight not ordinarily found in normal sera may be present in pathological sera.

When we consider the concentration relationships of the fractions in pathological sera it is seen in Table XIII that with the exception of the early scarlatinal sera and those from M.L. (nephritis) and A.S.L. (pneumonia) all the sera have higher proportions of G fraction than normal. On the one hand this is not surprising in view of the severity of most of the conditions; on the other, it is interesting to find these increased proportions of G fractions in diseases such as malignancy to which immunity is not ordinarily developed. It does not seem possible to associate the increased proportions of the G fractions with a purely protective mechanism. The increases occur in a wide variety of conditions. There seems to be nothing specific therefore about the occurrence of a high proportion of G fraction in pathological sera. Various observers have come to the same conclusion with regard to the proportion of globulin in pathological sera as estimated by precipitation with neutral salts (see reviews by Peters and Van Slyke [1931] and Boyland [1932].

In the various experiments of this series we have recorded a wide variety of values for the proportions of the X fractions, many of them lower and many higher than the extreme values obtained in our series of normal sera. We hesitate however to base any important conclusions on our individual figures because in many cases an element of uncertainty attaches to the process of graphical separation of the X curves from overlapping A curves. The general deduction is drawn from the values obtained that there exist in pathological sera variations in the proportions of X fractions which are wider than the variations found in normal sera.

A voluminous literature has been compiled in recent years by various observers [Schade and Clausen, 1924; Govaerts, 1925; Farkas, 1927; Krogh and Nagazawa, 1931; Kylin and von Pein, 1931; Iversen, 1932; to mention only a few contributions] on the colloid osmotic pressure of normal and pathological sera. A few of these observers have calculated the osmotic pressure per gram of serum protein and have deduced from this figure the presence of an abnormal concentration of the albumin fraction or of the globulin fraction as the case may be. It cannot be said that the application of this method has yielded consistent results and the centrifugal data furnish an explanation of this. So long as there are more than two variables, *i.e.* more than two molecular fractions in the serum, a measurement of the osmotic pressure (presuming this to be reliably corrected for the effects of the diffusible ions) can give no idea of the relative concentrations of the fractions. The method cannot be applied to normal sera because of the presence of A, G and X fractions, and may be applied still less to pathological sera in which additional fractions may be present. It appears to us that the recorded measurements of colloid osmotic (oncotic) pressure in pathological sera can have little precise significance in relation to the protein composition of the sera.

Consideration of the spreading coefficients in Table XIII shows that the following sera, all with A fraction n_1-n_0 values greater than 0·00500, have abnormally high A boundary spreading coefficients; A.B. (myeloma), C.P. (malignancy), H.A.A. (malignancy), A.S.L. (pneumonia), K.J.K. (nephritis) and L.E. (albuminuria of pregnancy). The variety of the pathological conditions indicates that this physico-chemical index appears to have no specific disease relationship. The striking fact however is that with the exception of C.P., of whom unfortunately we have no accurate urinary details, all the patients are passing protein in the urine. It appears probable that the poly- or hetero-disperse protein of the A fractions in these sera is capable of passing through the kidneys. On the other hand we cannot say that poly- or hetero-dispersity of serum protein is an essential condition for proteinuria because in our series there are two cases of chronic albuminuria (P.P. and M.L.) in which the spreading coefficients of the

A boundaries are normal. We give some further important evidence on this subject in a later paper dealing with the analysis of urinary proteins.

We believe that the existing methods of serum protein analysis by precipitation with neutral electrolytes do not give rise to fractions of even approximately uniform composition and therefore the results have a doubtful significance. Our evidence for this will be given in a later paper. The question arises whether the results of ultracentrifugal analysis are likely to have a greater significance. In the first place we may expect the results to be consistent since they represent measurements of a single well-defined property of serum, *viz.* the molecular dimensional distribution of the protein. Secondly, they have the merit of being obtained in circumstances which involve little, if any, change in the physico-chemical properties of the environment of the protein. This helps to eliminate arbitrary assumptions. It is true that the chemical natures of the fractions of concentrated sera which separate in the centrifugal field are not determined. This constitutes an important limitation in the interpretation of the results which we hope will be eliminated in the future. On the other hand, it is conceivable that the concentrations of molecules of a few particular sizes—no matter of what chemical constitution—may be of great significance. When one considers the relationship of protein molecular size to the viscosity and colloid osmotic pressure of serum, and the vital functions which those two serum properties have in the organism, it is realised that the results of the purely molecular dimensional analysis of serum protein may be of considerable importance. Finally, it is clear that in the consistent measurement of a single property of serum—no matter if the true significance of the property is obscure—there is a higher probability of finding an empirical relationship with some general or local condition in the organism, and this is frequently the object of serum protein analysis. For these reasons we believe that the ultracentrifugal method of analysis is at present a more rational procedure to use in the investigation of pathological sera than the precipitation method of analysis.

We have shown that the concentration values of the protein fractions obtained in the ultracentrifuge are dependent on the protein concentration in which the serum is examined. This dependence of the results on protein concentration means that it is necessary to use one of three procedures in order to give the results for various sera a comparative significance. We must determine the molecular dimensional distribution of the sera, by direct or indirect methods: (1) in the undiluted state; (2) in a state of dilution such that no change in the concentration of the fractions occurs on further dilution; or (3) at a constant concentration of protein. The second procedure is a difficult one in practice as the graphical analysis of the serum diagrams is often unsatisfactory, or impossible, in the case of highly diluted sera. Frequently also, there occur irregularities in the diagrams which are of doubtful significance. The third is not always ideally applicable because it is impossible by mere dilution of two sera each containing several fractions to obtain comparable conditions for all the fractions. The method is nevertheless frequently capable of giving valuable comparative information, and it is proposed in the continuation of these studies in the future to depend on a combination of this method and of the first procedure mentioned above.

SUMMARY.

A series of pathological sera from cases representing a variety of diseases has been examined in the ultracentrifuge.

1. In the cases of two antidiphtheritic horse sera examined without treatment of any kind it was found that the protein is approximately equally distri-

buted between an albumin and a globulin fraction. Dilution of the sera causes a marked increase in the proportion of the globulin fraction.

2. The majority of the pathological human sera examined contain three molecular fractions. In some of these sera the fractions have the sedimentation constants characteristic of the *A*, *G* and *X* fractions of normal human sera. In others the sedimentation constants are different indicating either that the fractions have different molecular weights or that some unknown and variable factor is present in pathological serum which affects the sedimentation rates of the fractions.

3. In two sera definite evidence has been found of the presence of fractions of molecular weight not normally found in human sera. In one case of malignant disease 30 % of a substance of substantially lower molecular weight than serum albumin was present in addition to the *A*, *G*, and *X* fractions. In another case of myeloma 22 % of a substance of molecular weight intermediate between the *X* and *G* fractions of normal sera was present. In this case *A* and *G* fractions were present but no *X* fraction.

4. In a considerable majority of these pathological sera the proportions of the total proteins in the untreated or slightly diluted sera represented by the *G* fractions are greater than in normal sera. The increase in the proportion of *G* fraction appears to have no special relationship to one or more diseases but to represent a general form of reaction to a number of unrelated pathological states.

5. A wide variety of values for the proportions of *X* fractions are recorded and it is evident that in a number of diseases the proportion of this fraction does not fall within the limits for a normal serum.

6. Some of the sera examined react more readily to simple dilution than do normal sera. The nature of this reaction consists as in normal sera in an increase in the proportion of *G* fraction at the expense of the lighter fractions. Fractions not normally present in serum appear to exist also in equilibrium with the other fractions.

7. Untreated pleural exudate from a case of malignancy behaved in the centrifuge like the serum of the same patient diluted to the same concentration of total protein.

8. Certain sera show an unusual phenomenon which takes the form of an abnormal spreading of the overlapping *A* and *X* boundaries. There is evidence that this is partly or wholly due to the presence of polydisperse protein molecules of mean molecular weight approximately the same as that of the *A* fraction. In four out of five such cases protein was present in the urine.

APPENDIX OF CLINICAL NOTES.

A.J. Female. 60 years. Ascites since December, 1933, with loss of weight. 21. ii. 34: large tumour palpable on right side of abdomen, exudate in left pleura, no signs of pulmonary metastases on X-ray examination, trace of protein in urine but this was not consistently present. 17. iv. 34: many large abdominal tumours palpable suggesting peritoneal metastases. Died 29. iv. 34. Permission for P.M. refused. Diagnosis: ovarian tumour with secondary metastases. Blood taken for centrifugal examination of serum on 18. iii. 34.

K.H.B. Male. 23 years. Very tired in summer of 1933 and unfit for work, later became hoarse. December, 1933: blood in sputum and attacks of shivering. 19. ii. 34: temperature 104° F., pulse 100–120, sputum T.B. + +, X-ray showed advanced T.B. in both lungs. Died 27. iii. 34. P.M.: cavities in both lungs, tuberculous ulceration of larynx, trachea and intestines, inflammation of spleen. Blood taken on 16. iii. 34.

B.I.L. Male. 4 years. 16. v. 34: headaches and throat pains. 17. v. 34: rash on chest and back, temperature 103° F., pulse 120. Diagnosis: typical scarlatina. Blood taken on 22. v. 34 and again on 14. vi. 34.

J.O.D. Male. 11 years. 10. v. 34: throat pains, difficulty in swallowing. 11. v. 34: typical rash all over body, swollen submaxillary glands, inflamed throat and tonsils. 18. v. 34: desquamation, temperature 100–102° F., pulse 90–120. Diagnosis: typical scarlatina. Blood taken on 18. v. 34.

A.B. Female. 47 years. Pains in lumbar region and chest for one year until 10. xi. 33. Urine gave typical Bence Jones precipitate at 50°, clear at 100°, 6–12 $^{\circ}/_{oo}$ Esbach, non-protein nitrogen 35 mg./100 ml., B.P. 170/140. X-ray on 20. xi. 33 showed enlargements on 1st and 2nd ribs on right side and several tumours of pelvic bones accompanied by much destruction. 17. iii. 34: spontaneous fracture of right femur, X-ray showed neck and trochanter destroyed. Patient still alive on 27. vi. 34. Diagnosis: myeloma. Blood taken on 18. xi. 33 and on 27. vi. 34.

G.L.E. Male. 68 years. January, 1933: pain in lumbar region and both shoulders, girdle pain at 11th and 12th thoracic vertebrae, later also at 8th and 9th thoracic and 2nd and 3rd lumbar, poor appetite but no emaciation, dyspnoea, coughing and hoarseness but no X-ray evidence of pulmonary metastases, liver slightly enlarged, prostate normal, symmetrical atrophy of both legs, marked osteoporosis of vertebrae with compression of several in lumbar and upper thoracic regions, several ribs quite soft, fracture of 8th and 9th, old fracture of 4th (right side), only a trace of protein in the urine (giving slight opalescence at 67°, definite at 70°, and no change at 100°), Esbach 0·5 $^{\circ}/_{oo}$. Died 8. x. 33. P.M.: medullary tumour (myeloma). Blood taken on 9. ix. 33.

K.M. Male. 78 years. Increasing tiredness and emaciation for a month. 13. v. 34: intense jaundice, urine dark brown and frothy, clay-coloured stools, plasma colour equivalent to 71 Meulengracht, mobile tumour in epigastrium (finger-thick, cord-shaped, and very hard). Diagnosis: malignant tumour of bile duct. Blood taken on 15. v. 34.

C.P. Female. 67 years. October, 1933: pains at stool, constipation and diarrhoea alternately, mucus and blood in faeces. 15. v. 34: tired, pale and emaciated, 5 inches inside rectum hard stenotic tumour with finger-wide central opening and ulcerated. Diagnosis: rectal carcinoma. Blood taken on 15. v. 34.

J.A.F. Male. 62 years. 10. xii. 33: complained of weakness. 19. iii. 34: emaciated and pale, blood in faeces, palpable tumour in epigastrium, liver not palpable, temperature 100° F., treated with cobra venom. Diagnosis: gastric carcinoma. Blood taken on 6. iv. 34.

G.N. Male. 28 years. 20. ii. 34: temperature 100–104° F., pulse 110–140, a trace of protein in urine. 6. iii. 34: two pleural punctures without result, B.P. 115/70. Died 19. iii. 34. P.M.: thrombophlebitis of iliac vein, bilateral emboli of pulmonary artery and large infarcts, organised pneumonia on right side and acute on left secondary to infection of infarct, acute nephritis. Blood taken on 13. iii. 34.

K.L. Female. 78 years. 10. iii. 34: rigors, temperature 102° F., 12. iii. 34: 270 ml. purulent fluid obtained from right pleural cavity. Died 20. iii. 34. P.M.: cardio-arterio-sclerosis, croupous pneumonia, mucopurulent bronchitis, emphysema, pleural empyema, uterine fibromyomata, ovarian cyst. Blood taken on 18. iii. 34.

A.K. Male. 59 years. Dry pleurisy in 1930. Feb. 1934: much coughing, phthisis diagnosed, sputum T.B. + + +, patient treated with pneumo-thorax. 27. vi. 34: still in hospital. Blood taken on 11. v. 34.

E.K.L. Male. 69 years. In sanatorium in April 1922. 14. iii. 34: temperature 97–98° F. in morning, 100–101° F. in evening, pulse 72–120, X-ray showed T.B. in upper third of both lungs with large cavities, sputum T.B. +. Discharged rather better 1. v. 34. Diagnosis: chronic pulmonary tuberculosis. Blood taken on 21. iv. 34.

P.P. Male. 65 years. Dyspnoea for 10 years with intermittent oedema and palpitations. 11. iv. 34: oedema, ascites, enlargement of liver, pleural effusion, Esbach 3–7 $^{\circ}/_{oo}$, non-protein nitrogen 120 mg./100 ml., W.R. negative. Went home rather better on 12. v. 34. Diagnosis: chronic glomerulo-nephritis. Blood taken 20. iv. 34.

M.L. Female. 45 years. Protein in urine and high blood pressure since 1931. 16. iii. 34: slight oedema of legs, no eye symptoms, Esbach $1\,^{\circ}/_{oo}$, blood and casts in urine, non-protein nitrogen 37·5 mg./100 ml., B.P. 165–100. Went home rather better on 3. v. 34. Diagnosis: recurrent nephritis (? acute). Blood taken on 18. iii. 34.

K.A.B. Male. 17 years. Partially deaf in both ears, becoming quite deaf in right ear in 1927. 1933: accident to knee, swollen and painless, yellow fluid in joint (Esbach $2{\cdot}5\,^{\circ}/_{oo}$), C.S.F. gave negative protein reactions, W.R. +, Kahn + +. Treated with malaria on 24. iii. 34. Diagnosis: congenital syphilis. Blood taken on 23. iii. 34.

H.A.A. Male. 59 years. Pain in right leg in January, 1934, with later pain in lumbar region. 6. iii. 34: movements impaired, emaciated, X-ray showed collapse of vertebrae with atrophy and sclerosis of surrounding tissue. No protein in urine until 3. v. 34 and thereafter only present intermittently in small amounts. Patient was treated with snake venom but died on 1. vi. 34. P.M.: sympathico-gonioma in region of superior ganglion with metastases in ribs and vertebrae, cardio-arterio-sclerosis. Blood taken on 9. v. 34.

A.S.L. Male. 27 years. Treated five times for croupous pneumonia. 1. iii. 34: acute attack of shivering and pains in chest, haemorrhagic sputum, X-ray showed pneumonia in upper lobe of right lung, typical pneumonia temperature chart, temperature normal on 8. iii. 34, urinary protein up to $16\,^{\circ}/_{oo}$ Esbach, non-protein nitrogen 33–40 mg./100 ml. Went home better on 11. v. 34. Diagnosis: pneumonia. Blood taken on 26. iv. 34.

K.J.K. Male. 42 years. October, 1933: oedema of legs, eye symptoms, swollen abdomen, tiredness, dyspnoea. 16. i. 34: oedema of penis, scrotum, and legs, urine 600–1700 ml. per day, protein always present up to $3\text{–}15\,^{\circ}/_{oo}$ Esbach, casts and a few red cells, B.P. 145/90–180/110. Diagnosis: chronic nephritis. Blood taken on 24. iv. 34.

L.E. Primipara. 21 years. No miscarriages. Protein first found in urine on 20. iv. 34, thereafter present every day in large amounts (Esbach $10\text{–}12\,^{\circ}/_{oo}$), no eclampsia, B.P. 165/90. Twins were born on 16. v. 34. Diagnosis: albuminuria of pregnancy. Blood taken on 12. v. 34.

CXLVII. THE BEHAVIOUR OF URINARY PROTEINS IN THE ULTRACENTRIFUGE.

By ARTHUR SPROUL McFARLANE[1].

From the Institute of Physical Chemistry, Upsala, Sweden.

(*Received April 1st, 1935.*)

The question whether the proteins found in the urine in certain diseases have the same composition as the proteins in the blood is one of great importance. With the probable exception of two conditions, *viz.* orthostatic and Bence Jones proteinuria, it is believed that the presence of protein in the urine may be taken as a sign of impaired renal function. If the urinary protein is the same as the plasma protein it is reasonable to assume that the disease has damaged the kidneys in such a way as to give rise to a form of leakage of plasma into the urinary tract. If the protein is different, leakage of a gross type can be excluded and it is not at all clear how the protein finds its way into the urine. We may assume that the composition of the plasma protein is changed in the renal cells by the disease process at the same time as the protein is excreted; or we may postulate that the altered urinary proteins arise in remote parts of the circulation and are excreted by normal kidneys. Since the presence of Bence Jones protein in the blood has been demonstrated in certain cases, the group of diseases with which this protein is characteristically associated has been regarded as unique (if we except the orthostatic albuminurias) in conforming to the latter hypothesis, although a few observers [Forbes *et al.*, 1933] identify renal changes with Bence Jones proteinuria. Kerridge and Bayliss [1932] have shown that Bence Jones protein readily passes through the kidneys of the cat while normal human serum proteins do not. Kerridge [1934] has shown also that the urinary proteins from ten cases of chronic nephritis did not pass through the kidneys of the cat. The inference from this (which incidentally Kerridge avoids making) is that the proteins in the urine in chronic nephritis are the same as the proteins in the plasma, and that the theory of leakage of plasma protein through the kidneys holds. The view of the identity of urinary and plasma proteins is supported by many observers. Hewitt [1927; 1929] has shown that urinary and serum albumins from cases of chronic nephritis have the same optical rotatory powers. Smith, quoted by Hewitt [1929], has shown that they have the same absorption spectra. Cavett and Gibson [1931] have shown that they have similar racemisation curves. Widdowson [1933] has investigated the optical rotation, racemisation, osmotic pressure and specific refraction of urinary and serum protein fractions in nephritis and nephrosis and concludes that the proteins from urine and serum are identical. Kozawa *et al.* [1933] claim to have shown that the amino-acid composition, albumin/globulin ratio and isoelectric(?) point of urinary proteins are the same as those of serum proteins.

Nevertheless, there are certain points which are not explained. The fibrinogen of plasma is never found in the urine. The urinary proteins seldom have the same albumin/globulin ratio as the serum proteins, and not infrequently globulin is absent altogether from the urine. It thus becomes necessary to postulate a selective permeability of the leaking kidneys to the different protein fractions of serum. Kerridge and Bayliss [1932] have put forward evidence in support of the view that the renal glomeruli function as graded filters capable of allowing molecules smaller than serum albumin to pass and withholding all others. This theory fails to explain the ready passage of haemoglobin (which has approximately the same molecular weight as serum albumin) through the kidneys, and we shall show in due course that molecules of greater dimensions than serum albumin are undoubtedly found in the urine. A major criticism of theories based on the dimensions of protein molecules is that one can never be sure of the physico-chemical conditions in the renal cells across which the proteins must pass from blood stream to urine. The proteins as a class are rather prone to molecular dimensional changes in unusual environmental circumstances, particularly when the hydrogen ion concentration is abnormal.

---

[1] Beit Memorial Research Fellow.

We have described in a previous paper [McFarlane, 1935, 3] an unusual phenomenon which appeared when serum protein from certain patients passing protein in the urine was examined in the ultracentrifuge. This consisted in an abnormal degree of spreading of the *A* boundary which suggests that the "albumin" fraction is wholly or in part heterogeneous in respect of the dimensions of the constituent molecules. A less likely possibility that the molecules of the fraction are homogeneous but are endowed with an abnormal power of diffusion cannot, however, be excluded. Whatever may be the interpretation of the phenomenon the appearance denotes a fundamental change in the serum protein and it is clearly of interest to find if any similar appearance can be detected in the urinary protein. We shall report in this paper the ultracentrifugal analysis of five specimens of urinary protein obtained from patients whose sera had all been examined and reported on in the previous paper [1935, 3]. The clinical notes relating to these patients will be found appended to that paper.

The general procedure adopted was to dialyse a sample of the fresh urine in a collodion sac against 1 % sodium chloride and under pressure until equilibrium between protein solution and dialysate was reached. The refractive indices of solution and dialysate were then measured, and the solution was examined in the ultracentrifuge. The subsequent procedure was exactly as detailed in previous papers [1935, 1, 2, 3] for serum proteins.

Approximate values for the concentrations of albumin and globulin fractions in the urinary proteins were obtained by the following procedure. The dialysed and concentrated urinary protein solution was diluted with ten times its volume of 1 % sodium chloride and an equal volume of saturated ammonium sulphate added. Precipitation was given 2–4 hours for completion and then the mixture was centrifuged until the globulin precipitate was well packed down on the bottom of the tube. The supernatant albumin solution was poured off and the precipitate drained carefully and redissolved in water. The globulin solution was then dialysed against 1 % sodium chloride and the concentration of globulin measured refractometrically. Only in the cases of two of the urines (K.J.K. and L.E.) was a significant globulin precipitate obtained. The other urines appeared to contain only albumin.

Exp. 1. Urinary protein from A.S.L. (pneumonia and nephrosis) and A.B. (myeloma).

Neither urine in this experiment gave a globulin precipitate but the urinary protein of A.B. had all the characteristics of Bence Jones protein, precipitating at 50° and redissolving completely at 100°. We isolated the protein from this urine by the following procedure. To 1 volume of urine 2 volumes of saturated ammonium sulphate were added, and the precipitate was centrifuged off after

4 hours and washed with 66 % saturated ammonium sulphate. The precipitate was redissolved in a small volume of water, the turbid solution filtered and the protein reprecipitated with a large excess of 66 % saturated ammonium sulphate. The precipitate was redissolved and second and third reprecipitations carried out in the same manner. The final solution was dialysed until free of sulphate ions and electrodialysed for 4 hours at 440 volts. The liquid was pale brown and clear. Before examining a portion of this in the ultracentrifuge, sufficient solid sodium chloride was added to it to make a 0·9 % solution.

Table I shows the collected results for experiments on the two specimens of dialysed whole urinary protein and on the preparation of Bence Jones protein. Fig. 1 *a* shows the curve of an exposure taken $54\frac{1}{2}$ minutes after reaching full speed in the experiment on the urinary protein of A.S.L. The corresponding curve in the case of A.B. shows no significant points of difference from this curve. Fig. 1 *b* shows the curve of an exposure taken 81 minutes after reaching full speed in the experiment on Bence Jones protein. The curves of these proteins show no signs of a globulin fraction, thus differing markedly from the curves of the parent sera [*cf.* 1935, 3, Fig. 9 *b*]. They also show no signs of the presence of an

X protein, which is a point of similarity with the parent serum in the case of A.S.L. The sedimentation constants of the urinary proteins appear to be slightly higher than corresponds to the *A* fractions in the parent sera. The most important point, however, is the high values of the boundary spreading coefficients. These are much higher than correspond to homogeneous boundaries of the same sedimentation constants. Figs. 1 *a* and 1 *b* show the high ratio of breadth at the base to height in these curves. The urinary proteins in these cases therefore show essentially the same phenomenon as the *A* fractions in the parent sera. In the case of A.S.L. the spreading coefficient of the urinary protein boundary is in good agreement with the value for the *A* boundary of the serum. This is not so with the serum and urine of A.B. It must be realised, however, that the serum *A* fraction may contain both homogeneous and polydisperse protein, whereas the urinary protein may only contain the latter and would in that case have a larger boundary spreading coefficient.

The boundary spreading coefficient in the case of the purified Bence Jones protein is very high. The total protein concentration however is low, and the experiment was carried out with a lower mean centrifugal force than usual. The value may not therefore be compared with the others, but it is higher than that of horse serum albumin in the same circumstances. The $S_{W,20}$ value corresponds with the value for horse serum albumin in the same concentration. It is definitely higher than the values obtained by Svedberg and Sjögren [1929] in the examination of a specimen of Bence Jones protein which had the same mean molecular weight as egg albumin, *viz.* 35,000. It is also interesting to find that the isoelectric point of this specimen of Bence Jones protein as measured by Tiselius is at p_H 5·20, whereas the isoelectric point of our protein, measured by Pedersen, is at p_H 6·56. It appears that the term Bence Jones protein does not always refer to the same substance, but that urinary protein of varying composition can give the characteristic Bence Jones reactions. Some specimens of Bence Jones protein for instance crystallise easily while others cannot be crystallised. Svedberg and Eriksson-Quensel (private communication) have had a sample of Bence Jones protein which proved to be quite polydisperse. Mainzer [1932, 1, 2, 3], by investigating the electrometric titration values and transport cataphoresis of Bence Jones protein, also comes to the conclusion that it is not a chemical individual.

Exp. 2. Urinary protein from K.J.K. (chronic nephritis), L.E. (albuminuria of pregnancy), and H.A.A. (metastatic tumour of bone).

In the precipitational analysis of two of these sera (K.J.K. and L.E.) substantial globulin precipitates were obtained while the urinary protein of H.A.A. gave only a faint opalescence. The results of the analysis were

Proportion of globulin in urinary protein of K.J.K., 19 %
Proportion of globulin in urinary protein of L.E., 14 %
Proportion of globulin in urinary protein of H.A.A., less than 2 %

The results obtained in the investigation of one specimen of dialysed and concentrated whole urinary protein from each of the three patients are shown in Table II.

Fig. 2 *a* shows the curve of an exposure taken 115½ minutes after reaching full speed in the experiment on K.J.K.'s urinary protein, and Fig. 2 *b* shows the curve of an exposure taken 149 minutes after reaching full speed in the experiment on H.A.A.'s urinary protein. The curves in the third experiment (L.E.) are very similar to those for K.J.K., and differ significantly from the curves in

Figs. 1 *a* and 1 *b* in showing the presence of a *G* fraction. No significance attaches to the fact that the proportion of *G* fraction in the urines is not the same as in the original sera, because it is probable that in the precipitation method of analysis a globulin fraction is obtained which is contaminated with considerable amounts of albumin.

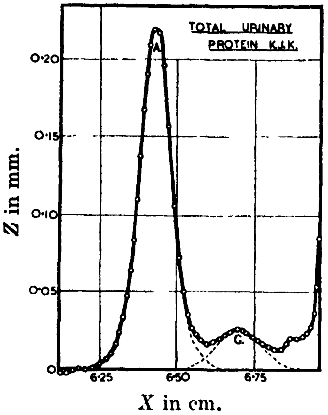

Fig. 2*a*.

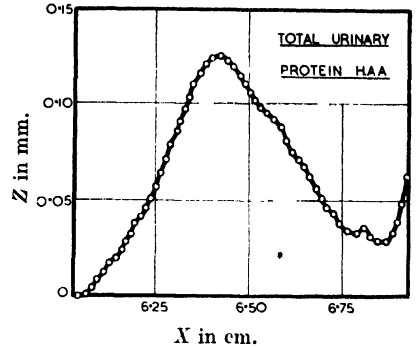

Fig. 2*b*.

	G fraction	0·00150	0·00066	—
	Total	0·01121	0·00970	0·00567
"% difference" total $n_1 - n_0$		-2·6 %	-18·5 %	-33 %
Proportion of total calculated $n_1 - n_0$ due to *G* fraction		13 %	6·8 %	—
Spreading coefficient of *A* boundary (cm.²/sec. × 10⁷)		2·7	4·9	18·5

It is obvious that the urinary protein of H.A.A. is almost completely polydisperse. Considerable amounts of protein had reached the bottom of the cell before all the protein had left the region of the meniscus. The $S_{W,20}$ value has little meaning in such a case because of the asymmetry of the curve and the doubtful significance of the apex at any instant. The value recorded in Table II, *viz.* 1·44, is obtained from measurements of the rate of movement of the apex.

Also, the apparent area of the curve is not constant but diminishes steadily as the experiment progresses. The values for $n_1 - n_0$ are all much lower than the measured total $n_1 - n_0$ value of the original preparation. The $n_1 - n_0'$ value in Table II corresponds to the mean area. The boundary spreading coefficient is calculated from the mean area and from the height of the apex above the base line in two exposures.

The *A* and *G* fractions in the other two urines have sedimentation constants corresponding approximately to those of the *A* and *G* fractions in the sera from the same patients. The *A* boundary spreading coefficients are lower in the urinary proteins but this is not inconsistent with the much higher concentrations in which they were examined. The values are greater than those for horse serum albumin in corresponding concentrations, and a comparison of the general dimensions of the curves with those of *A* curves of normal human serum of the same, or slightly smaller, total protein concentration [*e.g.* 1935, 2, Fig. 15] confirms that abnormal spreading of the *A* boundaries is present.

DISCUSSION.

We conclude from the results of these experiments that in the cases examined there is a difference between urinary protein and normal serum protein. The difference consists in an abnormal degree of spreading in the centrifugal field of the lighter fraction in the urinary protein. There is evidence that the same abnormal spreading characterises the *A* fractions in the sera of the patients. But the total urinary and serum proteins from the same patients have not identical compositions. In three cases no globulin fraction is present in the urine although in two of the three there is an abnormally high concentration of globulin in the serum.

There are various theories which fit these facts. An attractive one is that there is present in the sera effete polydisperse protein which the kidney is able to excrete by virtue of some vital activity. The existence of a vital activity which enables the kidneys to discriminate between homogeneous and heterogeneous protein would not be surprising in view of the fact that nature appears only to elaborate monodisperse proteins and these readily become polydisperse when subjected to artificial treatment. Denaturation and insolubility appear to be terminal stages in a state of progressively increasing molecular polydispersity. It would clearly be of importance therefore for the organism to be able to rid itself of polydisperse protein arising as the result of disease processes in the tissues.

Another explanation depends on the fact that many proteins are irreversibly altered by treatment with urea. Anson and Mirsky [1929], Wu [1929], Hopkins [1930], Pauli and Weiss [1931], and Burk [1932] have all investigated the effect of urea on proteins. A denaturation of the protein takes place which is apparent as an insolubility at the isoelectric point. Hopkins [1930] also obtains a positive nitroprusside reaction indicating constitutional changes in the protein molecule. Saturated or very concentrated solutions of urea are used to produce these effects. Hopkins finds that the proteins of diluted serum or of solutions of serum albumin are rendered insoluble much less readily than those of solutions of egg albumin, although they give the nitroprusside reaction at once after treatment with high concentrations of urea. This fact suggests that insolubility is a gross terminal stage of the effect and is preceded by less obvious chemical structural changes in the molecule. It may be therefore that lower concentrations of urea, such as are present in urine and in some pathological sera, are capable of causing an early partial denaturation of serum proteins which is only detectable by ultracentrifugal analysis. If this is the case it is possible that the polydispersity of the urinary and serum proteins which we have found is unrelated to the mechanism of protein excretion. Further ultracentrifugal investigation of the effect of moderate concentrations of urea on the serum proteins is required before we can come to a conclusion regarding this possibility.

In the two cases of our group which had globulin in the urine, *viz.* K.J.K. and L.E., the first was a characteristic case of chronic nephritis and the other was in an advanced state of toxaemia with a high probability of renal damage. In the other three which had no globulin in the urine there were no clinical grounds for suspecting renal disease. These facts suggest that when there is globulin in the urine the kidneys are damaged, and when the urinary protein gives only an albumin precipitation reaction we are concerned with polydisperse protein excreted by normal kidneys.

SUMMARY.

1. Five specimens of urinary proteins have been investigated in the ultracentrifuge. Two of these contain albumin and globulin fractions while three contain only albumin.

2. The albumin in all five specimens has an abnormally high power of boundary spreading, which suggests that the protein is wholly or partly polydisperse. The sera from the same five patients show similar signs of a polydisperse albumin fraction.

CXLVIII. THE ULTRACENTRIFUGAL ANALYSIS OF NORMAL AND PATHOLOGICAL SERUM FRACTIONS.

By ARTHUR SPROUL McFARLANE[1].

From the Institute of Physical Chemistry, Upsala, Sweden.

(*Received April 1st, 1935.*)

In this paper, which is the concluding one of the series, we are concerned with the fractionation, by means of a neutral electrolyte and electrodialysis, of a few sera which have already been investigated in the ultracentrifuge [McFarlane, 1935, 1, 2, 3]. The particular objects in view have been (1) to investigate the composition of the globulin fractions obtained by a single precipitation with ammonium sulphate; (2) to compare the analytical results of the fractionation procedures with the results of ultracentrifugal analysis of the same serum; and (3) to discover in the case of certain sera whether new molecular types which have been shown to be present are precipitated or remain in solution on half saturation with ammonium sulphate.

For several reasons we have relied on ammonium sulphate as protein precipitant. It was advisable to use only one neutral electrolyte in order to be able to compare the results for one serum with those for another. Ammonium sulphate has been the most widely used electrolyte in the past in the fractionation of sera, although sodium sulphate is becoming increasingly used as a result of the work of Howe [1923]. It may be noted, however, that Howe finds the values for the albumin and globulin concentrations in cow sera obtained by a single precipitation with ammonium sulphate to agree with those obtained with sodium sulphate. Wu [1922] obtains the same analytical results with saturated magnesium sulphate as with half-saturated ammonium sulphate. Cullen and Van Slyke [1920] and Sørensen [1925; 1930] and others have used ammonium sulphate extensively in fractionating serum proteins.

It has been shown [1935, 1] that when horse serum albumin and globulin, prepared by ammonium sulphate fractionation, are mixed together in concentrated solution and the mixture is analysed in the ultracentrifuge, the concentration of the albumin fraction is found to be abnormally high and that of the globulin fraction correspondingly low. These proteins exist in concentrated solution in a form of equilibrium with each other. The same has been shown indirectly to be true for cow and human serum proteins by ultracentrifugal analysis of the concentrated and diluted sera. Since we know very little about the action of ammonium sulphate as a protein precipitant and in view of this difference in the state of the proteins in concentrated and diluted sera, it was decided in the first place to investigate the composition of the globulin precipitates obtained by half saturating a concentrated and a diluted cow serum with ammonium sulphate.

It is not proposed to repeat here the numerous details of the technique of an ultracentrifugal experiment which will be found in the earlier papers referred to. In the following tables we show the concentrations of the various protein fractions in g./100 ml. calculated from measurements of protein refraction increment using the values given in Table I of a previous paper [1935, 2] for the specific refraction increments (α) of the proteins. As already pointed out some of these α values cannot be regarded as generally established, and our concentration values may therefore be subject to errors. They are the best available α values and it serves a useful purpose here to record even approximate values for the protein concentrations.

---

[1] Beit Memorial Research Fellow.

Exp. 1. Total globulins from normal cow and horse sera by precipitation with ammonium sulphate.

We employed in this experiment a portion of the cow serum used in Exps. 1–11, and a portion of the horse serum used in Exps. 12, 13, 15 and 16 of a previous paper [1935, 2]. The cow serum was treated in the following ways.

(*a*) 4 ml. of serum were diluted with 40 ml. of 1 % sodium chloride in a stoppered centrifuge-tube. 44 ml. of saturated ammonium sulphate were then added slowly and with constant shaking. The mixture was left for 2 hours during which time the globulin precipitate settled to the bottom. The tube was then centrifuged until the precipitate was well packed down on the bottom and the supernatant fluid could be poured off completely and the precipitate drained. This globulin precipitate was dissolved in water and dialysed against 1 % sodium chloride under pressure until equilibrium was reached. The solution (1·0 ml.) was transferred to a small graduated cylinder and the small collodion sac washed out with drops of dialysate which were transferred to the cylinder to make a final volume of 2·2 ml.

Results.

Refraction increment of globulin	0·01060
Therefore refraction increment of globulin in original serum ...	0·000583
Total protein refraction increment of original serum	0·01414
Therefore proportion of total protein refraction increment due to globulin fraction	41·2 %

(*b*) To 4 ml. of serum were added slowly and with shaking 4 ml. of saturated ammonium sulphate solution. The mixture was left for 2 hours and then centrifuged. The supernatant fluid was poured off and the precipitate drained and then stirred up with 8 ml. of saturated ammonium sulphate. After one hour the precipitate was again separated by centrifuging, suspended in a little water and dialysed against 1 % sodium chloride. The volume of combined protein solution and washings from the dialysis sac was in this case 3·0 ml.

Results.

Refraction increment of globulin	0·00818
Therefore refraction increment of globulin in original serum ...	0·00614
And proportion of total protein refraction increment due to globulin fraction	43·4 %

It is thus seen that the difference in the analytical results by these two procedures is very small.

The horse serum was treated as described under method (*a*) and the results were:

Volume of globulin solution	2·50 ml.
Refraction increment of globulin	0·01021
Therefore refraction increment of globulin in original serum ...	0·00638
Total protein refraction increment of original serum	0·01310
Therefore proportion of total protein refraction increment due to globulin fraction	48·7 %

Table I shows the results of the ultracentrifugal experiments on these three specimens of globulin. Fig. 1*a* shows the curve of cow serum globulin precipitated from dilute solution (exposure taken 57½ minutes after reaching full speed), and Fig. 1*b* shows the curve of horse serum globulin prepared in a similar way (exposure taken 116½ minutes after reaching full speed). The curves at corresponding times for cow serum globulin precipitated from concentrated and dilute solutions are all closely similar and differ markedly from the curves for horse serum globulin precipitated from dilute solution. In both specimens of cow serum globulin 30–35 % of other molecules (mainly *A* fraction) are present. All of this proportion, of course, does not represent albumin which we might hope to recover by repeated fractionation under ideal circumstances because the globulin was examined in concentrated solution. In such circumstances the

concentration of the *A* fraction in a mixture is greater than corresponds to the albumin added. We have examined concentrated globulin solutions because these afford better possibilities of detecting traces of albumin.

Although the horse globulin was examined in more concentrated solution than the two cow globulin preparations the curves (*e.g.* Fig. 1*b*) show the presence of only some 10 % of an *A* fraction. From our experience with artificial mixtures of horse serum albumin and globulin [1935, 1] in various concentrations we estimate that at least 5 % of "recoverable" albumin is present in this preparation. Similarly, it is probable that some 15–20 % of recoverable albumin is present in both cow globulin preparations.

It is interesting to find so little difference in the two cow globulin preparations. We deduce from this experiment that when ammonium sulphate precipitates globulin from solution it is a matter of little importance whether all the globulin is present with the usual molecular dimensions, or is present, as in native sera, in a low molecular form probably in some way associated with albumin. Presumably, immediately the *G* fraction is precipitated from a concentrated mixture the equilibrium between *A* and *G* fractions results in the production of more *G* fraction which is precipitated, and this goes on until only albumin remains in the solution.

The preparation of horse serum globulin is surprisingly homogeneous for a single precipitation, in view of the fact that a preparation from another serum [*cf.* 1935, 1, Fig. 2*d*] after repeated reprecipitation contained nearly 20 % of an *A* fraction.

Exp. 2. Total globulins from normal human sera by precipitation with ammonium sulphate.

In this experiment we used the sera from O.D.B. and C.A. [1935, 2, Table XVII] and fractionated in accordance with method (*a*) above.

Results.

4 ml. of serum from O.D.B. gave 3·13 ml. of globulin solution.	
Refraction increment of globulin	0·00615
Therefore refraction increment of globulin in original serum ...	0·00482
And proportion of total protein refraction increment due to globulin fraction...	33 %
4 ml. of serum from C.A. gave 2 ml. of globulin solution.	
Refraction increment of globulin	0·00815
Therefore refraction increment of globulin in original serum ...	0·00407
And proportion of total protein refraction increment due to globulin fraction...	25·5 %

The results are shown in Table II and Fig. 2*a* shows the curve of an exposure taken 65 minutes after reaching full speed in the experiment on O.D.B.'s globulin, and Fig. 2*b* that of an exposure taken 69½ minutes after reaching full speed in the experiment on C.A.'s globulin. It is clear from these curves that both globulin preparations contain considerable amounts of albumin. It is calculated from the area of the curves that O.D.B.'s globulin contains no less than 43 % of an *A* fraction and C.A.'s contains 22 % of an *A* fraction.

It would clearly have been informative to examine the globulin preparations in a highly diluted state in order to determine how much of the *A* fraction represents theoretically recoverable albumin. This we have not done because the graphical analysis of the curves of very dilute mixtures is not accurate, particularly when we are concerned with a mixture containing excess of globulin. The data from the examination of these concentrated globulin solutions suffice to show, however, that the results of serum analysis which depend on a single precipitation with ammonium sulphate are not consistent. Heterogeneous globulin fractions result from the precipitation, and the degree of heterogeneity appears to vary not only between sera of different species but also between normal members of the same species. Results given later in this paper lend further support to these conclusions.

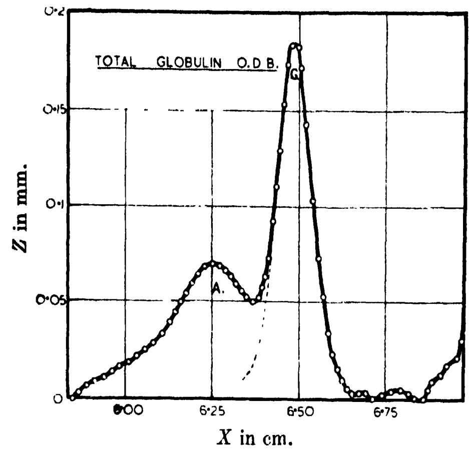

Fig. 2a.

It appears that some additional factor or factors other than the concentrations of the fractions determine whether ammonium sulphate produces a globulin precipitate which is free from albumin. It is well known that the results of the precipitation analysis of sera vary with the hydrogen ion concentration of the mixture. No doubt this is due to variable quantities of albumin which are precipitated with the globulin. It is also noteworthy in connection with the gross heterogeneity of the above normal human globulin preparations that Roche and Bracco [1934] found much lower molecular weights (103,000) for human globulin than for horse globulin (150,000) by osmotic pressure measurements.

Exp. 3. Serum fractions after drying.

We have described previously [1935, 2] the investigation of a human serum which had been dried by the Hardy-Gardner procedure using ether and alcohol at low temperatures. Much work has been done using albumin and globulin preparations obtained from this redissolved powder, and it seemed to us that by repeated fractionation it might be possible to obtain albumin and globulin fractions which were free from the polydisperse matter which we have shown to contaminate the dried serum. A dilute solution of the serum powder was therefore treated with an equal volume of saturated ammonium sulphate and the globulin precipitate separated off and reprecipitated twice from dilute solution. The precipitate was also washed once with half saturated ammonium sulphate solution between each precipitation. The albumin fraction was precipitated three times in all using saturated ammonium sulphate. The albumin and globulin solutions after dialysis against 1 % sodium chloride were examined in the ultracentrifuge and the results are shown in Table III.

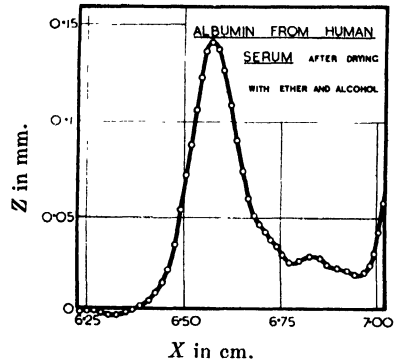

Fig. 3*a*.

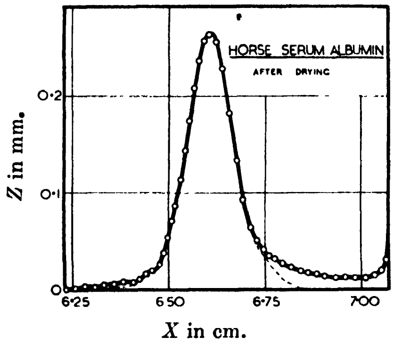

Fig. 3*b*.

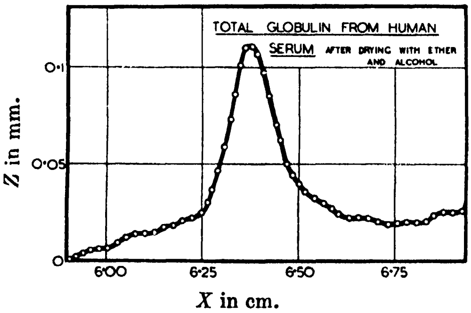

Fig. 3*c*.

Fig. 3*a* shows the curve of an exposure from the albumin experiment obtained 37½ minutes after reaching full speed. It is clear that considerable amounts of polydisperse protein still contaminate this protein. The curves of the globulin preparation show the presence of even greater amounts of polydisperse protein. We show a curve from this experiment in Fig. 3*c* obtained from an exposure taken 30 minutes after reaching full speed. From the curves it is calculated that less than 30 % of the total protein may be regarded as homogeneous globulin.

We show in parallel (Table III) the results of an experiment on a recrystallised preparation of horse serum albumin which had been dried by simple evaporation under reduced pressure and then redissolved. The dried albumin, unlike the serum dried with ether and alcohol, did not redissolve completely. The experiment is also not an exact parallel with the earlier one because we have used horse instead of human albumin, and because in one case we are dealing with a dried albumin preparation whereas in the other we are dealing with an albumin fraction from dried whole serum. The results, however, together with the curve of Fig. 3*b* (from an exposure taken 40 minutes after reaching full speed) serve to illustrate an important fact which we have already recorded for dried cow serum, *viz.* that the soluble protein after drying by this technique has all the normal characteristics of the original protein.

Exp. 4. Fractions arising in the cataphoresis of normal human serum.

We have not obtained by any fractionation process a specimen of human serum albumin comparable in homogeneity with specimens of recrystallised horse serum albumin. Nor have we obtained a specimen of human globulin so nearly homogeneous as the best horse globulin preparations obtained by repeated precipitation [1935, 1] although these are not perfect in this respect. We therefore decided to try the method of transport cataphoresis and in this experiment we used an apparatus described by Theorell [1934][1]. About 100 ml. of fresh serum from a healthy student volunteer were placed in the bend of the special U-tube, the limbs of which are built up of short glass sections. By sliding shutters it is possible to close off the ends of each section without leakage so that each limb becomes subdivided into a number of closed cylindrical compartments and the fluid may be withdrawn from each compartment. Liquid junctions in the two limbs between the serum below and a phosphate buffer of the same p_H (7·21) and conductivity above were carefully made and cataphoretic movement of the serum protein induced in the usual way by means of a high potential applied through silver/silver chloride electrodes. The serum pigment migrated with the

[1] I am indebted to Med. Kand. O. Mellander for assistance in this experiment.

more rapidly moving albumin boundary. After 12 hours the various compartments were shut off and the solutions withdrawn, and a portion of each was tested for albumin and globulin. The solution from the upper compartment in the positive limb of the U-tube gave only an albumin reaction. The solutions from the upper three compartments in the negative limb gave no protein reactions, and that from the fourth gave only a globulin reaction. These albumin and globulin solutions were then dialysed against 1 % sodium chloride to determine the protein refraction increments and were then examined in the ultracentrifuge.

Spreading coefficient of boundary (cm.^{2}/sec.$\cdot 10^7$)	6·3	4·9

Table IV shows the results of the two experiments, and Fig. 4*a* a curve from the albumin experiment from an exposure taken 55 minutes after reaching full speed. The curves show that the albumin contains only very small amounts of globulin, if any. It is the most nearly homogeneous human albumin preparation which we have obtained and suggests that the method of transport cataphoresis has considerable possibilities in the preparation of pure serum albumins where these are not crystallisable. It should be noted in particular from Table IV that the boundary spreading coefficient of the albumin corresponds well with the value for recrystallised horse serum albumin in corresponding concentration [*cf.* 1935, 1, Fig. 4]. The curves from the globulin solutions are also satisfactory and show no signs of an *A* fraction such as contaminates the human globulin preparations of Figs. 2*a* and 2*b*. The discrepancy between measured and calculated total $n_1 - n_0$ is rather high in this case. We conclude from this experiment that the cataphoresis method is on the whole a satisfactory one for fractionating human sera.

The object of this experiment was to obtain human albumin and globulin preparations which could be mixed together again and the mixture examined in the centrifuge. We obtained just sufficient of the above solutions to make a mixture of 3·57 g./100 ml. total protein concentration, and we show in Fig. 4*b* a curve of this mixture obtained from an exposure taken 55 minutes after reaching full speed. From the curves of this experiment we calculate the albumin/globulin ratio to be 2·9. The ratio of the quantities of albumin to globulin added was 1·3. Even if we regard the globulin preparation as only 80 % monodisperse it is clear that on mixing the two together a considerable shift has occurred in the ratio of the fractions. From this experiment it is deduced that the equilibrium between the fractions in human serum is reversible just as we have shown it to be in the case of horse serum fractions. It is, however, not reversible in one respect. It will be noted that the *A* curve in Fig. 4*b* is quite symmetrical, no signs of an *X* fraction being detectable. We have noted [1935, 2] the same irreversible change when cow and horse sera are treated with ammonium sulphate. The significance of the phenomenon is obscure.

Exp. 5. Globulin fractions from antidiphtheritic horse serum.

It will have been noted in the examination of the total globulins of normal sera that no distinct molecular types exist in these which might correspond to the pseudoglobulin and euglobulin fractions. If these two fractions represent different proteins we must conclude either that the two have the same molecular weight but different chemical constitutions, or that they are produced by the process of electrodialysis which leads to their separation. To investigate this matter we prepared the total globulin from an immune serum[1] [1935, 3, Exp. 1, Serum 2] by one precipitation with ammonium sulphate and electrodialysed a portion of this to give pseudoglobulin and euglobulin fractions.

Results.

10 ml. of serum 2 gave 16·34 ml. of globulin solution.

Refraction increment of globulin	0·00833
Therefore refraction increment of globulin in original serum ...	0·01361
Total protein refraction increment of original serum	0·01770
Therefore proportion of total protein refraction increment of original serum due to total globulin fraction	77 %

It may be mentioned here incidentally that antidiphtheritic serum 1 [1935, 3] when subjected to the same analytical procedure gave a globulin proportion of 79·5 %.

The total globulin of serum 2 was centrifuged and Fig. 5*a* shows the curve of an exposure taken 50 minutes after reaching full speed. It will be seen from this and from the results in Table V that the preparation is nearly homogeneous

[1] The fractionation of immune sera into eu- and pseudo-globulin fractions is now a process of considerable commercial importance.

which is surprising for a single precipitation. We may assume that the proportion of homogeneous globulin in the original serum is slightly less than the analytical figure—say 75 %—on account of traces of albumin in the globulin preparation. Ultracentrifugal analysis of the undiluted serum [1935, 3] showed that exactly equal amounts of *A* and *G* fractions were present. This means that the area of the *A* curve corresponds to twice the amount of albumin which is recoverable from this serum and the area of the *G′* curve to two-thirds the recoverable globulin. These figures give some idea of the extent to which the albumin/globulin ratio in an untreated immune serum may be altered by the equilibrium between the fractions.

10 ml. of the total globulin of serum 2 were dialysed at 4° against distilled water and then electrodialysed according to the procedure described by Ettisch and Ewig [1928]. As recommended by Ettisch and de Loureiro [1933] we have

used at the cathode a membrane of parchment and at the anode a membrane of glycine-collodion. The electrodialysis was completed inside an hour with no detectable rise of temperature in the cell. The liquid in the centre compartment was stirred up and poured off. The precipitate was separated by centrifuging, drained and stirred up with 1 % sodium chloride in which it redissolved slowly and incompletely to an opalescent solution. After standing overnight in contact with the insoluble globulin the solution of euglobulin was dialysed against 1 % sodium chloride and examined in the ultracentrifuge. The pseudoglobulin solution was dialysed against 1 % sodium chloride and similarly examined. The results are shown in Table V, and Fig. 5*b* shows the curve of an exposure taken 43 minutes after reaching full speed in the experiment on the euglobulin fraction. The pseudoglobulin fraction differs in no significant details from the original total globulin preparation. The euglobulin preparation, on the other hand, is largely polydisperse, as is shown by the shape of the curves, the large "% diff." values, and the abnormally large boundary spreading coefficient. Svedberg and Sjögren [1930] and Mutzenbecher [1931] found both the pseudoglobulin and euglobulin of normal horse sera to be polydisperse, the former fraction much less so than the latter. Svedberg and Sjögren did not use differently charged membranes and their electrodialysis lasted for 36 hours. Mutzenbecher used the same technique as that described above but electrodialysed whole serum instead of total globulin. These differences may explain why our pseudoglobulin preparation appears to be more nearly homogeneous than theirs. Alternatively, antidiphtheritic horse serum may be capable of giving a relatively homogeneous pseudoglobulin fraction while normal horse serum is not. We may say at least that the polydisperse nature of euglobulin seems to be fully substantiated. Our experiment also shows that the pseudoglobulin of antidiphtheritic horse serum does not contain any homogeneous fraction of significantly different molecular weight from that of the total globulin.

Exp. 6. Arbitrary globulin fractions from the serum of G.N. *(septic pneumonia).*

It has been shown in Exp. 8 of a previous paper [1935, 3] that in the untreated state the protein of G.N.'s serum is approximately equally distributed between *A*, *G* and *X* fractions. We employed for this serum a purely arbitrary method of fractionation. 4·24 ml. of serum were diluted with 40 ml. of 1 % sodium chloride, and saturated ammonium sulphate was added with shaking until a substantial precipitate had appeared as judged by the turbidity of the solution. This required 23 ml. of the ammonium sulphate solution. The precipitate was centrifuged off, dialysed and examined in the ultracentrifuge (fraction 1). More saturated ammonium sulphate (4 ml.) was added until another substantial precipitate had appeared and this was also separated and dialysed (fraction 2). Sufficient ammonium sulphate (17·24 ml.) was now added to make half saturation and the remainder of the globulin separated off (fraction 3). From the results of the refractive index measurements we obtain the following values for the proportions of the total refraction increment of the original serum which are due to each fraction.

Fraction 1	15 %
,, 2	16 %
,, 3	30·5 %

The results of the ultracentrifugal examination of these three fractions are shown in Table VI, and Fig. 6*a* shows the curves of an exposure taken 56 minutes after reaching full speed in the experiment on fraction 2. The results for the three globulin fractions indicate that these have approximately the same composition, if we except differences in the "% diff." values which indicate mainly differences in the amount of polydisperse protein in each fraction. It is interesting to find also that the curves of all three fractions show very small proportions of *A* fractions to be present—much less than we have found in the globulin fractions of normal human sera. These erratic results all support the view already stated that some factor—probably electrochemical—of which we have no precise knowledge determines the ultimate degree of homogeneity of the globulin precipitates obtained by treating serum with ammonium sulphate.

Total n_1-n_0, by refractometer, $\lambda=589\,m\mu$	0·0106	0·00796
Corresponding total protein concentration (g./100 ml.)	4·84	3·64
Total n_1-n_0, corrected to $\lambda=366\,m\mu$	0·0115	0·00860
Average $S_{W,20}\cdot 10^{13}$	5·01	5·56 (Y) 6·77 (G)
Average n_1-n_0 from curve of sedimentation diagram, $\lambda=366\,m\mu$	0·00930	0·00443 (Y) 0·00247 (G)
Total n_1-n_0 from curve of sedimentation diagram, $\lambda=366\,m\mu$	0·00930	0·00690
"% diff." total n_1-n_0	−19 %	−20 %

The total globulin from A.J.'s serum appears to be almost completely free from any A fraction and except for the discrepancy of −19 % between calculated and measured refraction increments it has the characteristics of a homogeneous protein. It is also noteworthy in this experiment that the proportion of globulin fraction obtained by precipitation analysis, *viz.* 39·3 % is in exact agreement with the proportion obtained by ultracentrifugal analysis of the serum diluted with 4 volumes of 1 % sodium chloride.

Fig. 7*b* and the results in Table VII show that the globulin precipitate from G.L.E.'s serum is composed of two molecular types corresponding approximately in sedimentation constants to the Y and G fractions of the original serum. Both fractions appear to be homogeneous.

Exp. 8. Total albumin and total globulin fractions from the serum of K.M. (malignant disease).

In the earlier examination of this serum [1935, 3] we found that four molecular fractions were present and the evidence was in favour of the view that the lightest fraction is an abnormal type and the three heavier fractions correspond to the A, X and G fractions of normal sera. The serum was fractionated by the simplest possible procedure. The total globulin precipitate obtained according to procedure (*a*) was redissolved, dialysed and examined in the centrifuge. The mother-liquor from this precipitation was dialysed under pressure whereby all the ammonium sulphate was removed and the protein was obtained in concentrated solution. This solution was then examined in the centrifuge.

Results.

4 ml. of K.M.'s serum yielded 2·4 ml. of globulin solution.

Refraction increment of globulin	0·00662
Therefore refraction increment of globulin in original serum	0·00397
Total protein refraction increment of original serum	0·0118
Therefore proportion of total protein refraction increment of original serum due to globulin fraction	33·6 %

The results of the ultracentrifugal experiments are shown in Table VIII. The curve of Fig. 8*a* is from an exposure taken 100 minutes after reaching full speed in the experiment on the total albumin; that of Fig. 8*b* is from an exposure taken 46½ minutes after reaching full speed in the experiment on the total globulin. These curves and the results obtained from them demonstrate clearly what has happened to the new molecular type in the processes of fractionation. The new (A_1) molecule has remained in solution in close association with the A fraction. The ratio of the concentration of A_1 to A molecules in the albumin fraction is however markedly different from their ratio in the original serum. There are several possible explanations of this, but none that can be substantiated in the meantime.

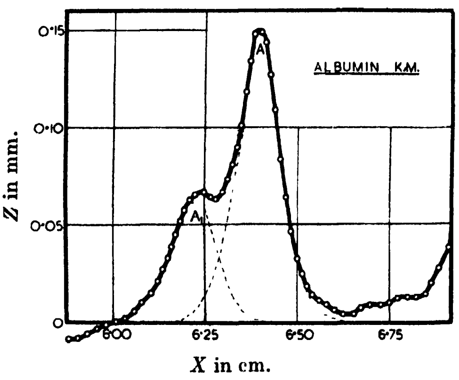

Fig. 8*a*.

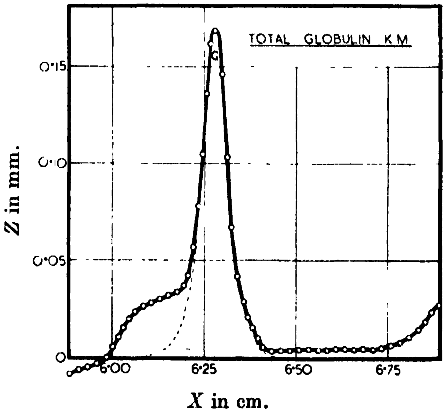

Fig. 8*b*.

The globulin fraction contains slightly more than 20 % of an A fraction. In this respect it differs from the preceding pathological globulin preparations and resembles the preparations from normal human sera (Exp. 2).

GENERAL DISCUSSION.

The view that the albumin and globulin which can be isolated from serum represent stable chemical individuals probably existing as such in the original untreated serum has been widely accepted for many years. The popularity of the view is due to the agreement which has been obtained by many workers studying various physical and chemical properties of these proteins. Serum albumin has become generally regarded as an amphoteric substance of well-defined elementary chemical composition, molecular weight, isoelectric point, electrophoretic mobility, specific refraction increment, specific light absorption and optical rotation. When one considers the possibilities for differences between the results of various observers which are due to differences and errors in the techniques of observation, it is probably fair comment to say that the general measure of agreement in regard to the properties of serum albumin is satisfactory and in support of the view that all observers are examining essentially the same substance. The same cannot be said confidently of serum globulin, because in this case the measure of agreement among different observers has not been good. There has been, however, a strong undercurrent of belief in regard to this substance that the disagreements arise from the presence of quantities of contaminating substances, and that in the preparation of each observer there is present in greater or smaller concentration, a common substance.

Sørensen, to whose earlier work on egg albumin is due probably more than to anything else, the inception of the view that the proteins are stable chemical entities, has recently [1930] given good reasons for doubting the fundamental principles on which this view is based. It is now Sørensen's contention that the uniformity of the results obtained for the serum proteins is not a criterion of the eventual individuality and purity of these substances but only of the reproducibility of the physical and chemical conditions under which the proteins are prepared. He regards both proteins of serum as component or "co-precipitation" systems made up of stable main valency units (probably polypeptides) which are loosely held together by residual valencies. The ultimate size, number and general properties of these loosely constructed units is determined by the physical conditions which hold in the solution at any instant. Since practically all observers have obtained their albumin and globulin fractions from solutions of closely prescribed ammonium sulphate content it is to be expected that they should obtain fractions of similar composition.

Sørensen's conclusions would be more convincing to us if his carefully conducted experiments had been carried out with fresh untreated serum instead of with serum powder dried by the Hardy-Gardner procedure, and also if his proof had contained more definite physical evidence of the existence of his protein co-precipitation systems in native protein solutions. The facts which we have related in the foregoing series of papers, however, neither support nor disprove his theory because our proof of the existence of albumin and globulin fractions in mixtures over a range of concentrations is purely arbitrary. Our practice has been to find first an empirical relationship between the concentration and sedimentation constant of a protein, and thereafter to use the sedimentation constant to identify the protein in any concentration. The original relationship may depend on the effects of viscosity alone or on a combination of viscosity effects and changes in the molecular dimensions of the protein. The real test of Sørensen's theory is whether or not the observed molecular weights of the serum proteins tend to a constant value in dilute solutions. From a consideration of the data of Svedberg and Sjögren [1930] on the sedimentation equilibrium of serum proteins, and of Adair and Robinson [1930] on the osmotic pressure of the serum proteins we incline to the view that serum albumin at least has a constant molecular weight in high dilutions.

We can say from the results of this work that untreated sera or concentrated mixtures of the serum proteins do not contain a collection of residual valency units which are all of the same particle size. Sørensen does not say whether his co-precipitation systems might be expected to contain under a given set of conditions a small or a large number of different particle sizes. The ultracentrifuge shows that in normal serum there are present three fractions each of which if not completely homogeneous can only be heterogeneous within very narrow limits. We may assume with Sørensen that the serum represents a set of three co-precipitation systems, but we must postulate that specific molecular forces are operative in producing and maintaining only those three sets of loosely bound residual valency units. Sørensen's theory does not explain the nature of these forces.

In one important respect Sørensen's views coincide strikingly with the facts of our experiments. To quote his own words "an interaction must be assumed, for example in serum, between the protein systems mutually as well as between these and other substances present". The equilibrium which we have shown to exist between *A* and *G* fractions in serum appears to agree with his prediction in all essentials. It must be remarked, however, that this equilibrium phenomenon does not necessarily require that the *A* and *G* fractions separately should be reversibly dissociable systems. The phenomenon is equally well explained by the theory that two stable proteins are able to form loose combinations when present in sufficient concentration. Neither point of view offers any explanation of the really unusual fact about this equilibrium, *viz.* that the protein complex or compound (according to the viewpoint adopted) has lower molecular dimensions than at least one of the disruption systems (or stable proteins) to which it gives rise on dilution.

Whether Sørensen's view that the proteins as a class are reversibly dissociable polypeptide systems is true or not is of great importance in connection with the results of investigations on isolated proteins. On the other hand it has only a small significance for the results of investigations on untreated serum. In the latter case it is frequently only desired to know the nature of the protein fractions as they exist in serum and it is of minor importance whether these fractions represent proteins which may be isolated from the serum or dissociable systems of no fixed composition. In general, however, the prospect of enlarging our knowledge of the protein constitution of serum will be greatly increased if it is possible to separate the proteins in stable form and examine the pure solutions. For this reason we have conducted the preliminary fractionation investigations reported in this paper.

The outstanding feature of these few experiments is the lack of uniformity in the composition of the globulin precipitates obtained by half saturation with ammonium sulphate. Whereas certain sera, *e.g.* normal human and cow sera, gave rise to globulin precipitates which contained relatively large quantities of albumin, other sera, *e.g.* normal horse and some pathological human sera, gave rise to globulin fractions which contained only small amounts of albumin. The results of the latter experiments suggest that under certain conditions even a single precipitation with ammonium sulphate is capable of giving rise to satisfactorily homogeneous globulin preparations. The results of the experiments as a whole, however, suggest that we have still to find out what constitute ideal conditions for quantitatively fractionating serum by means of ammonium sulphate.

An experiment with the transport cataphoresis method of fractionation has indicated that there are possibilities inherent in this technique, particularly with regard to the fractionation of human sera. On theoretical grounds the method appears to be an ideal one for the preparation of serum proteins and it is hoped to attempt its application later to the isolation of the new molecular types which have been shown to exist in certain pathological sera.

We have examined the ammonium sulphate fractions from two pathological sera in which the evidence for the existence of new molecular types could be regarded as quite definite. The results indicate that in both cases the new molecular types have retained their individuality after the treatment with ammonium sulphate, a behaviour which does not seem to be shared by the *X* fraction of normal sera. This fact holds out considerable prospect that they represent stable proteins which like albumin and globulin are capable of being isolated in a comparatively pure state. The only satisfactory proof of this is, of course, actually to isolate them and demonstrate their purity. We anticipate, however, that many methods of fractionation will need to be tried and the results tested at every step by ultracentrifugal analysis before a suitable fractionation technique will be found.

SUMMARY.

Fractions obtained from various sera have been investigated in the ultracentrifuge.

1. The total globulin from a normal cow serum, whether precipitated from concentrated or dilute solution with ammonium sulphate, was found to be markedly heterogeneous due to the presence mainly of albumin.
2. The total globulins precipitated from two normal human sera in dilute solution with ammonium sulphate also contained quantities of albumin.
3. Albumin and globulin fractions were isolated from a human serum which had been dried with ether and alcohol. In spite of repeated precipitations with ammonium sulphate these fractions contained large amounts of polydisperse protein.

4. Albumin and globulin fractions obtained by cataphoresis of a normal human serum were found to be satisfactorily homogeneous.

5. The total globulin from an antidiphtheritic horse serum after one precipitation with ammonium sulphate contained only insignificant amounts of albumin. The pseudoglobulin obtained from this preparation by electrodialysis had approximately the same composition as the total globulin but the euglobulin was at least 50 % polydisperse.

6. In the fractionation of two pathological human sera in dilute solution by means of ammonium sulphate, homogeneous globulin fractions were obtained.

7. Two pathological sera in which the presence of new proteins had previously been demonstrated were fractionated by means of ammonium sulphate. In one case the new protein was found in the albumin fraction and in the other in the globulin fraction.

The general conclusion is drawn that a single precipitation with ammonium sulphate is not a satisfactory method of fractionating sera particularly for purposes of quantitative analysis.

It is a pleasure to acknowledge the unfailing interest and valuable advice of Prof. Svedberg in the course of this work and the generous hospitality afforded in his laboratory. To his assistants, particularly to Dr Kai O. Pedersen, I wish to express my great indebtedness. The expenses of this investigation have been defrayed by grants from the Andersson Foundation, the Nobel Foundation and the Rockefeller Foundation.

It will be possible to continue this work at the Lister Institute, London, where an ultracentrifuge now under construction in Upsala will be installed in the near future.

CXLIX. DETERMINATION OF VITAMIN A WITH THE HILGER VITAMETER EQUIPPED WITH A DEVICE FOR PHOTOGRAPHIC RECORDING.

By OLAV NOTEVARP.

From the Norwegian Fisheries Research Station and Official Cod Liver Oil Control Laboratories, Bergen, Norway.

(Received March 23rd, 1935.)

The ultraviolet absorption at 328 $m\mu$ has now been generally accepted to be, with certain limitations, a measure of the content of vitamin A [League of Nations Commission, 1934]. The spectrographic determination of this, however, requires elaborate and expensive apparatus and a considerable amount of work by expert hands, which makes it unsuitable for use as a general method of analysis. For the Official Norwegian Cod Liver Oil Control Laboratories under technical leadership of the Fisheries Research Station, it was very desirable to be able to carry out the determination by means of some simpler apparatus, and as early as 1932 enquiries were made with the leading makers of optical instruments whether it was possible to manufacture a simple apparatus suitable only for measuring $E_{328\,m\mu}$. At that time only the usual spectrophotometers were available, but early in 1933 the firm A. Hilger, London, sent out their vitameter, which was exactly the instrument we were looking for, and the first one manufactured was delivered to our laboratories.

A description of the vitameter has been published by Adam Hilger, Ltd. The measurement, as far as the observer is concerned, consists of the matching of intensity of two fluorescent lines. We soon found that the matching of the intensity of the two fluorescent lines was difficult, determinations carried out at different times and by different observers giving discrepancies of up to ± 10–15 %. In order to avoid this I tried to record the intensity of the lines photographically, and it was found that they had sufficient photographic activity to give prints within a few seconds on the most vigorous gaslight printing paper available. This material has the great advantage of being independent of a dark-room, which makes developing *etc.*, a very simple matter.

I therefore equipped our vitameter with a simple device for photographing the lines on such paper, and this has been in constant use during the last year and a half and has enabled us to obtain exact and objective observations quickly and easily.

The construction of the device will be seen in Fig. 1. Immediately in front of the fluorescent screen there have been made two narrow slits to allow the insertion of a holder for the paper. This runs in rails that are fixed to the support for the screen, both holder and rails being made so as to get the paper as close as possible to the screen. The paper is held in place by the turned down edges of the holder and is pushed in till it meets a stop, to ensure that it is always held in the same place. On the back of the holder there are marks to show where to begin and how far it is to be moved for each exposure. We have found a size of paper 9 × 4 cm. suitable.

To carry out the determination a suitable solution is first prepared, which should have an extinction coefficient of 0·6–1·0. The absorption is first determined approximately by eye, a shutter is placed in front of the lens and the paper brought into position in the holder. It should be marked to show which side is up. Exposures are then made at suitable intervals of E, the holder being moved about 5 mm. between each exposure. The time necessary increases as the aperture is reduced; we have found a suitable exposure to be ten times as many seconds as the aperture reading ($E = \log I_0/I$) running the copper arc at 45–50 volts, 0·45 ampere, and with a gap of about 1 mm. The paper is then developed for one minute in an ordinary, vigorous paper developer, and fixed. This can be done in electric or subdued daylight if the paper is protected from direct rays. Even greater freedom can be obtained by using a desensitising bath first.

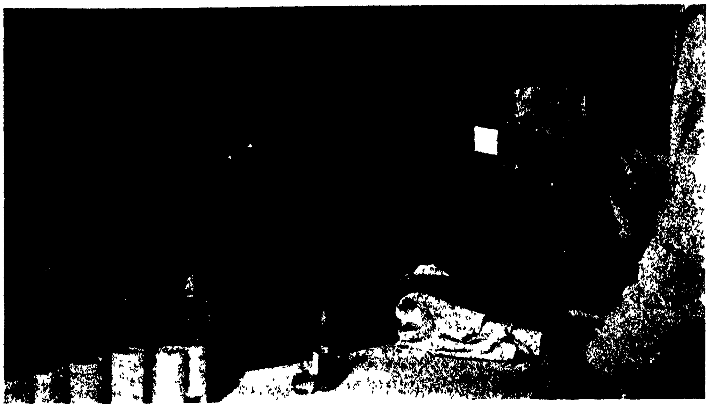

Fig. 1.

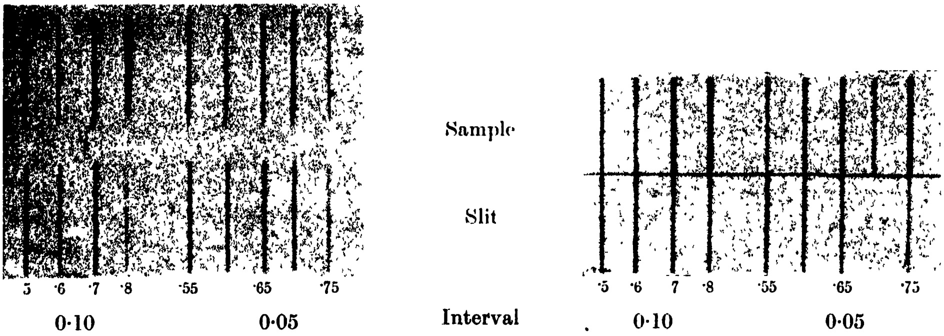

Original print.

Print with lines brought together to facilitate reading.

Fig. 2.

It will be necessary to expose from about 20 % below to 20 % above the approximate value, the intervals being chosen according to the accuracy desired. If the apertures have been correctly chosen it will be found that the print of the line that has passed through the solution is weaker than that from the aperture for the lowest values, the difference growing less until there is equality and then the case is reversed. A typical set of exposures is shown in Fig. 2.

The intervals may be chosen down to $0{\cdot}05E$ and it is possible to read with an accuracy of $\pm 0{\cdot}01$. Parallel determinations should not differ more than $\pm 0{\cdot}02$, that is $\pm 3\ \%$ if the observation is carried out at 0·6–0·7.

It will be seen that the accuracy is considerably greater than is obtainable by ocular readings and approaches the accuracy obtainable by usual spectrographic methods.

Corrections. The increased accuracy makes it necessary to take certain precautions. The glass cell must be perfectly clean and should be polished before each observation with a piece of clean wash-leather. The solutions must be free from any turbidity, and a correction must be introduced for the solvent used. This makes the choice of solvent unimportant as long as its absorption is low and it does not in any way harm the vitamin.

Table I gives some of the values found for various solvents in one of the cells that have been used. It should be noted that these cannot be regarded as absolute values of $E_{328\,m\mu}$. They may be expected to vary with different instruments and cells, as the latter and the compensating glass plates may differ slightly. No special precautions have been taken to purify the solvents, the chloroform is ordinary B.P. and the alcohol may be expected to contain aldehyde, as it has not been protected from air.

Table I. E *for solvents in vita-glass cell No. II.*

						Mean value
Chloroform	0·04	0·05	0·03	0·04	0·03	0·04
Alcohol, absolute	0·07	0·09	0·11	0·10	0·08	0·09
The same + 10 % chloroform	0·07	0·07	0·05	0·07	0·08	0·07
Toluene	0·07	0·07	0·08	—	—	0·07

Although it has a relatively great absorption, and dissolves only a limited quantity of oil, we have found that absolute alcohol is the most suitable solvent, as vitamin A is more stable in this than in other solvents, and it does not evaporate very quickly.

Setting of the vitameter. It is imperative that the arc should be placed exactly at the correct distance from the lens, as the changes in aperture are not symmetrical. The prints of the two lines will then appear exactly one above the other and be equally broad, and variations in density across the lines, if any, should correspond. If the arc is out of focus, the line from the aperture will be blackened unsymmetrically, and it is difficult to obtain correct readings. To set the vitameter it is best to use a solution with a density of 0·8–1·0. The arc is then set and the lines matched as nearly as possible by eye. Exposures are made with the arc at slightly different distances (2–4 mm.), it being then easy to see from the prints which is the right distance. The setting can be checked by determining the same substance in several concentrations. Table II gives some values of the same oil in two concentrations in different solvents.

Table II.

Solvent	Concentration g./l.	$E_{328\,m\mu}$	Correction for solvent	Corrected $E_{328\,m\mu}$	$E^{10\,g./l.}_{328\,m\mu}$
Chloroform	13·0	0·92	0·04	0·88	0·68
,,	6·4	0·47	0·04	0·43	0·67
Alcohol	13·0	0·96	0·09	0·87	0·67
,,	6·4	0·52	0·09	0·43	0·67
Toluene	13·0	0·90	0·07	0·83	0·64
,,	6·4	0·50	0·07	0·43	0·67

It will be seen that the various conditions give good agreement for $E^{10\,g./l.}_{328\,m\mu}$.

Vitameter values as compared with spectrographic determinations.

It is of course vital to the value of the readings in the vitameter that they agree with or stand in some constant relation to values determined spectrographically. We have carried out numerous determinations on cod-liver oils, halibut-liver oils and also various concentrates that give good agreement, and the values give the usual parallelism with the blue values obtained.

Table III shows results which have been found after the present technique had been worked out.

The blue value, colour and Kreis test have all been determined in a standard Lovibond Tintometer. The last test has been carried out with 5 ml. cod-liver oil + 5 ml. concentrated hydrochloric acid + phloroglucinol and measured in a 2 cm. layer [Taffel and Revis, 1931; Notevarp and Pillgram-Larsen, 1932].

Practical applications of the vitameter.

$E_{328\,m\mu}$ *of oils and their concentrates.* The directions for the determination of vitamin A by means of the absorption at 328 $m\mu$ regard it as necessary to carry out the determination on the unsaponifiable fraction, except in the case of very potent preparations. It seems, though, as if the relation between the biological potency and spectrographic value is chiefly based on E of cod-liver oils themselves [Coward *et al.*, 1932; Chevallier and Chabre, 1933]. Separation of the unsaponifiable fraction is a considerable complication and greatly increases the demand for accuracy if the results are to be reliable. By the introduction of the photographically recording vitameter the measurement of absorption has become quite a simple operation with few sources of error, and if it were possible to avoid the preparation of the concentrate the determination of E would approach the determination of the blue value in simplicity. This latter is now in very extensive use for commercial and other mass analysis, but it is known to be a less good measure of the vitamin content than the absorption; it is messy and uses an unstable reagent, and it embraces a considerable number of sources of error. It would seem a great improvement if it were possible to replace it by the vitameter. We have therefore carried out a number of determinations on oils and their concentrates to obtain an estimate of the intrinsic absorption of the oils. These values will be found in Tables III and IV. Table III gives the values for three oils determined both spectrographically and in the vitameter, the values in Table IV are from the vitameter alone.

All due care has been taken when preparing the concentrates, the values marked * refer to concentrates prepared by a rapid method we have developed, which will not be described in detail here. The principle is that only a small amount of oil is saponified and the soap solution extracted with a known volume of toluene. This is then washed, dried and used directly for the determination. All values have been corrected for the absorption of the solvent. The values for the concentrates are calculated so that they correspond with the amount of oil from which they have been prepared as the amount of concentrate is of no interest in this connection.

It will be seen that the absorption values of concentrates of medicinal cod-liver oils of high quality are from 83 to 95 % of the corresponding absorption of the oil. Even crude oils with 3·2 g./100 g. free fatty acid have given absorptions in the concentrate of 83 and 88 % of that of the oil. To determine the $E_{328m\mu}$ of pure medicinal oils it would therefore appear unnecessary to separate the unsaponifiable fraction, and in the case of cruder oils it seems only necessary when a high degree of accuracy is needed. The intrinsic absorption of these oils must be small, especially as it cannot *a priori* be supposed that the concentrates can be prepared entirely without loss.

In this connection it is interesting to note that Morgan *et al.* [1934] state that the biological activity of concentrates is 85 to 95 % of the corresponding value of the oils and that Evers and Smith [1934] find values of E for concentrates of fresh medicinal cod-liver oils which are 83–94 % of the values for the oils themselves.

E *determined in the vitameter in relation to the blue value.*

We have obtained hundreds of parallel determinations of E and the blue value, as these are carried out simultaneously as a rule, and have found a satisfactory proportionality between the two. We are aware that this is not usually found for the oils by other authors [Coward *et al.*, 1932, *etc.*], whereas it is found for the concentrates [*e.g.* McWalter, 1934]. Our evaluation of the blue value differs from the usual, however, so it is necessary to explain this.

It is a well-known fact that the number of Lovibond glasses necessary for matching the antimony trichloride blue value is not proportional to the concentration of chromogen. If it is not possible to obtain a direct match for 0·04 g., owing to the depth of the colour, I have found that the true blue value, *i.e.* the value that would have been found if the matching of 0·04 g. in a 1 cm. cell had been possible, can be calculated by a formula of the following type:

$$B = b . d^x,$$

where b is the blue value actually measured, and d the dilution factor. x was originally determined to be 0·7 from a very great number of blue values carried out at different concentrations [Notevarp and Hjorth-Hansen, 1932]. Later on it was possible to check the formula over a much greater range (B.V. = 4 to B.V. = 150) in relation to spectrographic measurements, and it was found that $x = 0·8$ gave the best agreement [Notevarp and Weedon, 1933]. Detailed publications dealing with the subject are in preparation.

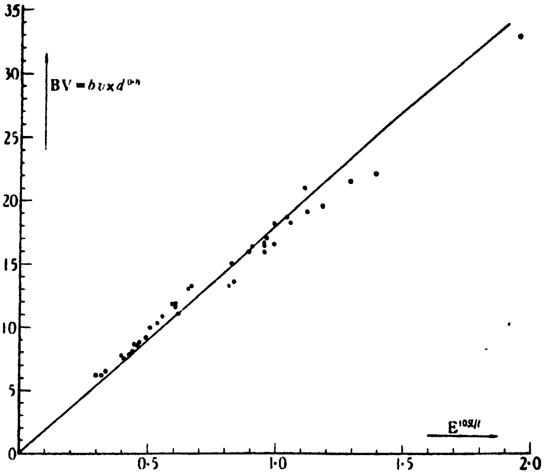

Fig. 3.

Fig. 3 shows how blue values calculated in this way give proportionality with E determined in the vitameter.

Destruction of the vitamin. Differential determinations.

The intrinsic absorption of absorbing oils may be eliminated by separating the unsaponifiable fraction, but this is of course not possible when the absorbing substances are of the same chemical nature as the vitamin. This will often be the case with oils and fats of a low vitamin potency, such as herring oils, muscle oils of other fat fishes, vitaminised margarine, butter *etc.*

To estimate the absorption due to vitamin A it will then be necessary to remove either the foreign absorbents or the vitamin. The removal of pigments by means of adsorbent carbon is mentioned by Gillam *et al.* [1933].

It has been attempted to remove the vitamin in various ways. McWalter [1934] describes the effect of heat and aëration; irradiation has also been mentioned. We have tried these various methods of destruction, with the result that oxidation and heat have been rejected as uncertain. Oxidation will often give rise to substances that absorb light at 328 $m\mu$, especially when there are minute quantities of fat present. Irradiation seems to give much better results; even when an oil is dissolved direct in alcohol, it appears to be possible to destroy vitamin A by light without the formation of appreciable amounts of absorbing substances. The difference agrees with what would be expected from the absorption of the concentrate or the blue value.

This subject will also be treated more in detail in a later publication, as there are still points that need closer investigation. Thus we have observed a hitherto inexplicable rise in the absorption of concentrates after destruction in a few cases. I will therefore only mention a few differential determinations here. The destruction has been effected through irradiation with a 500 watt Osram Vitalux lamp, the solutions being placed about 4 cm. from the surface of the lamp, usually for about 6 hours. The samples were cooled by a strong current of air, yet the temperature of the solution rose to about 40°.

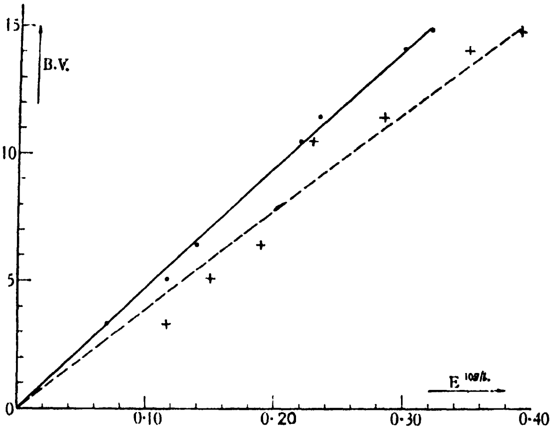

Fig. 4. + Gross values. • Net values (differential).

Fig. 4 shows the results for the ether extracts of samples of a vitamin preparation intended as a substitute for cod-liver oil. The gross absorption values do not agree very well with the blue values, while the differential determinations show as good agreement as may be expected from these methods. The blue values and E have been determined absolutely independently.

I would further mention that concentrates of a pure light cod-liver oil, or a pure halibut-liver oil, give values after irradiation from 5 % of the original value down to 0. This would appear to indicate that no substances that absorb light at 328 $m\mu$ are produced during the irradiation.

Destruction of the vitamin in the undiluted oil.

A sample of cod-liver oil was left on the roof for about 6 months (April 4th to October 10th, 1934) in a full, stoppered bottle of white glass. The following results were found:

	Colour 2 cm. Y.V.	Free fatty acid g./100 g.	Kreis value R.V.	Peroxide value	B.V. 0·04 g.	$E^{10\text{g}/\text{l}}_{328\,m\mu}$
Oil before irradiation	2·6	0·85	10·5	5·5	9·0	0·52
Oil after irradiation	0·3	1·00	1·4	6·3	0·5	0·027

The irradiated oil has only about 5 % of the original E value, which agrees with the blue value. This may indicate that the light has destroyed the vitamin without forming new absorbing substances, but the possibility exists that the irradiation has destroyed other absorbents.

E *for the unsaponifiable fraction of herring oil, mackerel oil and margarines.*

As a last instance of determinations of E by means of the vitameter I will mention some values for concentrates of herring and mackerel oils and margarines, in Table V. The values are calculated so as to correspond with the amount of original substance.

Table V. *Concentrates of different oils and margarines.*

Sample		$E_{328\,m\mu}$ calc. for 10g. oil/l.			Blue value calc. for 0·04 g. oil ($B=b.d^{0\cdot8}$)
		Gross value (initial)	After destruction	Net value difference	
Herring oils:					
From fresh herrings	I	0·081	0·014	0·067	2·4
	II	0·119	0·059	0·060	2·4
Salted	Males	0·072	0·031	0·041	1·6
	Females	0·057	0·018	0·039	1·8
Herring meal		0·066	0·029	0·035	0·9
Mackerel oils:					
From frozen mackerel	I	0·173	0·072	0·101	4·0
	II	0·157	0·030	0·127	5·0
Margarines:					
Vitaminised I		0·019	0·012	0·007	0·3
II		0·013	0·009	0·004	0·15

The unsaponifiable fractions have been prepared in the usual way or by the rapid method mentioned earlier. E and the blue value have been determined in the concentrate, and then the solution has been irradiated until the E value was constant.

SUMMARY.

The Hilger vitameter A has been equipped with a simple device for photographic recording of the readings, which makes it possible to determine $E_{328\,m\mu}$ of oils, concentrates and the like with considerable accuracy.

The vitameter values give good agreement with spectrographic values, both for oils and their concentrates. Determinations have been carried out on pure and crude cod-liver oils, halibut-liver oils, concentrates of herring oil and extracts of commercial vitamin A preparations.

The vitameter values agree with the blue values found. The absorption of the unsaponifiable matter of pure cod-liver oils approaches that of the oil itself; normally 85–90 % is found. The reduction in absorption may be chiefly due to unavoidable losses during the preparation of the concentrate.

Vitamin A may be destroyed by irradiation, and it is thus possible to determine the vitamin by the difference in absorption before and after exposure to strong light. This eliminates any absorption due to substances other than vitamin A.

The Hilger vitameter A equipped with a device for photographic recording has proved to be a very useful instrument for the rapid determination of $E_{328\,m\mu}$ as a measure of vitamin A, and may be expected in many cases to replace the tintometer for rapid assay of the vitamin.

The author wishes to express his sincerest thanks to H. W. Weedon for much valuable help, especially in carrying out the spectrographic determinations and translating the manuscript. Further to L. Aure, who has carried out the majority of the vitameter determinations and a considerable part of the analytical work. Several other members of the staff have also contributed interested and helpful work.

Our thanks are due to Prof. B. Helland-Hansen, of the Geophysical Institute, Bergen, for placing their spectrograph at our disposal.

CL. MONOLAYERS OF PROTEOLYTIC ENZYMES AND PROTEINS.

III. ENZYME REACTIONS AND PENETRATION OF PROTEIN MONOLAYERS.

BY JACK HENRY SCHULMAN AND
ARTHUR HENRY HUGHES[1].

From the Laboratory of Colloid Science, Cambridge.

(*Received March 23rd, 1935.*)

IN a recent publication Schulman and Rideal [1933] have studied the action of pancreatin and of specific proteolytic ferments on monolayers of protein. The changes which occurred in these films were such as might be expected from the properties of enzymes in bulk. Pancreatin differed from the specific proteolytic enzymes examined in that inactivation for reaction in the bulk phase did not destroy its surface reactivity on protein monolayers.

It was at that time suggested that this behaviour might be ascribed to a free enzyme or active group which on separation from some colloidal carrier could only operate on a substrate presented in the form of a monolayer. This original hypothesis has now been modified. In respect to crude enzyme preparations the situation is rendered more complex by the presence of highly capillary active materials of the class of the long chain fatty acids bound in such a way that they cannot be removed by fat solvents such as chloroform, light petroleum or benzene. It was found, however, that they could be removed by hot ethyl alcohol.

Further work showed that the surface activity of these inactivated pancreatin solutions was due to a fatty acid-protein complex. This reacts in a similar manner to pancreatin itself in respect to the p_H optimum and inhibition by sodium fluoride. It further has the property of replacing a film of tripalmitin by a film indistinguishable from one of palmitic acid.

Purified enzyme preparations such as Northrop's proteinase and crystalline pepsin and proteinases prepared by the method of Waldschmidt-Leitz caused hydrolysis of protein monolayers as they would in the bulk phase, and these preparations were found to contain no alcohol-soluble material. Before proceeding further in the study of these surface reactions it was thought advisable to examine the mechanism by which a film of one substance may be displaced by another substance present in solution, in order to differentiate the two phenomena as clearly as possible. The displacement mechanism as distinct from a chemical reaction is of intrinsic importance and presents some novel features. Experiments will be described showing that two processes may take place; first penetration of the original film by the second substance to form a stable mixed film, or alternatively complete displacement of the one by the other may ensue. The result is in some measure specific to the type of molecules engaged.

---

[1] Beit Memorial Research Fellow.

lowering. The tripalmitin film on the other hand exerts too high a maximum surface pressure to be displaced.

It is of interest that if we study displacements by a soap-protein complex instead of by soap alone, no displacements occur in solutions more acid than about p_H 3–4, since there is no free fatty acid, while again beyond p_H 12 no displacement occurs, either of tripalmitin or of protein films. The protein, by forming this relatively stable complex in acid and alkaline solutions, thus greatly reduces the concentration of free fatty acid or soap and accentuates the apparent p_H optimum of film displacements.

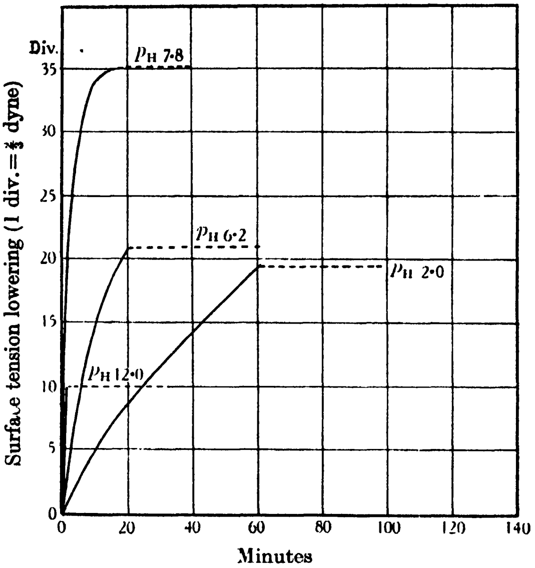

Fig. 4. Temperature 18–20°; Na oleate 0·0005 %.

The effect of 1 % sodium fluoride in coagulating a caseinogen-sodium oleat complex has been referred to. Inhibition of displacements results owing to th diminished concentration of free soap. Sodium fluoride has no effect on di placement caused by soap in the absence of protein.

Belfanti [1924] has described the isolation of fatty substances (Y) fron pancreatin by alcoholic extraction. Treatment of the alcoholic extract witl ether effected a further separation into a water-soluble and a water-insolubl fraction. Belfanti found that the former substance was strongly haemolyti and the latter much less so. These findings have been re-examined in the cours of the present work. Commercial pancreatin was extracted with alcohol sever times in the cold. The residue was found to be non-haemolytic while the origina pancreatin was strongly haemolytic. Further, the whole of the haemolyt principle was concentrated in the alcoholic extract. This extract on evaporati was indeed insoluble in water but dissolved readily in alkali. It behaved in f like a complex mixture of fatty acids. The haemolytic properties are, theref not surprising since sodium oleate at a concentration of 0·25 mg./ml. ca instantaneous haemolysis of washed guinea-pig erythrocytes at room tempera Again the precipitate obtained on acidifying alkali-treated pancreatin lik after redissolving in a neutral solution contained all the haemolytic power original pancreatin. It is significant further that the following specific proteinases obtained from pancreatin cause no haemolysis of guinea-pig erythrocytes: (1) Pancreatin freed from lipase and lipoids by alumina *B* adsorption. (2) Northrop's crystalline trypsin. (3) Northrop's chymotrypsin.

It would appear that haemolysis is attributable to the cholesterol-lecithin portion of the erythrocyte wall being exposed to the peptising action of the protein-fatty acid complexes present in ordinary pancreatin and not to proteolysis of any protein in the membrane.

Langenbeck [1934] describes several organic catalysts of the type of benzyl alcohol which in concentrations of some 20 mg./ml. cause a sevenfold acceleration of the autolysis of certain fats and esters. It is perhaps significant that sodium oleate acts in a manner similar to these compounds of Langenbeck under the same conditions, *i.e.* at 80–90° and at much smaller concentrations.

For example 6 ml. of a solution of a protein-fatty acid complex containing 15 mg. of solid matter obtained from pancreatin treated with NaOH increased the autolysis of 0·1 ml. of monobutyrin more than seven times at a temperature of 85°. In 3½ hours 6·75 ml. *N*/80 NaOH were required for the titre at 85° compared with 0·9 ml. in the absence of the peptising agent. With 10 mg. sodium oleate in 3 hours at 95° 5·8 ml. *N*/80 NaOH were required compared with 1·8 ml. *N*/80 NaOH when the sodium oleate was absent. It is clear that sodium oleate increases the autolysis in a quite definite manner but the increased autolysis of the protein-soap complex is rather marked. It was further noticed that on addition of sufficient ethyl alcohol to render homogeneous an emulsion of 0·1 ml. monobutyrin in 5 ml. H_2O, the rate of autolysis was increased compared with that of an alcohol-free emulsion, while addition of soap no longer caused increased autolysis.

Increased autolysis due simply to increased dispersion of an insoluble oil by a suitable emulsifying agent would seem, therefore, to be a factor which cannot be neglected in these systems.

SUMMARY.

It has been found possible to extract from pancreatin a fatty acid-protein complex. This complex simulates the action of ferments on monolayers of protein and fats spread at an air-liquid interface. This behaviour explained the activity towards surface films of pancreatin preparations which were inactive in bulk. Specific proteolytic ferments do not contain this complex and consequently behave towards protein monolayers as they do in bulk.

We are much indebted both to Prof. Northrop for specimens of the purified proteolytic ferments and to Dr D. R. P. Murray for helpful criticism.

CLI. MONOLAYERS OF PROTEOLYTIC ENZYMES AND PROTEINS.

IV. MIXED UNIMOLECULAR FILMS.

By JACK HENRY SCHULMAN and
ARTHUR HENRY HUGHES[1].

From the Laboratory of Colloid Science, Cambridge.

(*Received March 23rd, 1935.*)

WHILST a considerable knowledge exists as to the properties and reactions of unimolecular films of pure substances at an air/liquid interface, comparatively little is known of the behaviour of two or more different substances present together as a mixed film. Such information is of importance in connection with reaction kinetics in unimolecular films and also in regard to the properties of naturally occurring membranes, which cannot be treated in terms of one substance or even of one class of substance.

The most important observations on mixed films are those of Adam [1928] on the so-called "condensing" effect of large molecules on smaller molecules when both are present in a mixed unimolecular film. Thus addition of cholesterol or of tripalmitin to myristic acid, which itself forms an expanded type of film with a limiting area at zero compression of about 50 sq. Å., causes the myristic acid to assume the liquid condensed state with a much smaller limiting area per molecule. According to Adam the vibratory movements of the hydrocarbon chains, which are of large amplitude in the expanded state, are greatly hindered by the large and physically inert cholesterol or tripalmitin molecules. Adam further emphasised that there was no evidence of direct compound formation in the type of mixed films examined by him, since the two-dimensional vapour-pressure is not reduced more than would be expected from the proportion of cholesterol molecules present in the film. In a less simple case Leathes [1925] has observed a similar effect of cholesterol in condensing an expanded film of lecithin, a point of some interest in connection with the stability of living cell membranes. By the method of surface potentials Hughes [1935] showed that the condensation in this case was not accompanied by any appreciable change in the dipole moments of the two components, but that the molecular orientation was retained to a higher compression in an equimolecular mixture than in any other mixture.

In the present work a further study has been made of more varied types of mixed films and it is shown that the condensing effect is but one of several distinct phenomena observable in these systems. Thus it was found that the stability of mixed films was closely related to an effect sometimes encountered in studying chemical reactions in unimolecular films. This effect, which may be termed "film penetration", is met with in certain cases when a capillary active substance (B) is introduced into the solution beneath a pre-existent film of another substance (A). There are three possibilities. First, the film A may be completely replaced by a unimolecular film of B; secondly, B may penetrate the film of A and produce a stable mixed film of A and B; or finally neither replacement nor penetration occurs, *i.e.* no change can be detected in the original film. Examples of each behaviour have been observed and the relation of each to the physical and chemical properties of the system is discussed.

[1] Beit Memorial Research Fellow.

EXPERIMENTAL.

Equimolecular mixtures were prepared in light petroleum solution of the following pairs of substances: oleic acid and hexadecyl alcohol; sphingosine and hexadecyl alcohol; oleic acid and tripalmitin; and mixtures in the molecular proportions of 3 : 1 respectively were prepared of oleic acid and triolein; oleic acid and tripalmitin; hexadecyl alcohol and triolein.

The mixed films obtained by spreading from these solutions were examined by the methods of surface potentials and of surface pressures. The dark-field microscope technique of Zocher and Stiebel [1930] was applied to examine cases of doubtful homogeneity of the surface film. The results for the surface pressures and surface potentials are shown in the accompanying figures, where n as abscissa represents the total number of molecules per square centimetre of both kinds.

(i) *Oleic acid and tripalmitin* (Figs. 1 and 2).

At p_H 7·4 ($M/25$ phosphate buffer) oleic acid forms a liquid expanded film of the soap with a limiting area per molecule at zero compression of 53 sq. Å. At the same p_H the mixture gives a limiting area of 55 sq. Å. per molecule and on compression the surface pressure and potential rise uniformly till $n = 3{\cdot}1 \times 10^{14}$ mols./sq. cm. Beyond this point the surface pressure remains constant at 21–22 dynes/cm., while the surface potential falls rapidly to a constant value of 175 mv. at $n = 5{\cdot}35 \times 10^{14}$. The surface pressure level corresponds to the equilibrium breaking pressure of a tripalmitin film and up to this point the observed surface potential curve is that corresponding to a simple mixed film of the two constituents. On further compression it must be supposed that the tripalmitin is collapsing under the pressure of the oleate, which remains as a unimolecular film. The final surface potential is the maximum obtainable with sodium oleate alone at this p_H. Optical examination of the mixed film reveals numerous minute crystallites in the broken film. These are not observed with a pure tripalmitin film, which shows long parallel strain lines on fracture and has no tendency to break up into these highly characteristic crystallites noticed in the mixed film. In other words the oleic acid may be said to "peptise" the tripalmitin.

The condensing action of tripalmitin on the oleate molecules is not great in the 1 : 3 ratio. The area per molecule at zero compression for the oleate alone is 53 sq. Å. at this p_H of 7·4, while in the mixture it is 50 sq. Å. In the 1 : 1 ratio the area per molecule is reduced to 40 sq. Å. at zero compression, assuming that the tripalmitin molecules have a constant area per molecule of 60 sq. Å.

Compression of the 1 : 1 mixed film gives the same collapse point on the surface pressure curve and a similar peak in the potential curve at a higher surface potential corresponding to the greater number of molecules with the higher electric moment (μ for tripalmitin $= 10{\cdot}0 \times 10^{-19}$ E.S.U. and for oleic acid $2{\cdot}1 \times 10^{-19}$ at p_H 2, $1{\cdot}0 \times 10^{-19}$ at p_H 7·0). On further compression the potential falls to that of sodium oleate alone. The calculation of the condensing effect of the tripalmitin on the oleate molecules is made as follows.

Let n = total number of molecules/sq. cm. of surface. In the 1 : 1 ratio let A be area/mol. in sq. Å. of oleate molecules, assuming tripalmitin to have an area/mol.

of 60 sq. Å. The observed value of n at zero compression of mixed film $= 2{\cdot}0 \times 10^{14}$, $\frac{1}{2}n \times 60 \times 10^{-16} =$ area occupied by tripalmitin in 1 sq. cm. of film, therefore $(1 - 30 \times 10^{-16}\, n) =$ area occupied by oleate, *i.e.*

$$A = \frac{(1 - 30 \times 10^{-16}\, n)}{\frac{n}{2}} \times 10^{16} = 40 \text{ sq. Å.}$$

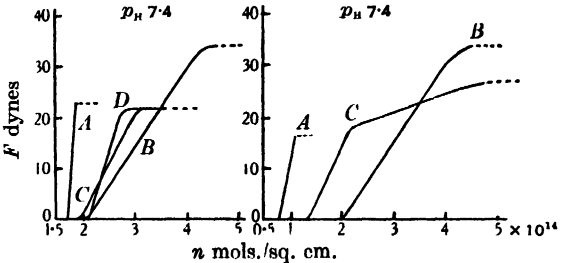

Fig. 1. Fig. 3.

Figs. 3 and 4. *A*, Triolein; *B*, oleic acid; *C*, 1 triolein : 3 oleic acid.

(ii) *Oleic acid and triolein* (Figs. 3 and 4).

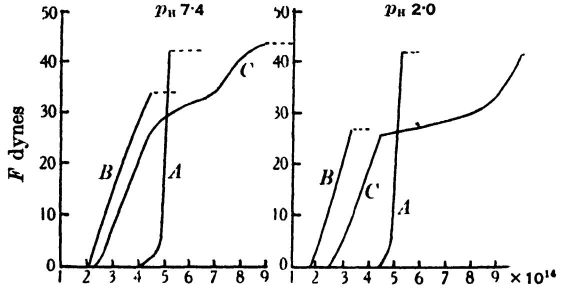
The 3 : 1 mixed film is homogeneous and liquid expanded from zero compression at $n = 1{\cdot}4 \times 10^{14}$ mols./sq. cm. up to $n = 2{\cdot}5 \times 10^{14}$ mols./sq. cm. At higher values of n the surface potential decreases while the surface pressure curve rises much less steeply than over the initial portion of the curve, indicating partial collapse of the triolein. The final collapse pressure and potential correspond to a mixture of triolein and oleic acid richer in oleic acid than the original 3 : 1 oleic acid : triolein.

The mutual effect of the two substances is negligible in that the observed limiting area per molecule in the mixed film (at zero compression) is within experimental error equal to that calculated for the simple mixture.

(iii) *Hexadecyl alcohol and oleic acid* (Figs. 5 and 6, 7 and 8).

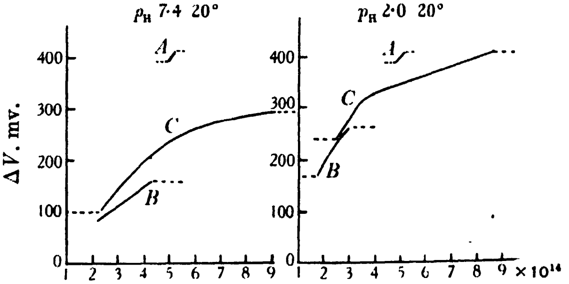
This mixed film was examined at p_H 2 (N/100 HCl) and at p_H 7·4.

At p_H 2 the mixed film collapses at the same pressure as oleic acid alone, indicating that the hexadecyl alcohol is displacing the oleic acid. The surface potential of the mixed film shows that in the early stages of compression a uniform mixed film is obtained, but that ultimately the potential rises to 410 mv. corresponding to a film of hexadecyl alcohol alone. The observed value of n at the final collapse point further shows that about half of the original total number of molecules in the film have been expelled, presumably as minute droplets of oleic acid. The condensing action of hexadecyl alcohol on oleic acid is negligible at this p_H (*cf.* Table I).



n mols./sq. cm.

Fig. 7. Fig. 5.



n mols./sq. cm.

Fig. 8. Fig. 6.

Figs. 5–8. *A*, Hexadecyl alcohol; *B*, oleic acid; *C*, 1 mol. alcohol : 1 mol. acid.

At p_H 7·4 the behaviour is different in that the surface potential never rises to that of hexadecyl alcohol alone. The surface pressure does not show a sharp collapse point corresponding to incipient collapse of the oleic acid but continues rising though less steeply beyond this point—as in the case of triolein and oleic acid. This difference in behaviour must be attributed to the formation of a relatively stable complex between the ionised oleate molecule and the hexadecyl alcohol, which increases their mutual adhesion at p_H 7·4 but does not exist at p_H 2.

Again, the limiting area at zero compression in the mixed film at p_H 7·4 is greater than that calculated assuming the areas of the components to be unchanged. Thus if we assume the hexadecyl alcohol to be unaltered, with an area per molecule of 20 sq. Å. the calculated area per molecule of oleic acid in the mixed film is 75 sq. Å. instead of 53 sq. Å. when alone. This must mean an expansion of the hexadecyl alcohol by the oleic acid molecules at this p_H (*cf.* Table I).

It is possible to calculate the surface potential in the mixed film from the known electric moments (μ_1, μ_2) of the two constituents, assuming that these have not been altered in the mixed film from the original values. We may write $\Delta V = 4\pi \frac{n}{2}(\mu_1+\mu_2)\times 300\times 10^3$ mv. for the surface potential of the mixed film of two components in equimolecular properties, n being the total number of molecules per sq. cm.

At p_H 2 it so happens that the vertical components of the electric moment per molecule of oleic acid and hexadecyl alcohol are identical ($\mu = 2{\cdot}1 \times 10^{-19}$ E.S.U.); and as seen in Fig. 6 the $\Delta V/n$ curve for the mixture is an extension of the $\Delta V/n$ curve for oleic acid or hexadecyl alcohol alone. At p_H 7·4 however, the value of μ for oleic acid has fallen to $1{\cdot}0 \times 10^{-19}$ E.S.U., owing to ionisation, and the mixed film of oleate and alcohol has a surface potential close to the value calculated by the above equation. At $n = 4{\cdot}0 \times 10^{-14}$ mols./sq. cm. (25 sq. Å.) the observed value of ΔV is 200 mv. The calculated value is 230 mv.

(iv) *Sphingosine and hexadecyl alcohol* (Figs. 9, 10, 11 and 12).

A much clearer example of complex formation in mixed films is afforded by an equimolecular mixture of sphingosine and hexadecyl alcohol.

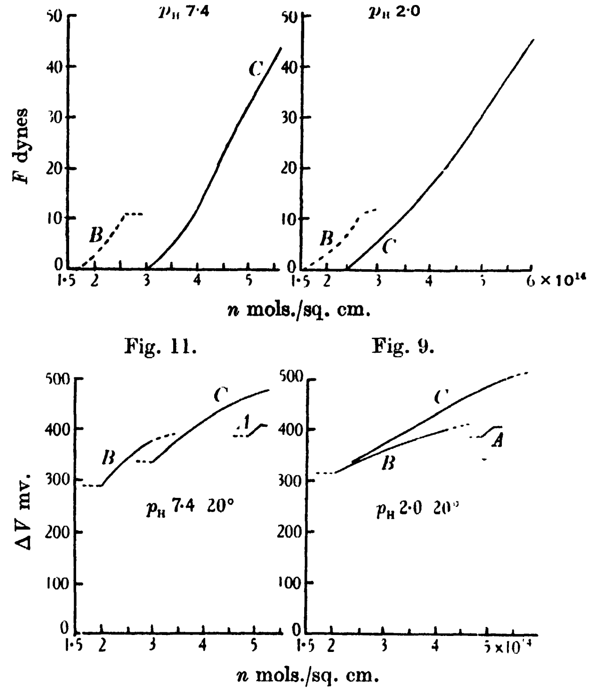


Fig. 11. Fig. 9.

Fig. 12. Fig. 10.

Figs. 9–12. *A*, Hexadecyl alcohol; *B*, sphingosine; *C*, 1 hex. alc. : 1 sphingosine.

Sphingosine alone on acid or neutral solutions forms unimolecular films which slowly dissolve in the underlying solution. The curves *B* for the surface pressures and potentials of sphingosine alone at p_H 2 and p_H 7·4 are obtained by compressing the films as rapidly as possible; the films are liquid expanded but the recorded areas per molecule are probably too small on account of the solubility effect. If now the equimolecular sphingosine-hexadecyl alcohol mixture be examined a stable mixed film is found at p_H 2 or p_H 7·4. This film collapses at an area per molecule of 20 sq. Å. and has a surface potential much higher than that of hexadecyl alcohol. The sphingosine is clearly not displaced by the hexadecyl alcohol although the latter can exert a much higher two-dimensional surface pressure than sphingosine. The alcohol must be supposed to hold the sphingosine in the film in an oriented mixed monolayer, or in other words the solubility of the sphingosine film is greatly reduced by the presence of the hexadecyl alcohol. The rise of surface potential is due to the high vertical component of the electric moment of sphingosine. As in the case of oleic acid and hexadecyl alcohol we may calculate the surface potential in the mixed film. The value of μ for sphingosine at p_H 7·4 is $3{\cdot}5 \times 10^{-19}$ E.S.U. at $n = 3{\cdot}0 \times 10^{14}$ mols./sq. cm., and for hexadecyl alcohol $\mu = 2{\cdot}1 \times 10^{-19}$ E.S.U. ($n = 5{\cdot}0 \times 10^{14}$ mols./sq. cm.).

The calculated value of ΔV in the mixed film at 25 sq. Å. ($n = 4{\cdot}0 \times 10^{14}$) is 422 mv. The observed value is 420 mv. Compression to $n = 5 \times 10^{14}$ (20 sq. Å.) gives an increase of ΔV to 470 mv.; the calculated value is 518, but the discrepancy is ascribable to partial collapse of the mixed film. It is clear that the potential of a mixed film may be equal to, less than or greater than that of one component, depending on the actual dipole moment of the other component and the degree to which the orientation is retained on compression of the mixture.

The condensing effect.

In the case of the hexadecyl alcohol and oleic acid mixed film at p_H 7·4 it was noted that the oleic acid apparently causes an expansion of the hexadecyl alcohol film, and that the hexadecyl alcohol is thus not condensing the expanded film of oleic acid. It is useful to summarise these area changes in the following manner. If there is no mutual effect on the limiting area per molecule, and x is the mol-fraction in the mixture of component 1, we may write:

$$A = A_1 x + A_2 (1 - x),$$

where A is the calculated area per molecule at zero compression, A_1 and A_2 being the values for the two components.

In Table I these calculated values are compared with the observed values in the various mixed films.

Table I.

Components		(Sq. Å.)						
1	2	p_H	x	A_1	A_2	A (calc.)	A (obs.)	Difference
Hexadecyl alcohol	Oleic acid	2	0·5	21	55	38	41	+3
		7·4	0·5	21	53	37	48	+11
Hexadecyl alcohol	Sphingosine	2	0·5	21	(67)	(44)	42	(−2)
		7·4	0·5	21	63	42	33	−9
Tripalmitin	Oleic acid	7·4	0·25	60	53	55	53	−2
		7·4	0·5	60	53	56·5	50	−6·5
Triolein	Oleic acid	7·4	0·25	132	53	73	72	−1
Triolein	Hexadecyl alcohol	2	0·25	132	21	49	57	+8

(The solubility of sphingosine at p_H 2 makes the estimated area per molecule in this case low.)

The cases of condensation, *i.e.* a negative result in the final column, are seen to occur with sphingosine and hexadecyl alcohol and with the equimolecular mixture of tripalmitin and oleic acid. In each case the expanded film must be considerably reduced in its limiting area. But this effect is clearly not dependent merely on the physical nature of the films of the two components. If instead of sphingosine and hexadecyl alcohol we take oleic acid and hexadecyl alcohol we now observe an increase in total area per molecule, slight at p_H 2 but at p_H 7·4 amounting to a 30 % increase. This must mean that the expanded film of oleic acid is causing an expansion of the condensed film of hexadecyl alcohol.

A similar expansion is noticed in the mixed film of 3 mols. oleic acid to 1 mol. of hexadecyl alcohol, to the extent of a 16 % increase on the estimated value. The original view of Adam that the inert molecules simply hinder the vibrations of the expanded molecules must now be extended to cases such as these where expanded molecules may increase the thermal agitation of the condensed molecules. It is of interest that where both components are in the expanded state, as in the case of triolein and oleic acid, the mutual effect is negligible.

The case of tripalmitin and oleic acid appears to be of the type discussed by Adam, the effect being one of condensation and proportional to the amount of tripalmitin in the mixture. The diversity of the other cases indicates that the area changes in a mixed film may be to some extent specific to the chemical nature of the molecules concerned, in that a complex film may be produced whose characteristics are very different from those of either component.

FILM PENETRATION.

In the introduction mention has been made of the possible effects of introducing a capillary active substance (*B*) beneath a unimolecular film of a substance *A*. Three possibilities were noted, (i) displacement of *A* by *B*, (ii) penetration of *A* by *B* to give a mixed film of *A* and *B*, (iii) no change in the film of *A*.

Examples of the third and simplest case are found when *B* is a relatively soluble substance. Thus ethyl alcohol, ethylamine, benzenesulphonic acid or aniline hydrochloride produces no change in any unimolecular films of insoluble substances so far studied. Again, sodium acetate in concentrations up to 30 % causes no displacement of a unimolecular film of tripalmitin, but sodium oleate at a concentration of 0·0005 % completely displaces the tripalmitin film in 2 hours at p_H 7·4. This same concentration of sodium oleate will not displace a film of hexadecyl alcohol, but penetrates to form a mixed unimolecular film of oleate and hexadecyl alcohol in about 20 minutes. These preliminary results were extended.

The experimental procedure was to inject the constituent *B* beneath the film of *A* spread on a solution of appropriate p_H. The bulk concentration of *B* was 5.10^{-14} %, unless otherwise stated; the temperature was 18–20°. The films were examined by the methods of surface potentials and surface pressures and by the ring surface tension apparatus. It was found that the ease of displacement or of penetration of *A* by *B* depended on several factors:

(*a*) the physical nature of the film;

(*b*) the nature of the penetrating molecules *B*;

(*c*) the bulk concentration of *B*;

(*d*) the degree of adsorption of *B* at the interface as dependent on the Gibbs adsorption relation.

These factors are exemplified in the following cases. The cases of displacement, as opposed to penetration alone, are few and will be considered first.

Displacement. A = tripalmitin or triolein; B = sodium oleate.

(*a*) *Physical nature of film.* At p_H 7·4 a tripalmitin film in the solid condensed state with an area of 58 sq. Å. per molecule at 15 dynes/cm., corresponding to close-packed vertical chains, is completely displaced in 2 hours by sodium oleate. A triolein film in the liquid expanded state at 100 sq. Å. per molecule and 14 dynes/cm. is displaced in about 30 minutes. This indicates that close packing of the film reduces the ease of penetration and thus also of displacement.

(*b*) *Nature of molecules of B.* At p_H 12 sodium oleate does not displace tripalmitin. At p_H 2 oleic acid takes from 3 to 4 hours to displace tripalmitin, but around neutrality the rate of displacement is a maximum. The fact that no displacement occurs at high p_H values is probably related to the much smaller surface tension lowering caused by the soap in this region as opposed to the very large lowering brought about in neutral solutions. The diminished rate of displacement in acid solutions is due to the formation of an emulsion of oleic acid and the resulting diminution in molecular concentration.

(*c*) *Bulk concentrations of B.* The rate of displacement of tripalmitin films by sodium oleate at the fixed p_H of 7·4 depends on the bulk concentration of oleate. At 5×10^{-3} % displacement is complete in about 30 minutes, at 5×10^{-4} % in about 2 hours, while at 5×10^{-5} % it is incomplete in 10 hours.

(*d*) *Surface adsorption of B.* As already mentioned, relatively soluble capillary active molecules such as ethyl alcohol even in high concentrations (up to 5 %) cause no displacement; presumably since the adsorption beneath the film is too small. Very long chain substances, stearic and higher fatty acids and their sodium salts are much less effective than sodium oleate (or myristate) since they are too insoluble in the bulk solution to give a high enough concentration in the Gibbs layer.

Penetration (without displacement).

In these cases the experimental observation is that a film *A* at an initial very high surface compression, say 20 dynes/cm., can admit molecules of a second substance *B*, from the underlying solution, although this substance itself may only be capable of exerting a much smaller surface pressure. The surface pressure rises rapidly to the highest value—up to 40 dynes/cm. in some cases—which can be exerted by *A* alone, while the surface potential may rise, fall or remain unchanged.

An example of this behaviour is afforded by the injection of sodium oleate beneath hexadecyl alcohol.

1 mg. of sodium oleate was injected beneath a film of hexadecyl alcohol at a compression of 12 dynes/cm. spread on 300 ml. of *M*/25 phosphate buffer at p_H 6·5. The initial value of the surface potential of the alcohol film, 410 mv., fell in 20 minutes to 290 mv. and reached a final value of 270 mv. The film changed from the viscous liquid condensed state to a very rigid mixed film. The value of the surface potential of the acid soap film on the free surface of the liquid was 132 mv. Simultaneously the surface pressure rose from 12 to 40 dynes/cm. as measured by the ring method and by the Langmuir trough. At p_H 2 no change in ΔV occurs, μ for oleic acid and hexadecyl alcohol being identical ($\mu = 2{\cdot}1 \times 10^{-19}$), although a similar change in surface pressure takes place as at p_H 6·5. A more spectacular case is shown by the injection of 1 mg. of psychosine sulphate beneath a film of hexadecyl alcohol at 10 dynes/cm. compression and a surface potential of 420 mv. at p_H 2. The surface pressure measured by the ring method rose in 30 minutes to a constant maximum value of 33 dynes/cm., while the surface potential increased by 178 mv. to 598 mv.

Similar large rises in surface pressure and film potential are observed with both sphingosine and psychosine in solution beneath films of hexadecyl alcohol, cholesterol and palmitic acid, and to a lesser extent beneath films of triolein, lecithin and tripalmitin.

Another case is that of sodium hexadecyl sulphate in solution beneath hexadecyl alcohol. Using the sulphate at 5×10^{-4} % the surface pressure of the hexadecyl alcohol film increased from 16 to 40 dynes/cm. in 2 minutes at p_H 2. The corresponding change in surface potential was from 426 mv. to 336 mv. in 2 minutes, finally reaching a value of 291 mv. The remarkable feature to be noticed is that the surface pressure at the free surface of this solution of sodium hexadecyl sulphate was very small; between 5 and 6 dynes/cm. Reduction of the bulk concentration to 5×10^{-5} % merely increased the time of reaching the final equilibrium (which was unchanged), while the surface pressure at the free surface was now less than 1 dyne/cm.

The phenomenon is very general. The film (*A*) may be a long chain acid, alcohol, amine, ether, tripalmitin, triolein, lecithin or cholesterol. The substance in solution (*B*) may be a long chain amine, sulphate, sulphonate, psychosine or sphingosine. Mixed films result in all cases except for fatty acids beneath fats and ether, when displacement results.

The points requiring explanation are, first, the mechanism of penetration; secondly, the formation of a stable mixed film, although one constituent may possess a much higher solubility than the other; thirdly, the fact that the rise or fall in surface potential of the original film corresponds to the entrance of many more molecules of the second component than there was initially room for.

In regard to this last point, it is clear from the experiments, already described in the first section, on those systems where the mixed films can be studied, that whether the surface potential rises or falls depends simply on the respective values of the dipole moments of the two components. In no case is there convincing evidence of any interaction of the dipoles consequent on mixed film formation. It is, however, remarkable that in the cases of film penetration the final value obtained for the surface potential of the mixed film is never far removed from the value corresponding to an equimolecular mixture of the two components—although in the penetration cases the constituent in the underlying solution is present in about 100 times the actual amount of the material in the original film.

In illustration we may refer to the cases of psychosine and sphingosine. In the form of its sulphate, in neutral and acid solutions, psychosine is very soluble in water and insoluble in light petroleum or benzene, thus excluding a study of its mixed films obtained by direct spreading. The related compound, sphingosine, is capable of study by spreading from benzene solution, and its mixed films have been described. Thus the equimolecular mixed film of hexadecyl alcohol and sphingosine is remarkably stable in spite of the much greater solubility of sphingosine in water. Injection of 10^{-3} g. of sphingosine beneath a film of hexadecyl alcohol containing 10^{-5} g. gives a rise of surface potential to a value approximately equal to that of the equimolecular mixture of sphingosine and hexadecyl alcohol at its maximum compression. While it is impossible to measure the dipole moment of psychosine owing to its extreme solubility, yet the similarity of its behaviour to that of sphingosine on injection beneath unimolecular films implies that its action is much the same.

In these cases of film penetration with formation of stable mixed films it is difficult to avoid the conclusion that the stability of the resultant film is due to the formation of a complex molecule of the two constituents whose stability is due in part to the hydrocarbon chains, and whose formation is not attended by radical changes in the dipole moments of the polar portions of the molecule.

A tentative generalisation may now be made.

(1) If in a mixed film of A and B, compression results in expulsion of one component (A) from the oriented monolayer, then injection of B beneath a film of A will result in complete displacement of A. That is, the mixed film is unstable and the AB complex, if it exists at all, is unstable.

(2) If the mixed film is stable on compression, penetration alone will occur on injection of B beneath A, and will result in a stable (AB) mixed film.

The mechanism of penetration and of displacement is at present obscure, but it is highly probable that displacement is in the first stages due to the formation of an unstable complex of the two molecules which is itself rapidly displaced by excess of the second component beneath the film. In the case of penetration of a close-packed solid condensed film such as that of tripalmitin by sodium oleate it is possible that the soap molecules reach the surface through minute cracks in the film and then spread over and peptise the tripalmitin film. In cases of penetration of liquid films such a mechanism is improbable, since it is difficult to visualise cracks in a liquid film. A possible explanation may be found along the following lines. One must suppose that the molecules in the film (A) are in equilibrium with a definite, though small, bulk concentration of its molecules. The equilibrium $A_{\text{film}} \rightleftarrows A_{\text{dissolved}}$ will be disturbed on the introduction of a second molecule B, which would alone set up its own equilibrium $B_{\text{film}} \rightleftarrows B_{\text{dissolved}}$. When a molecule of A leaves the surface, either A or B may now return and an interchange of A and B will be effected to an extent dependent on the relative adhesional forces of A to A, A to B, and B to B. If the attractive forces between A and B are greater than the cohesional forces between A and A or B and B a mixed film of an AB complex will result, whose stability is related to the stability of this complex. Such molecular complexes are formed between hexadecyl alcohol (or cholesterol) and oleic acid, hexadecylsulphonic acid, hexadecyl sulphate, psychosine or sphingosine; and their stability is sufficient to prevent ultimate displacement by the more soluble constituent. In other cases, such as triolein and oleic acid, the complex must be regarded as being very loose, and complete displacement ensues.

SUMMARY.

A study of two-component unimolecular films has been made, the components being long chain alcohols, acids, glycerides, sphingosine and psychosine. On compression of a mixed film one of two phenomena was found to occur: one component may displace the other from the surface or both components may remain as a stable mixed film. In the latter case there is some evidence of the existence of a complex between the two components which does not involve measurable dipole interaction. In these cases also it is possible to obtain the same mixed film by injection of the one component into the solution beneath a film of the other component. Otherwise complete displacement of the film results.

Our thanks are due to Prof. E. K. Rideal for helpful encouragement and advice, and to the Medical Research Council for financial assistance to one of us (J. H. S.).

OBITUARY NOTICES.

JUAN PEDIGE CHARLES CHANDRASENA.

(1887–1934.)

Juan Pedige Charles Chandrasena was born in Colombo on March 27th, 1887. He received his early education at Ananda College, Colombo, and always continued throughout his life to render valuable service to Buddhist education and religion. After qualifying as a trained teacher he joined the Government Technical School; his aptitude for Chemistry was encouraged by Dr A. F. Joseph, the Professor of Chemistry at the Ceylon Medical College and, after passing the Intermediate Examination in Science, Chandrasena was appointed Demonstrator in Chemistry at the latter institution on January 1st, 1914. The first examinations for the London Pass Degree in Science were instituted in Ceylon a little later and Chandrasena was one of the first to take the B.Sc. degree locally. In 1920 he proceeded to England on a Government Scholarship and studied at the Imperial College of Science for two years under Prof. Thorpe and Dr Ingold. The work done at the Imperial College, mostly on polycyclic structures, was published in the *Journal of the Chemical Society* (1922, **121**, 1306, 1542, 1552; 1925, **127**, 1677), and led to the Ph.D. degree and the D.I.C. On his return to Ceylon Chandrasena became Lecturer in Chemistry at University College, Colombo, and, on the retirement of Prof. N. Rae in 1933, he was appointed to the Chair of Chemistry, being the first Sinhalese Professor. He was also for some time Registrar of Patents.

Chandrasena became a member of the Biochemical Society in 1923.

Chandrasena's main research interest was with the economic and medical plants of Ceylon; he published two papers on the coconut in this *Journal* (1930, **24**, 1493; 1933, **27**, 3) and a note on atisine (*J. Chem. Soc.* 1933, 740). He had completed a monograph on the Medicinal Plants of Ceylon, which is to be published. One other paper appeared in 1930 (*J. Chem. Soc.* 1930, 2035).

Chandrasena's powerful influence as a teacher has been spoken of elsewhere (*J. Chem. Soc.* September 1934). The writer is glad to take this opportunity of referring to his untiring kindness to his colleagues in other Scientific Institutions in Ceylon; he was always interested and helpful in their particular problems, and his unexpected death on June 10th, 1934, has left a serious gap in local scientific circles.

R. C.

JOHN JAMES RICKARD MACLEOD[1].

(1876–1935.)

J. J. R. Macleod was born in the little village of Cluny, near Dunkeld; but his father, the late Rev. Robert Macleod, was shortly afterwards called to a charge in Aberdeen, and it was at the Aberdeen Grammar School and Aberdeen

---

[1] I wish to thank my colleague, Dr D. L. Thomson, a native of Aberdeen and an acquaintance of long standing of Prof. Macleod, for his help in furnishing the details of this biographical sketch.—J. B. C.

University that the son received his education. He graduated with honours in medicine in 1898, winning the Matthews Duncan and Fife Jamieson medals; he was also awarded the Anderson Travelling Scholarship, which enabled him to spend the following year in study at the Physiological Institute of the University of Leipzig. He returned to become Demonstrator in Physiology, and eventually Lecturer in Biochemistry, at the London Hospital Medical School; during this period he obtained the Diploma of Public Health at Cambridge, and was elected Mackinnon Research Scholar of the Royal Society. In 1903, however, he became Professor of Physiology at the Western Reserve University, Cleveland, Ohio, and retained this appointment until he went to the chair of Physiology at the University of Toronto in 1918. He had by this time attained an outstanding position in the field of carbohydrate metabolism, and it was both appropriate and fortunate that the discovery of insulin should have been made in his laboratory. Well-deserved honours were showered upon him; he received the 1924 Nobel prize for Medicine, jointly with his collaborator, Doctor (now Sir Frederick) Banting; he was elected a Fellow of the Royal Society in 1923, and awarded the Cameron prize of Edinburgh University; he received honorary degrees from Toronto, Western Reserve, Aberdeen, and Jefferson Medical College in Philadelphia. He retained the strongest affection for his native land, which he often revisited; and in 1928 was glad to accept appointment to the chair of Physiology at the University of Aberdeen, in succession to Prof. J. A. MacWilliam. Here he continued his researches, and stimulated others to investigation on similar lines, both within the University and at the Rowett Research Institute; he also served as an enthusiastic member of the Medical Research Council. He had built a most attractive home at Bieldside, from whose windows he could look up the beautiful valley of the Dee to the outliers of the Grampians, and in whose sunny garden he greatly delighted. Unhappily he fell a victim to an obstinate and crippling arthritis. He bore his disabling and most painful affliction with the greatest courage and fortitude and continued to direct the work of his Department long after he was forced to give up active participation. His health became gradually worse; pleurisy and at last pericarditis set in, and he died at his home on March 16th, 1935. He was married to a compatriot, Mary McWalters, by whom he is survived.

Macleod's first contributions to physiology were studies on the intracranial circulation (a subject to which he later returned) and on caisson disease, which were partly carried out in conjunction with Sir Leonard Hill. In his first years at Western Reserve he published a series of papers on the carbamates and one on purine metabolism. In 1907 there appeared the first of a long series of "Studies in Experimental Glycosuria", in the *American Journal of Physiology.* These in fact resolve themselves into a series of studies on the breakdown of liver glycogen, whether produced by piqure, stimulation of the splanchnics, reflexly, by asphyxia, or by injection of adrenaline. He probably owed to his year in Germany a vivid conception of the problem as one fundamentally involving the access of the diastatic enzyme to the stored glycogen and was at pains to show that fluctuations in the amount of enzyme present need not be taken into consideration. He became convinced that stimulation of the sympathetic supply, while it doubtless liberated adrenaline whose efficacy in accelerating glycogenolysis was indubitable, also affected the hepatic cells directly. In the later years of this epoch the increase in lactic acid production by the muscles in presence of experimental alkalosis was convincingly demonstrated.

In his first years at Toronto he studied the peculiarities of respiration in decerebrate animals and of the effects of anoxaemia and of excess oxygen thereon.

However, when Banting and Best, to whom he had accorded the facilities of his laboratory, succeeded in their attempts to demonstrate reduction of the hyperglycaemia and glycosuria of depancreatised dogs after injection of crude extracts of degenerated or of foetal pancreas, he returned to the problems of carbohydrate metabolism with renewed enthusiasm. The story of this collaborative research, which at length made insulin available in a form suitable for clinical and experimental use, has often been told. Macleod immediately took up the task of unravelling the mechanism whereby insulin reduced the blood sugar level and was at once able to dispose of obvious but erroneous theories, such as increased glycolysis within the circulation. That the action of insulin was at least not wholly hepatic was shown in his laboratory by Hepburn and Latchford, who demonstrated an effect of insulin on the sugar consumption of the isolated rabbit heart. With the technique at his disposal, it was not possible for him to account for the disappearing sugar in terms of increased oxidation and glycogen formation, as was subsequently done by Best, Dale, Hoet and Marks.

Macleod, influenced by his earlier studies with Pearce on the disappearance of sugar from the circulation of the eviscerated animal even in the absence of the pancreatic hormone, rejected the view that the oxidation of carbohydrate is seriously impeded in pancreatic diabetes, in favour of the view that in this state there is excessive production of glucose from protein and (since the observed protein metabolism is inadequate to account for the flooding of the body with glucose, if the oxidative destruction of carbohydrate is assumed to proceed unchecked) from fatty acids. This attitude involved regarding the respiratory quotient as made up of two components, representing hepatic glyconeogenesis and peripheral carbohydrate oxidation, and rejecting as fictitious the alleged constancy of the urinary dextrose-nitrogen ratio in the fasting diabetic animal. It at once brought him into conflict with the majority of American physiologists, headed by the late Graham Lusk. He obtained further evidence for his stand in careful studies, especially with Chaikoff, on dogs which had recovered from the trauma of pancreatectomy under insulin treatment and were then allowed to pass into diabetes; such animals, he maintained, displayed most variable dextrose-nitrogen ratios, and showed elevated respiratory quotients during exercise (shivering). In his discussion of insulin in *Physiological Reviews*, and in the monograph *Carbohydrate Metabolism and Insulin*, Macleod's extreme position is less apparent than in the later lectures published under the title *The Fuel of Life*, in which he felt that he was not speaking *ex cathedra*. Macleod's position in this difficult question has been loyally upheld by many of his pupils; but it is not improbable that the truth may lie in a compromise between the two extreme views, admitting some restriction of carbohydrate metabolism on the one hand, and increased glyconeogenesis, from protein at least, on the other.

One very important contribution was the discovery, by Karczag, Macleod and Orr (1925), that with proper precautions the liver and muscle glycogen stores of inbred rats could be brought by fasting to a level predictable with some accuracy; this made possible the use of rats for studies on glycogen distribution after insulin injection, or in other experimental conditions, and led to valuable studies by Macleod and his collaborators, and elsewhere, especially by Cori and Cori at Buffalo.

After his translation to Aberdeen, Macleod collaborated with workers at the Rowett Institute on problems of the specific rates of absorption (from the intestine) of various sugars and drew attention to the part played by the stomach in retaining highly concentrated solutions until considerable dilution had occurred. At the University he, with Peterson and others, resumed the study of the metabolism of the decerebrate eviscerated animal, with special reference to the respiratory quotient. His last important publication, with Donhoffer, marks a return to one of his early problems, the nervous control of the glycogenic function of the liver; they sought to show that the hyperglycaemia which follows trauma to the pons, in the rabbit (a modified piqure), was not wholly explicable in terms of adrenaline discharge, nor indeed in terms of hydrolysis of preformed glycogen at all, but in some cases at least indicated a stimulation of hepatic glyconeogenesis by the parasympathetic innervation.

In 1903 Macleod wrote a *Practical Physiology,* which is now little known. His later text-book, *Physiology and Biochemistry in Modern Medicine*, achieved greater success; it was distinguished from the start by a character which it still possesses, though the recent seventh edition is in the form of a symposium: that physiological and biochemical subjects are treated with equal care and mastery, and that the application of these studies to medicine is indicated without being over-emphasised.

Macleod was distinguished by cheerfulness, kindliness and patience; he was always willing to discuss the problems of his juniors sympathetically, and without a trace of condescension. It was typical of him that he would not allow an enthusiastic colleague or assistant to embark on an investigation without pointing out all the technical or theoretical difficulties which would probably be encountered, and yet would supply encouragement and all the practical assistance at his disposal.

CLII. THE PERIPHERAL ACTION OF INSULIN IN NORMAL ANIMALS.

By NELLES BOYD LAUGHTON
AND ARCHIBALD BRUCE MACALLUM.

From the Departments of Physiology and Biochemistry, University of Western Ontario, Faculty of Medicine.

(*Received March 14th, 1935.*)

SINCE the discovery of insulin little advance has been made in knowledge of its mode of action and of the changes which it brings about in the tissues.

Macleod [1934], summarising the work of the past 15 years, concludes that the conversion of blood sugar into muscle glycogen is not a conspicuous feature of insulin action in normal animals. In so far as oxidation of glucose in the tissues is responsible for the fall in the blood sugar, attention is called to the demonstration by Cori [1931] of a relationship between sugar disappearing from the blood and sugar metabolised after administration of insulin to normal animals. Macleod cites experiments by himself and collaborators which show that the respiratory quotient does not rise during the period when the blood sugar is falling, but only when the convulsive level of hypoglycaemia is reached, indicating that increased oxidation is not responsible for the lowering of blood sugar in the early stages of insulin action. Since it requires only the removal of 75 mg./100 ml. to reduce the blood sugar to the convulsive level in a rabbit, Macleod believes that his hypothesis, that insulin acts by converting the glucose into some intermediate form in the tissues still holds good, although the evidence is against this form being hexosephosphate.

A new approach to this problem is now possible as a result of the recent coordination of views on tissue respiration [*cf.* Keilin, 1933] and of conceptions of intermediary carbohydrate metabolism [*cf.* Cori and Cori, 1933].

This method of approach is illustrated in Fig. 1, which indicates the possible correlation of the respiratory system of the cell and the various intermediate stages in the breakdown of glucose to lactic acid. Certain agents are well known to inhibit various stages of cellular respiration in tissue slices and to interfere with intermediate stages in the conversion of glucose into lactic acid by the action of minced muscle preparations, pressed muscle juices and extracts. In Fig. 1 these inhibiting agents are indicated by frames. The arrows extend from the frames to the points where their specific retarding actions are exercised. Ethylurethane and cyanide inhibit dehydrogenase and oxidase respectively [Keilin, 1933], sodium fluoride has been used to prevent formation of pyruvic acid, and iodoacetic acid inhibits the interaction of pyruvic and glycerophosphoric acids [see Pollard and Pryde, 1933]. We have based our conclusions on the assumption that the same processes take place *in vivo* and that massive inhibition at any of the stages indicated in Fig. 1 will interfere with carbohydrate metabolism in the tissues generally, resulting in hyperglycaemia during the period when the inhibitor is active. Such behaviour is known to result from the action of cyanides [Ohmi, 1933, 1, 2] and of iodoacetic acid [Irving, 1934]. The hyperglycaemic action of anaesthetics and some narcotics is well known; as indicated later we have shown that fluorides have a similar effect. It has indeed been shown that insulin can lower the high blood sugar values produced by iodoacetic acid, cyanides and anaesthetics, but massive doses of insulin have been used and the observations have been made by different individuals so that it is impossible to assess any relative values to the insulin-antagonising actions of the above-mentioned compounds. We have therefore attempted to ascertain the point of maximum activity of insulin by using a standard amount of the latter and studying its relative effects on animals which have been given maximum tolerated doses of one of the inhibitors. A preliminary report has already been published [Laughton and Macallum, 1934].

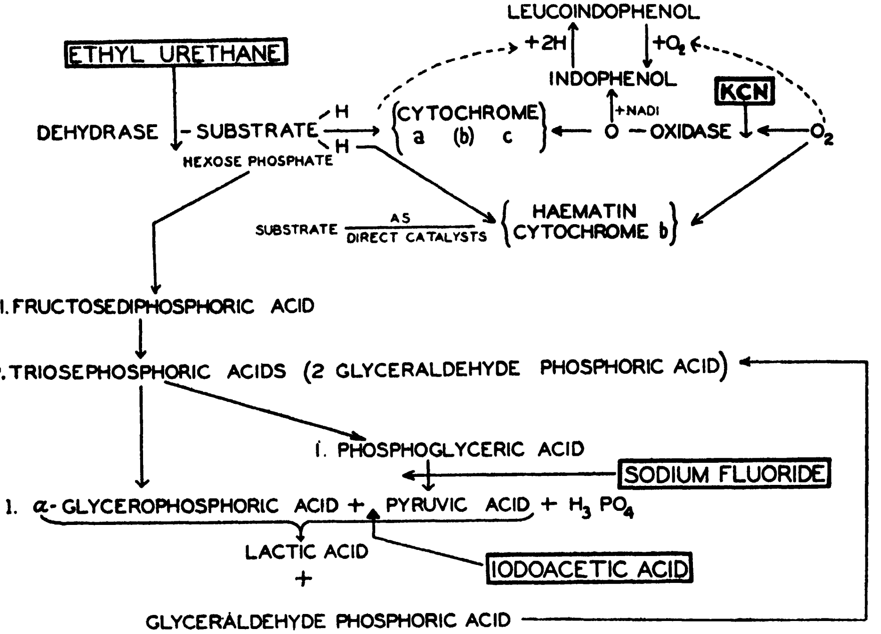

Fig. 1.

During the progress of this study 73 different animals were used. The maximum tolerated dose of each of the compounds was ascertained and records of the blood sugar under its action obtained over a period of time. In other groups of animals the maximum tolerated doses of the respective agents were administered to animals which had received 1 rabbit unit per 2 kg. body weight of insulin 30 or 60 minutes previously, and also in some cases insulin and the inhibitor were administered simultaneously; in a few cases insulin was given 60 minutes after the retarding substance. In all cases the blood sugar values were observed at specified intervals for a period of 3 hours.

Effects of inhibitors on action of insulin.

Cyanide. Curve 1, Fig. 2, represents the effect of 1 rabbit unit of insulin per 2 kg. on a normal rabbit. Curve 3 shows the blood sugar curve of a normal rabbit to which 1·2 mg. of KCN per kg. were administered intravenously, while curve 2 indicates the effect on the blood sugar of a rabbit of the standard dose of insulin at the beginning of the experiment followed 30 minutes later by intravenous injection of 1·2 mg. of KCN per kg. As indicated by the immediate rise in blood sugar, cyanide exercised a temporary inhibiting effect on the insulin which was comparable in duration to its hyperglycaemic effect in the normal rabbit.

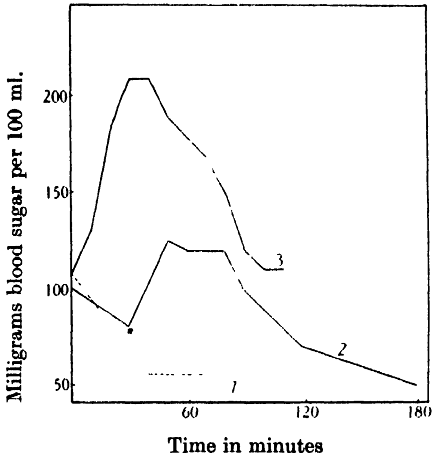

Fig. 2.

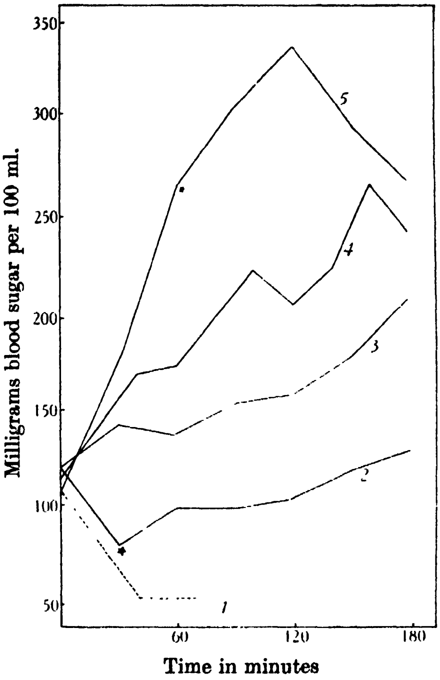

Fig. 3.

Fig. 2. 1. Insulinised rabbit; 2. Insulinised rabbit. *Cyanide injected; 3. Cyanide hyperglycaemia.

Fig. 3. 1. Insulinised rabbit; 2. Insulinised rabbit. *Urethane administered. 3. Insulin and urethane administered simultaneously; 4. Urethane hyperglycaemia; 5. Urethane hyperglycaemia. *Insulin administered.

Ethylurethane. Curve 1, Fig. 3, shows the normal action of the standard dose of insulin. Curve 2 shows the blood sugar values following the administration of the standard dose of insulin at the beginning of the experiment, followed 30 minutes later by intraperitoneal injection of 2·5 g. urethane per kg. (15 % soln.). Curve 3 gives the effect of simultaneous injection of the standard doses of insulin and urethane at the beginning of the experiment. Curve 4 shows the characteristic hyperglycaemia following the administration of the standard dose of urethane alone. Curve 5 indicates the effect of the standard amount of urethane given at the beginning of the experiment followed 60 minutes later by the standard dose of insulin.

Fluoride. Here again Curve 1 is the effect on a normal rabbit of the standard dose of insulin. Curve 3 shows the influence of 75 mg. of NaF (5 % soln.) given intraperitoneally and curve 2 that of the standard dose of insulin followed 60 minutes later by 75 mg. of NaF per kg.

Iodoacetic acid. Curve 1 shows the effect of the standard dose of insulin. Curve 2 gives the blood sugar values in a rabbit which was given the same dose of insulin followed 60 minutes later by intraperitoneal injection of 35 mg. of iodoacetic acid (1 % soln.) per kg., and curve 3 those of an animal which received 35 mg. iodoacetic acid per kg. and 60 minutes later the standard dose of insulin. Curve 4 represents the changes in blood sugar resulting from the administration of 75 mg. of iodoacetic acid per kg. at the beginning of the experiment.

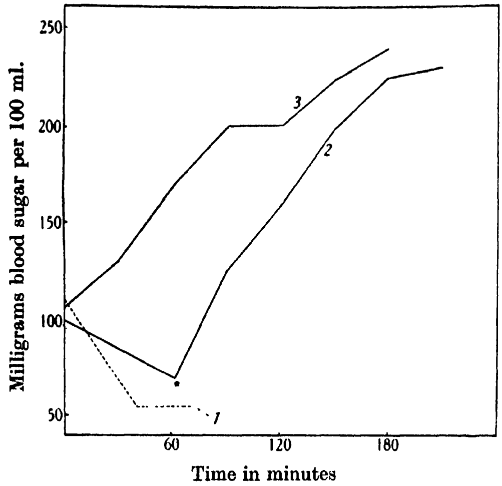

Fig. 4.

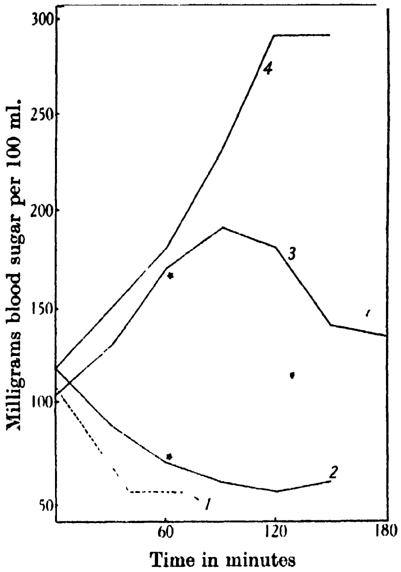

Fig. 5.

Discussion.

It will be noted that the inhibitors by themselves all produce marked hyperglycaemia. It is possible and probable that this effect is caused by inhibition of glucose breakdown at the points indicated in Fig. 1. In the case of cyanide it is obvious that insulin does not counteract the hyperglycaemic action (curve 2, Fig. 2), but that the hypoglycaemic action of insulin is delayed and reappears after the effect of cyanide has passed off. In the presence of insulin the duration of the inhibiting action of cyanide approximates to the duration of its hyperglycaemic action in the normal animal.

In the case of urethane the animals were deeply narcotised and the effect persisted throughout the duration of the experiment (curve 4, Fig. 3). It is also shown by curves 2, 3 and 5 that the urethane effect inhibited the usual action of insulin (curve 1).

In the animals treated with sodium fluoride steadily increasing hyperglycaemia was noted upon which insulin was without influence.

The most striking effects were found after administration of iodoacetic acid. As seen in curve 2, Fig. 5, where iodoacetic acid was administered 60 minutes after the standard dose of insulin, the hypoglycaemic action of insulin still persisted although it was somewhat delayed. The effect of insulin was again demonstrated (curve 3, Fig. 5) when it was injected 60 minutes after the standard amount of iodoacetic acid; here the lowering of blood sugar was not immediate, but in the course of an hour there was a distinct drop in the hyperglycaemia in direct contrast to the effect shown in curve 4 which followed the administration of iodoacetic acid alone.

A survey of the previously noted results indicates that insulin exercises its maximum activity at the point where pyruvic acid reacts with glycerophosphoric acid to form lactic acid and glyceraldehydephosphoric acid [see Pollard and Pryde, 1933]. It is also evident that interference with cell respiration (urethane and cyanides) lowers the efficiency of insulin and that sodium fluoride, which prevents the formation of pyruvic acid from glyceraldehydephosphoric acid is antagonistic to insulin. These results must be considered on a strictly relative basis since it is well known that the hyperglycaemia of narcosis and anaesthesia can be reduced by massive doses of insulin.

The principal criticism to be advanced against the preceding conclusions is that the hyperglycaemia is due to rapid mobilisation of liver glycogen rather than to retardation of tissue metabolism.

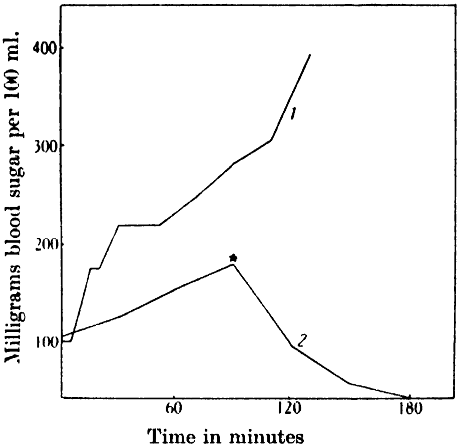

Fig. 6. 1. Adrenaline hyperglycaemia; 2. Adrenaline hyperglycaemia. *Insulin administered.

This criticism can be refuted by the experiment shown in Fig. 6 which illustrates the effect of the standard dose of insulin on adrenaline hyperglycaemia. In this series of experiments the peripheral metabolism was intact and here we see in curve 1 the characteristic response to adrenaline alone (1 ml. of 1:10,000 per kg.). In the experiment illustrated by curve 2, 90 minutes after the adrenaline was given, the rabbit received the standard dose of insulin used throughout the course of this work as a result of which there was a characteristic hypoglycaemic reaction terminating in a convulsion 90 minutes after the injection of insulin. Similar results were obtained in other animals in this series. We may then conclude that the amounts of insulin which have been used in the course of this work will effectively control hyperglycaemia originating from mobilisation of liver glycogen and consequently it is both possible and probable that the hyperglycaemias following the actions of the inhibitors are due to the specific actions of the latter in the respiratory cycle of the tissues and in the intermediate stages of glucose breakdown; this view has already been expressed by Irving [1934] in regard to iodoacetic acid. These experiments tend to support Macleod's view that insulin converts the sugar into an intermediate form in the tissues.

SUMMARY.

1. The action of maximum tolerated doses of cyanide, urethane, iodoacetic acid and sodium fluoride produces a hyperglycaemia which, except in the case of iodoacetic acid, neutralises, at least temporarily, the action of 1 rabbit unit of insulin per 2 kg. body weight.

2. Iodoacetic acid in maximum tolerated doses delays but does not neutralise the effect of 1 rabbit unit of insulin per 2 kg. body weight.

3. Insulin exercises its maximum effect upon the reaction between pyruvic and glycerophosphoric acids.

4. Mobilisation of liver glycogen is not the sole factor in the hyperglycaemias resulting from the substances used in the preceding experiments.

CLIII. STUDIES ON THE KINETICS OF HAEMOLYTIC SYSTEMS.

VII. THE DISAPPEARANCE OF LYSIN DURING STROMATOLYSIS.

BY ERIC PONDER.

From the Biological Laboratory, Cold Spring Harbor.

(*Received March 15th, 1935.*)

THE observations to be described in this paper are related to others which have been recently published on the disappearance of lysin during the process of haemolysis. Since lysin disappears during the latter process, presumably as a result of its combining with some component of the cell envelope [Ponder, 1934, 1], it is not surprising to find that the disappearance continues after haemolysis is complete, and during that period in which the cell envelopes are being further destroyed (stromatolysis). A study of the later stages of the process, however, reveals certain unexpected relations.

METHODS.

These are an extension of methods already described [Ponder, 1934, 1] and can be summarised as follows.

A suspension of thrice washed red cells is prepared, the cells from 1 ml. of blood being finally suspended in 20 ml. of 1 % NaCl. A suspension of stromata is also prepared from the blood of the same animal, the stromata being obtained by freezing and thawing, with subsequent washing until all haemoglobin is removed. This suspension is diluted so that 0·4 ml. of it is exactly equivalent, so far as its power to combine with lysin is concerned, to 0·4 ml. of the red cell suspension.

To find that quantity of lysin, *e.g.* saponin, which has disappeared from a system at the end of any time t_1, 0·4 ml. of the equivalent stroma suspension is allowed to react with 1·6 ml. of a given dilution of the lysin for this time at a constant temperature (30° in the following experiments, except where otherwise stated). At the end of the time t_1, 0·4 ml. of the red cell suspension is added to the system and the time t_2 required for its complete haemolysis determined. From a suitable time-dilution curve, the quantity of lysin which corresponds to t_2 is found, and this is the amount of lysin left free in the system at time t_1. Subtraction gives x, the quantity which has disappeared. This quantity can be found by this method for any initial concentration of lysin which is not so great as to give exceedingly rapid lysis or so small as to give values of t_2 in excess of about 60 minutes, and also for any value of t_1, from values much less than that which would correspond to complete lysis of 0·4 ml. of red cell suspension by the lysin initially present, up to values very much greater.

A detailed description of the procedure will be found in the paper referred to above, and it is enough to say that the results to be described here were obtained with cell and stroma suspensions made from the blood of both the rabbit and of man. The lysin used was saponin throughout, principally because its disappearance follows a regular course as haemolysis and subsequent stromatolysis proceed. Digitonin, the bile salts and the soaps, all show a rapid "initial absorption" at the cell surfaces, and only when this is complete do these lysins disappear in a regular manner; digitonin, moreover, is difficult to work with because of the high order of its time-dilution curves, and the bile salts and the soaps tend to be unstable.

EXPERIMENTAL RESULTS.

The course of the disappearance.

It can readily be shown that the disappearance of free saponin from a system containing stromata does not cease at a time corresponding to the complete lysis of an equivalent number of red cells but continues at a slower rate for a long time thereafter. This is shown in Table I and in Fig. 1.

Table I.

Initial lysin, γ	"Complete lysis"	γ lysin disappeared after 30 mins.	90 mins.	180 mins.	300 mins.	900 mins.
400	(30)	80	100	130	—	170
200	30	60	70	82	85	90
100	30	46	50	51	53	54
67	31	34	36	36	37	37

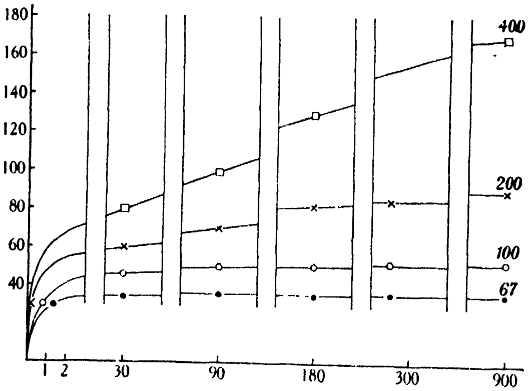

Fig. 1. Ordinate, γ of lysin used up; abscissa, time in mins. The scale on the abscissa has been broken up in order to show the general course of the curves. Squares, initial lysin concentration of 400γ; crosses 200γ, circles 100γ, dots 67γ.

Table I and Fig. 1 show (*a*) that after the lysin and stromata have reacted for a time which would just be necessary for haemolysis of 0·4 ml. of the equivalent red cell suspension ("complete lysis"), a constant amount of lysin has disappeared from the system, in this case 30γ [*cf.* Ponder, 1934, 1], and (*b*) that afterwards there is a continuous disappearance of lysin, the quantity which disappears tending to reach a final value asymptotically. The time it takes for the final value to be approached varies with the initial concentration of the lysin, for when the latter is small the final value is reached quite rapidly, whereas when it is great the concentration of lysin can be shown to be still falling even after many hours. Further, the amount of lysin which ultimately disappears is a function of the initial concentration and an almost linear function moreover, at least within the comparatively small range in which reliable experimental values can be obtained[1]. For very large values of initial lysin concentration the quantity finally removed appears to be less than would be obtained by extrapolating linearly from the values shown in Table I, but with very high lysin concentrations the errors of observation are enormous.

The essential point is that the disappearance of lysin apparently ceases while there is yet a large quantity of free lysin present in the system, and not, as has been supposed hitherto, when the concentration of free lysin has fallen to zero. It is unsafe, however, to attempt to determine the exact form of the curves in Fig. 1, for at least two reasons. (1) There is doubt regarding the reference time-dilution curve which should be used in finding how much lysin is left free in the system. During the early stages of the reaction, when the lysin is being used up rapidly, one must use a reference curve obtained by adding 0·8 ml. of cell suspension to 1·6 ml. of different dilutions of the lysin, for a system in which free lysin is energetically reacting with 0·4 ml. of stroma suspension *plus* 0·4 ml. of cell suspension is more like one in which the lysin is reacting with 0·8 ml. of cell suspension than it is like any other. When the reaction between lysin and stromata has reached equilibrium, on the other hand, the free lysin left reacts only with the added 0·4 ml. of cell suspension, and the proper reference time-dilution curve is one for 0·4 ml. of cell suspension added to 1·6 ml. of lysin *plus* 0·4 ml. of saline. The fact that one has to use one reference curve at the beginning of the reaction and another at the end introduces uncertainty into the units in which the disappearance of lysin is measured. The uncertainty may not be great, for there is not much difference between the two reference curves, but it is great enough to make a detailed analysis of the curves in Fig. 1 almost futile. (2) The results in Table I under the head "complete lysis" are those obtained at times which would be required for complete haemolysis of 0·4 ml. of the red cell suspension by the particular lysin dilution concerned. Now when lysin reacts with a red cell suspension, haemolysing it in time *t*, lysin is used up in reacting both with the cell envelopes (as in the case in which it reacts with a stroma suspension) and also in reacting with liberated haemoglobin; when the lysin reacts with a stroma suspension, on the other hand, there is no pigment and no inhibition, and so more lysin will be used up as a result of a combination with the cell envelopes in the same time *t*. It will be apparent that the quantity which has to unite with the envelopes in order to produce complete lysis cannot be found exactly unless the inhibitory effect of the liberated pigment is allowed for, and this cannot be done quantitatively in the meantime.

Although these difficulties prevent one from analysing the situation fully, there is no doubt as to the departure of the curves from the course which would be expected on the basis of existing theory, and at the same time the experimental results are sufficiently definite to allow the course of the disappearance of lysin to be discussed in a general sort of way. More specifically, it will be observed that the experimental curves are not described by the equations[1]

---

[1] For very large initial amounts of lysin, the times for complete haemolysis are too short to be measured exactly, and even such measurements as can be made are complicated by the mixing of the cell suspension and the lysin requiring appreciable time [*v.* Ponder, 1932]. For amounts less than about 67γ, the times for complete lysis may be so great that no measurements can be obtained at all. The experimental range is therefore severely limited and the difficulty in obtaining results correspondingly increased.

$$dx/dt = k\,(c-x)^n \qquad \ldots\ldots(1),$$

or

$$kt = \frac{p}{p-1}\{c^{\frac{p-1}{p}} - (c-x)^{\frac{p-1}{p}}\} \qquad \ldots\ldots(2),$$

where

$$p = \frac{1}{n},$$

even if the values assigned to c are those which correspond to the equilibria finally reached (the values in the last column of Table I). Fig. 2 shows an experimental and a calculated curve side by side, and it will be seen that the former falls off much too quickly. The only simple way of accounting for its course is to suppose that the velocity constant of the reaction is continually diminishing, the reaction itself being generally described by expressions (1) and (2). The matter will be discussed more fully below.

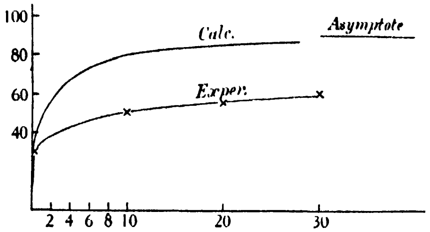

Fig. 2. An experimental curve and a calculated curve obtained from expression (2) with $n = 2{\cdot}0$, both approaching the same asymptote. Ordinate, x in γ; abscissa, time in mins.

The irreversible nature of the combination:

Since the equilibrium conditions are so different from those expected, it is important to test the assumption that the combination between lysin and cell component is irreversible. This is done in the following way.

To 1·6 ml. of a series of saponin dilutions, from about 1 in 5000 to about 1 in 20,000, is added 0·4 ml. of a stroma suspension about five times as concentrated as that used in the above experiments. The tubes are allowed to stand for several hours, at the end of which time the amount of lysin left free is determined. An exactly similar series of tubes is allowed to stand for the same length of time, at the end of which 2 ml. of saline are added to each; 2 ml. of the mixture are removed into a series of clean tubes, and the quantity of lysin left free is found by adding 0·4 ml. of cell suspension, as before. If the amount of lysin left free is exactly half that found in the case of the corresponding lysin dilution in the first series, addition of an equal volume of saline to the systems has done nothing more than dilute the free lysin, and has not caused any of the combined lysin to be liberated again.

The results given by this procedure are shown in Table II. In this experiment the stromata and lysin were allowed to react at 30° for 8 hours. All values are in γ.

---

[1] These equations ought to contain terms for the inhibitory effect of liberated haemoglobin on the course of the lytic reaction, but, as the introduction of these terms does not affect the general form of the expressions, the terms have been omitted. See Ponder [1932], and Ponder and Gordon [1934].

Table II.

Initial lysin concentration	Free lysin before dilution	Free lysin after dilution	Ratio
400	160·0	78·5	0·49
200	51·5	25·0	0·49
133	42·0	21·0	0·50
100	37·5	18·0	0·48

The fact that the ratio of free lysin found before and after dilution is so nearly 0·5 shows that the dilution does not cause lysin to be liberated from combination, *i.e.*, that the reaction between the cell component and the lysin is not reversible under these conditions. This is what has always been believed, and it is scarcely necessary to point out that had any other result been obtained the methods used in this and many earlier investigations would have been open to serious objection.

Temperature effects.

The failure of expressions such as equations (1) and (2) to describe the experimental results obtained during the whole course of haemolysis and subsequent stromatolysis is not altogether unexpected, for the expressions themselves have always been unsatisfactory in that they contain an arbitrary constant $n=1/p$. The values assumed by this constant under various conditions have always been puzzling, and it has already been recognised that the introduction of the constant may have no better justification than that it reconciles experimental results with a theory possibly faulty in itself [*v.* Ponder, 1934, 2]. It will suggest itself that the departure of the experimental curves (Fig. 1) from the course expected on the basis of the existing equations may throw light on the meaning of the constant n and its variations, and so I have carried out experiments which attempt to relate the behaviour of the constant to the course of the curves for the disappearance of lysin during haemolysis and stromatolysis. It happens that the easiest way in which n can be varied is by varying the temperature of the haemolytic systems [Ponder and Yeager, 1930].

1. The first step in such an investigation consists in showing that the concentration of the stroma suspension which is equivalent, so far as its power in reacting with lysin is concerned, to a given quantity of red cell suspension, does not itself vary with temperature. The procedure referred to under Methods, above, and already fully described [Ponder, 1934, 1], is repeated at 38, 22 and 7°, three temperatures associated with very different values of n for saponin systems. In each case one begins with a stroma suspension of unknown concentration (because of the variable yield in preparing it), and finds the extent to which it must be diluted so that 0·4 ml. of it is equivalent to 0·4 ml. of red cell suspension. It is necessary to select a dilution of lysin for which results can be obtained at all three temperatures, and so the lysin concentration with respect to which the determinations can be made is exceedingly limited; if the concentration is too great, lysis is so rapid at 38° that the time for complete lysis cannot be observed, and if the concentration is too small, complete lysis never occurs at 7°. This, however, is of little consequence, for the extent to which the stroma suspension has to be diluted seems to be virtually independent of the lysin concentration used to determine it. Table III shows typical results for an experiment in which the dilution of saponin was 1 in 30,000, and the cells and stromata were derived from the rabbit.

Table III.

Required dilution of stroma suspension	Temperature (° C.)
1 in 3·0	38
1 in 3·0	22
1 in 2·8	7

Allowing for experimental error, which in determinations such as these is considerable, these results show that the "equivalence" of the stroma suspension is independent of temperature.

2. The next step is to see whether the amounts of lysin which finally disappear from systems containing stromata and different initial concentrations of lysin are themselves affected by variations in temperature. This is done by repeating experiments such as shown in Table I at different temperatures, 0·4 ml. of equivalent stroma suspension being added to various dilutions of lysin, and the quantity of the latter left free after about 420 minutes being found as already described. For all practical purposes, equilibrium is reached within this time, even at 6°. Table IV shows results obtained for saponin and a rabbit stroma suspension at 38, 20 and 6°.

Table IV.

Initial lysin, γ	γ lysin disappeared after 420 mins. at		
	38°	20°	6°
670	—	420	370
500	—	300	280
400	220	230	210
333	170	190	180
250	130	140	130
200	120	120	120
100	70	70	—
67	51	49	—

Reading across the rows it will be seen that for each initial quantity of lysin the amount which finally disappears is substantially the same irrespective of the temperature, *i.e.*, the equilibrium conditions in these systems are not appreciably affected by temperature. This is interesting in view of the many theories which associate haemolysis *etc.* with an adsorption of lysin by the material of the cell envelope [Clark, 1933; Reiner, 1934], for in adsorption reactions larger amounts are usually adsorbed at lower temperatures. It may also be observed that the equilibrium conditions for the process of haemolysis, which is dependent on the value of x in expressions (1) and (2), are also scarcely affected by temperature. A study of the equilibrium conditions accordingly throws no light on the arbitrary constant n.

3. We can, however, extend the investigation by plotting the course of the curve for lysin utilisation at different temperatures, *e.g.*, at 38° and at 6°. Consider one concentration of lysis, such as 200γ, reacting with stromata at the two temperatures, and imagine the amount of lysin x which disappears plotted on the ordinate against time t on the abscissa (as in Fig. 3). When $t=0$, $x=0$, and when $t=\infty$ both curves pass to the same final value of x (2, above). They may nevertheless pursue entirely different courses between these two points, and on each there is a point of particular interest, *viz.*, the point which corresponds to the time required for the complete lysis of a quantity of red cell suspension equivalent to the amount of stroma suspension with which the lysin is

reacting. The peculiarity of this point lies in the fact that it has already been shown that, at any one temperature, the quantity of lysin used up at the time needed to produce complete haemolysis is constant, irrespective of the initial lysin concentration [Ponder, 1934, 1]. It is therefore important to establish whether or not the amount of lysin used up at the time required for complete lysis of a red cell suspension is constant irrespective of temperature, and at first sight it would appear that this could be done by plotting the curves for the utilisation of lysin in their entirety at the two different temperatures and seeing if both curves pass through points characterised by the same value of x on the ordinate and by values of t corresponding to the times for complete lysis of 0·4 ml. of red cell suspension at the two different temperatures on the abscissa. This, however, is impracticable, for if we select a concentration of lysin which produces complete haemolysis of 0·4 ml. of red cell suspension in a reasonable time at 6°, the time for complete lysis at 38° is so short that small variations from it cannot be measured with certainty. Conversely, if we select a concentration which gives complete lysis at 38° in a time sufficiently long to allow of small variations to be satisfactorily measured, lysis at 6° is not complete even in six or eight hours. We have accordingly to change the lysin concentration when we change the temperature, and to rely on the fact that the amount of lysin utilised at the moment of complete haemolysis is constant at any one temperature, irrespective of the initial lysin concentration. The procedure is best illustrated by a typical experiment.

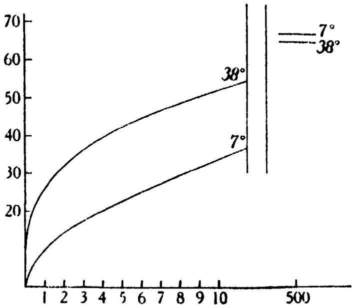

Fig. 3. Curves for the using up of lysin from an initial lysin concentration of 200γ at 38 and 7° respectively. Ordinate, x in γ; abscissa, time in mins. The equilibrium values, reached at about 500 mins. are substantially the same, and are shown by horizontal lines.

Taking 1·6 ml. of 1 in 100,000 saponin at 38° and adding 0·4 ml. of red cell suspension, one gets complete lysis in 11 seconds. Allowing the same amount of lysin to react with 0·4 ml. of equivalent stroma suspension for 11 seconds and then adding 0·4 ml. of cell suspension, one gets complete lysis in 42 seconds. The time required for complete lysis when 1·6 ml. of 1 in 120,000 saponin reacts with 0·8 ml. of cell suspension is 32 seconds, and that required when 1 in 160,000 saponin reacts under the same conditions is 90 seconds. Interpolating, the time of 42 seconds corresponds to a dilution of 1 in 134,000. Converting to the number of γ of lysin in the system of volume 2·4 ml., the initial amount of lysin is 40γ, and the amount left free at the end of 11 seconds is 30γ. The difference, x, is 10γ.

Repeating the same experiment at 6° with a lysin dilution of 1 in 1000, complete lysis of the 0·4 ml. of cell suspension occurs in 1·0 minute. Allowing the lysin to react with 0·4 ml. of equivalent stroma suspension for 1·0 minute, and then adding 0·4 ml. of cell suspension, we get complete lysis in 1·35 minutes. This corresponds to a lysin dilution of 1 in 10,300 reacting with 0·8 ml. of red cell suspension. Converting to γ, the initial amount of lysin is 400γ, and the amount left free after 1·0 minute is 389γ. The difference is 11γ, which is substantially the same as the difference obtained at 38°.

Experiments of this kind leave no doubt as to the constancy of the quantity of lysin which disappears in the time required for complete haemolysis, and that the amount appears to be independent of both temperature and initial lysin concentration. The determinations, of course, have a considerable experimental error attached, but the consistency with which the same result is obtained is, all things considered, remarkable.

4. Table V shows the result of an experiment in which the curves for the disappearance of lysin reacting with stromata are obtained in their entirety at 38 and at 7°. The lysin concentration used was 200 γ, and the times are in minutes.

Table V.

38°		7°	
t	x	t	x
0·0	0	0·0	0
0·017	(15)	2·2	15
2·2	33	5·0	23
10·0	52	10·0	34
500·0	65	500·0	67

Assuming equilibrium to have been reached in 500 minutes, both curves pass to the same equilibrium value (*cf.* 2, above). The point (0·017, 15) has been inserted in order to make the amount of lysin which disappears in 1 second at 38° and the time required for complete lysis of 0·4 ml. of red cell suspension at that temperature, correspond to the 15 γ of lysin used up in 2·2 minutes at 7°, this being the time required for complete lysis at 7°. The results are plotted in Fig. 3, and it will be seen that the two curves approach the same equilibrium value in quite different ways. They are like the curves of Fig. 1 in that neither can be described by expressions (1) and (2) with a constant value of k, but their course throws some light on the value of n in these equations, for the curve at 38°, with its sharp curvature, bears a general resemblance to a curve described by expression (2) with a value of n of about 3·0, while the flatter curve at 7° is not unlike that for a first order reaction, *i.e.*, a curve described by expression (2) with $n = 1{\cdot}0$. The variations of the value of n which have already been described as a result of changes in temperature are accordingly reflected in the form of the curve for the utilisation of lysin at various temperatures; at high temperatures, the value of n in the existing equations is 2·5 or greater, and the curve for the utilisation has a high degree of curvature, while at low temperatures the value of n approaches 1·0, and the curve for the utilisation of lysin is relatively flat.

DISCUSSION

The experimental curves for the process of haemolysis followed by stromatolysis differ from those expected on the basis of existing theory in two ways. (1) The equilibrium conditions are different, the using up of lysin ceasing while considerable quantities of lysin are still free in the system, and not when the free lysin concentration has fallen to zero. (2) The course of the curves for the utilisation of lysin cannot be described by the existing equations unless the value of the velocity constant k is imagined to vary. In considering the effect of these two observations on existing theory, it is convenient to treat them separately.

1. As shown in Tables I and IV, the amount of lysin which finally disappears as a result of reacting with the stromata is very nearly a linear function of the initial lysin present. Let the slope of the line be a. Rewriting (1) to express the idea that the velocity of the reaction is dependent on the quantity of lysin in excess of the equilibrium value, we have

$$dx/dt = k\,(ac - x)^n \qquad \text{......(3)},$$

which gives on integration

$$kt/a^{\frac{1-p}{p}} = \frac{p}{p-1}\{c^{\frac{p-1}{p}} - (c - x/a)^{\frac{p-1}{p}}\} \qquad \text{......(4)}.$$

Comparing this expression with expression (2), it will be clear that the two equations can be made to give the same values of t by multiplying every value of c in expression (4) by $1/a$, and changing the value of the velocity constant. Since the only way of measuring x is in terms of c and in units which are really arbitrary, and since there is no independent way of finding the value of the velocity constant of the reaction, the two equations are identical in so far as numerical results are concerned. The fact that the equilibrium conditions are other than those postulated in the existing theory accordingly makes no difference; this, of course, is wholly due to the relation between the values of x at equilibrium being linear with the initial values of c.

2. The fact that the course of the curves for the utilisation of lysin cannot be described by expression (2) with a constant value of the velocity constant, and therefore cannot be described by expression (4) either, leads to the unescapable conclusion that the existing theory is wrong in some fundamental respect. There are, of course, many ways in which it may be at fault, but the most obvious of these is that it supposes the velocity constant of the reaction to have the same value at all stages of the reaction, whereas in fact it may be steadily decreasing. On the basis that it is undergoing a continuous decrease it would obviously be possible to fit the experimental curves of Figs. 1 and 3 with a first order equation, or with an equation of any order less than that required to fit the time-dilution curve for haemolysis under the same conditions and by the existing equations, provided the velocity constant were allowed to decrease appropriately. If the possibility of such a decrease in k is once admitted, however, there is no justification for supposing that the decrease occurs only during stromatolysis and after haemolysis is complete; one might as well suppose it to begin to decrease from the very beginning of the process, and describe the entire course of the disappearance of lysin during both haemolysis and subsequent stromatolysis by a first order equation, together with an appropriate decrease in k as the reaction proceeds. Under such circumstances the meaning of the constant n in equations (2) and (4) would be clear, and this constant would merely express, in an arbitrary sort of way, the extent of the fall in the value of k during the course of haemolysis. For example, if the reaction were really of the first order, and n were 1·0, the value of k would not decrease at all, but if n were 2·0 and the reaction of the first order, k would have to decrease as the reaction proceeded, while if n were 3·0 the decrease would have to be greater. Such a hypothesis would, of course, leave us with no difficulty in accounting for the non-integral values which the constant n usually assumes.

Reaching a conclusion like this, of course, is tantamount to admitting that the equations hitherto used for describing the course of haemolysis are merely formal ones. In fact, it raises the disturbing doubt as to whether correct equations for the kinetics of any biological system can ever be formulated except in cases in which the behaviour of the velocity constant is first defined exactly, and such cases appear to be rare at the present time. The possibility of a mathematical description of the kinetics of haemolysis and stromatolysis, other than a purely formal one, at all events becomes rather remote[1].

---

[1] The reader will observe that, although the equations hitherto used to describe time-dilution and percentage haemolysis curves are probably only formal ones, the system of analysis used by myself and my collaborators in previous papers requires no essential modification. This is due to the analysis being based on the comparison of time-dilution and percentage haemolysis curves, obtained under one set of conditions, with similar "standard" curves obtained under simpler conditions. So far as the method of analysis is concerned, the experimental curves need never have been described by equations at all.

In conclusion, it ought to be remarked that the type of reaction which now appears to be responsible for haemolysis and stromatolysis is not a unique one. A reaction characterised by virtual irreversibility, a steadily decreasing velocity constant and an equilibrium which is reached when there is still free reactant in the system is met with in a number of processes, such as the dyeing of wool *etc.*, and is known as "pseudo-adsorption" or "anomalous adsorption", terms which mean little except that the reaction is not a stoichiometric one. In all such cases, as in the case of the reaction which results in haemolysis *etc.*, the decrease in the velocity constant is probably associated with the fact that the proper form of expression (1) is

$$dx/dt=k'.F\ (c-x).F\ (S-x) \qquad \ldots\ldots(5),$$

where S is the reacting surface of the substance which is acted on, and that the expression has to be simplified by writing $k=k'.F\ (S-x)$. Obviously, were $F\ (S-x)$ to equal $F\ (c-x)$, we would get expression (1) with $n=2$, but since we know nothing as to how the reacting surface decreases as the reaction proceeds, the whole problem is indeterminate.

SUMMARY.

This paper is concerned with the rate at which a lysin such as saponin is used up during the process of stromatolysis, or breaking down of the red cell envelopes, which follows haemolysis. It is shown that the equations which have hitherto been used to describe the using up of lysin during haemolysis are not applicable to the subsequent process. The contents of the paper do not lend themselves to detailed abstraction, but the principal conclusions are (*a*) that the reaction between cells and lysin is characterised by peculiar equilibrium conditions, in which using up of lysin ceases while there is still free in the system a quantity of lysin which is nearly linear with the amount initially present, (*b*) that the course of the disappearance of lysin is probably described by an equation, the exact form of which cannot be defined, in which there is a velocity constant which undergoes continual decrease as the reaction proceeds, (*c*) that such a decrease in the velocity constant is probably responsible for our having to introduce an arbitrary constant n into the existing equations for the kinetics of haemolysis, and (*d*) that although these existing equations are probably only formal ones, the conclusions based on the existing analysis of time-dilution and percentage haemolysis curves are themselves essentially unchanged.

CLIV. THE ANTIHAEMORRHAGIC VITAMIN OF THE CHICK.

By HENRIK DAM.

From the Biochemical Institute, University of Copenhagen.

(*Received April 8th, 1935.*)

Previous papers [Dam, 1929; 1930; Dam and Schönheyder, 1934] deal with a deficiency disease resembling scurvy in chicks which cannot be prevented by ascorbic acid and the cause of which is ascribed to the lack of a particular antihaemorrhagic factor (or factors) in the diet. Schönheyder [1935] has shown that there is an enormous retardation of the clotting of the blood of chicks suffering from this haemorrhagic diathesis.

The nature and distribution of the antihaemorrhagic factor have now been investigated. The investigation has led to the discovery of the fact that the factor is a fat-soluble vitamin occurring in hog-liver, hemp seed, certain cereals and vegetables, and must be different from vitamins A, D and E. It is proposed to term this factor *vitamin K* (Koagulations-Vitamin in German and the Scandinavian languages).

The following groups of foods have been tested: (1) cereals and seeds, (2) vegetables, (3) animal organs, (4) different fats and oils, (5) hen's egg.

Two of the most active substances, hog-liver and hemp seed, were divided into ether-soluble and ether-insoluble fractions, and, since the active principle was found to be fat-soluble, an elaborate fractionation of hog-liver fat was carried out. The question of the identity of the antihaemorrhagic factor with already known fat-soluble vitamins has been attacked by adding large amounts of vitamins A, D and E to the basal diet.

EXPERIMENTAL.

The animals (White Leghorns) were fed the experimental diets from the day after hatching. They were, as a rule, killed at the age of about 1 month. Housing *etc.* as described by Dam and Schönheyder [1934].

The examination of the animals includes, in addition to an inspection of the gizzard and other organs for haemorrhages, a determination of the time of clotting of the blood. The haemoglobin content of the blood has also been determined because it may give some information about the loss of blood through the haemorrhages.

The haemoglobin values were determined by the Sahli haemoglobinometer; the figures indicate the haemoglobin content in percentage of that in normal human blood.

The clotting time was determined by opening the brachial vein by a slight cut and allowing 2–3 ml. blood to drop slowly, during ½–¾ min., into a small porcelain bowl. The clotting time is reckoned from the venepuncture until complete clotting[1].

---

[1] Autopsy and clotting time determinations were kindly made by Dr F. Schönheyder to whom the author is indebted. Dr Schönheyder has in the meantime developed a new technique which enables the quantitative determination of the antihaemorrhagic vitamin to be made by a curative method based on a particularly exact measurement of the clotting time [1935]. The results presented in this paper were obtained by means of the former approximate method but give fairly accurate information about the degree of sickness of the animals.

* Dam and Schonheyder [1934].

Cereals and seeds were crushed and given instead of sucrose in diet 60 (with a small amount of $CaCO_3$ added roughly to balance the excess P_2O_5 in the cereals). *Organs* were dried in a current of air at a temperature not exceeding 45° and given as a powder instead of caseinogen in diet 60. *Vegetables* were minced and mixed into the diet or given in separate food containers. *Vitamin concentrates:* "vogan" (a vitamin A preparation from Merck, Darmstadt with 120,000 International Units per ml.), "vigantol" (pure vitamin D in sesame oil, from Merck, with 15,000 I.U. per ml.) and carotene (Hoffmann La Roche, Basel) dissolved in olive oil, were given *per os* by means of a tuberculin syringe, the doses being gradually increased from week to week. Vigantol was diluted with olive oil because the day doses otherwise would have been too small for accurate measurement with the syringe.

Hog-liver fat was put at the author's disposal by the firm of Medicinalco, Copenhagen. It was, according to the statement of the manufacturer, prepared by percolation of the desiccated liver with light petroleum several times, and thereafter with ether. The solvents were removed *in vacuo*. The percolated liver was used in diet 124 after having been further extracted with ether in a Soxhlet apparatus for 3 days. Hemp seed oil was prepared by percolating the crushed seeds with ether, and the seeds were further extracted with ether for several days before they were used in the diet as "ether-extracted hemp seed". Wheat germ oil was prepared from the fresh germ which had just been dried in air at 35°. The extraction was carried out in a large Soxhlet apparatus within 8 hours, the bulk of the ether was distilled off in CO_2 and the rest removed *in vacuo*. All oils were stored in the ice-box in completely filled containers and the liver fat *in vacuo*. The oils were used within 2 months of the day of preparation. The ether was in all cases freshly distilled and tested with mercury before use. Non-saponifiable matter of liver fat was prepared by cold saponification of 100 g. of the fat in 250 ml. ether with 40 g. KOH in 250 ml. methyl alcohol for 16–24 hours, addition of water and shaking 3–4 times with more ether; the ether extracts were shaken 3 times with aqueous KOH and then with water to neutral reaction. The extraction and purification of the ether extract were carried out in one day (in the dark room). After standing overnight in the ice-box with Na_2SO_4 and filtering, the solution was concentrated (in CO_2 and then *in vacuo*) to 100 ml. On standing overnight in the ice-box a precipitate of an amorphous substance, which is soluble in ether, could be filtered off. In the experiments in which the sterol and non-sterol fractions were tested, the bulk of the sterols was crystallised from light petroleum (after evaporation of the filtrate from the readily soluble substance). The rest of the sterols were precipitated by digitonin in small excess. The digitonin precipitate was decomposed by the pyridine-ether method of Schönheimer and Dam [1933] in the cold, and the sterol prepared in this way was added to the crystallised main portion. The filtrate from the digitonide was brought to dryness *in vacuo* and extracted with ether which takes up the "easily soluble non-sterol fraction".

The fatty acids were precipitated from the extracted soaps by sulphuric acid after evaporation of the alcohol *in vacuo*; the acids were washed with water by decantation.

In one experiment the non-saponifiable matter was divided into a "carotene" fraction and a "xanthophyll" fraction by partitioning between light petroleum and 90 % (by volume) methyl alcohol, after removing the sterols as far as possible by crystallisation.

* Dam and Schönheyder [1934].

RESULTS AND DISCUSSION.

Table I shows clearly that certain cereals and seeds will protect against the disease to a large extent whilst others are practically ineffective. Hemp seed appears to be particularly protective whilst unpolished rice, sunflower seed, yellow corn and rye are nearly valueless. The other cereals which have been tested appear to occupy a middle position.

Certain vegetables such as tomatoes, kale, orange peel *etc.* appear to have a fairly good action against the disease.

Among the organs so far tested, hog-liver is the most potent source of the active principle, while calf-brain, ox-lung and muscle are extremely poor. Ox-kidney, adrenals and calf-thymus occupy a middle position.

The hen's egg does not appear to be a very rich source, but the yolk will no doubt afford protection when given in large quantities.

All symptoms—clotting time, haemorrhages in the gizzard and other organs and haemoglobin content—are taken into consideration in estimating the condition of the animals, since at the present state of the investigation, the possibility that certain factors in the food may render the gizzard more resistant or may counteract the tendency to haemorrhage which is in turn due to the retarded clotting, has not been excluded. It is also possible that other factors or properties of the food may reduce the resistance of the gizzard or favour the occurrence of spontaneous haemorrhages.[1] Extremely retarded growth will undoubtedly counteract spontaneous haemorrhages.

It is not probable that the low haemoglobin values which are found in animals with large haemorrhages have anything to do with lack of copper, since similar results are obtained when the diet contains 10 % marmite. 1 g. marmite has been found to contain about 0·06 mg. Cu.

The results from groups 105, 124, 139 and 140 clearly demonstrate that the active principle in hog-liver fat can be extracted with ether. Corresponding experiments with hemp seed—groups 97, 120 and 132—lead to the conclusion that the ether extract of hemp seed is protective and that the action of the extracted seed is diminished but not entirely lost, thus suggesting that the active principle of hemp seed—like the carotene of green leaves—is not altogether in association with the fat. A series of other fats and oils was tested but none of them was found to be very potent.

McFarlane *et al.* [1931] have made the observation that chicks reared on an artificial diet with ether-extracted meat meal or ether-extracted white fish meal as the source of protein suffered from a tendency to haemorrhages whilst this was not the case when the meat meal or fish meal was not extracted with ether. This is in line with the results of the present paper. McFarlane *et al.* reported, however, that they could not observe haemorrhages when caseinogen, extracted or non-extracted, was used as protein. This latter statement is incompatible with the findings of Dam [1929; 1930] and Dam and Schönheyder [1934] as well as with the present experiments in which the diets contain caseinogen.

Fractionation of hog-liver fat into fatty acids—group 125—and non-saponifiable matter—group 126—revealed the fact that the antihaemorrhagic factor is to be found in the non-saponifiable fraction, and by further fractionation—groups 150, 151 and 152—the factor was found in the easily soluble non-sterol fraction, the sterols and a fraction sparingly soluble in ether being inactive. From a solution in light petroleum the factor could not be removed by repeated shaking with 90 % methyl alcohol—groups 171 and 172. In this respect the antihaemorrhagic factor behaves like vitamin E [Olcott and Mattill, 1931] and differs from vitamin A [Wolff *et al.*, 1930]. (The paper of the last-mentioned authors deals with the partition of vitamin A between light petroleum and ethyl alcohol, but, according to a personal communication from Prof. Wolff, it has been established that methyl alcohol behaves in the same manner.)

Addition of very large amounts of vitamins A and D to the diet does not prevent the disease—group 154, extra 4 % cod-liver oil—group 182, replacement of the cod-liver oil of the basal diet by halibut-liver oil containing 42,000 I.U. of A and 2800 I.U. of D per g. whereby the amounts of vitamins A and D are raised materially—group 175, addition of the concentrated vitamin A preparation "vogan"—group 163, addition of pure vitamin D in sesame oil "vigantol".

Commercial carotene (Hoffmann La Roche), which according to the statement of the firm contains 70–80 % β- and 30–20 % α- *plus* traces of γ-carotene, does not prevent the disease when given in quantities up to 9 mg. in 1 month.

---

[1] Certain food components, such as desiccated hog-liver, hog-liver fat, large amounts of cod-liver oil may produce symptoms resembling polyneuritis (3 animals in group 105, 3 in group 125, 2 in group 139). This polyneuritic condition is often accompanied by multiple minute haemorrhages in the cerebellum. Such haemorrhages, however, appear to be independent of the clotting time and general haemorrhagic condition since they may appear in groups where clotting time is normal and when no haemorrhages occur in other organs. The origin of these haemorrhages and of the polyneuritic symptoms is being studied further. Polyneuritic chicks are more liable to traumatic haemorrhages than others, owing to their convulsive movements.

According to Brockman and Völker [1934] hemp seed, which is very active, is practically devoid of carotene. The conclusion is therefore justified that the antihaemorrhagic vitamin cannot be identical with vitamins A or D or with α- or β-carotene. The antihaemorrhagic vitamin bears some resemblance to vitamin E. An experiment—group 185—in which the liver fat had been heated in a boiling water-bath for 12 hours in a 1–2 mm. thick film, showed that the factor is not destroyed to any great extent under these circumstances. According to Evans [1932] vitamin E will resist such treatment. On partition between light petroleum and 90 % methyl alcohol the vitamin behaves, as mentioned, like vitamin E. It appears that a loss occurs during the saponification.

Freshly prepared wheat germ oil, however, did not protect when given at a level of 4 or 10 % in the diet, and 24 % yielded an incomplete protection—groups 155, 148 and 186. 62 % wheat germ was rather inactive—group 86. Owing to the fact that such large amounts of wheat germ oil are insufficient to prevent the disease while 3–4 % of hog-liver fat is entirely protective, it must be considered very unlikely that the antihaemorrhagic vitamin is identical with vitamin E.

It is therefore suggested that the term *vitamin K* be used for the antihaemorrhagic factor until its chemical nature has been elucidated.

Comparison of the weights of the animals in groups 105, 124 and 172 appears to indicate that vitamin K does not promote growth.

The question whether the lack of this vitamin will produce the same symptoms in other animals than chicks is under investigation.

SUMMARY.

1. The nature and distribution of the antihaemorrhagic vitamin of the chick have been investigated.

2. The vitamin is fat-soluble and one of its richest sources is hog-liver fat, whilst cod-liver oil is practically devoid of it. The hen's egg contains the vitamin in the yolk but is apparently not an extremely rich source. In the vegetable kingdom hemp seed and certain vegetables are good sources, yellow corn, unpolished rice and sunflower seeds are very poor.

3. The vitamin occurs in the easily soluble non-sterol fraction of the unsaponifiable matter.

4. It cannot be identical with vitamin A or D because large amounts of these vitamins in the diet are completely ineffective in preventing the disease. It bears some resemblance to vitamin E with respect to solubility and resistance to heating in air, but is held to be different from E because large quantities of wheat germ and wheat germ oil do not afford complete protection against the disease.

5. It is suggested that the term *vitamin K* be used for the antihaemorrhagic factor.

6. The further chemical nature and the possible importance of the vitamin for other animals than the chick are under investigation.

Thanks are due to Medicinalco, Mfg. Co., for kindly supplying dried organs, liver fat *etc.*, and to Dr Sk. V. Gudjonsson, Statens Vitaminlaboratorium, for a standardised sample of halibut-liver oil.

CLV. GROWTH OF BLOW-FLY LARVAE ON BLOOD AND SERUM.

II. GROWTH IN ASSOCIATION WITH BACTERIA.

By RALPH PERCIVAL HOBSON.

From the Department of Entomology, London School of Hygiene and Tropical Medicine.

(*Received April 11th, 1935.*)

In the previous paper of this series [Hobson, 1933] it was shown that aseptic blow-fly larvae cannot develop on sterile blood or serum owing to lack of vitamin "B". The present paper deals with the growth of larvae on these foods when bacteria are present. The species of blow-fly used was *Lucilia sericata*, Meig., the Sheep Maggot Fly. The nutrition of these larvae on blood and serum has a direct bearing on the sheep maggot problem. Mackerras and Freney [1933] examined infested sheep in Australia and found that the maggots feed at first on a serous exudate and later on blood; this has been confirmed by field observations made by the present author in North Wales[1].

METHODS.

The larvae were reared on sterile horse blood and serum. The procedure adopted in the growth trials with pure bacterial cultures was identical with that used in the aseptic experiments [Hobson, 1933], except that the food was inoculated with the organism to be tested. The method of rearing naturally infected larvae on blood was as follows: 0·6 ml. samples of blood were diluted to 1·1 ml. and absorbed on standard lengths of surgical bandage in small test-tubes. A batch of eggs laid by one fly was incubated on a small piece of beef until the weight per larva was approximately 0·5 mg. 3 larvae were transferred to each tube, which was then closed with fine muslin and incubated in a moist atmosphere at 27°. Growth was measured by weighing the larvae at intervals. If eggs were used instead of young larvae, the results were essentially the same, but the individual variation was greater. In parallel experiments good agreement was found between duplicates, but in different series the growth rate varied somewhat, perhaps owing to differences in the bacterial flora.

Growth of infected larvae on blood and serum.

Although *Lucilia* larvae cannot develop on blood under aseptic conditions, fair growth occurs when bacteria are present owing to synthesis of vitamin "B". Fig. 1 shows some typical results. It will be seen that infected larvae grew more slowly on blood than on muscle (their natural food), and that the difference almost disappeared when yeast autolysate was added to blood. However, the effect of this extract was not entirely due to organic substances since yeast ash stimulated growth on infected blood. These curves also show that a considerable time elapsed before the larvae began to make rapid growth on blood; thus, when

[1] Most of the work described in this paper was carried out in London. The writer is now investigating the sheep maggot problem at the School of Agriculture, University College of North Wales, Bangor.

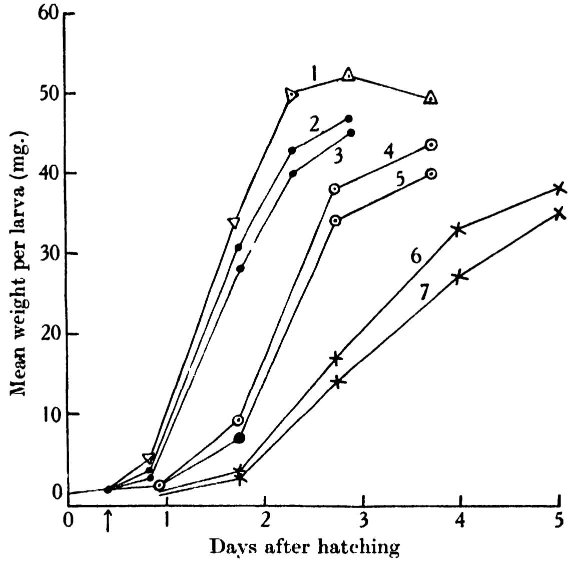

Fig. 1. Growth of blow-fly larvae on meat and blood. 1 △ meat; 2 and 3 • blood + yeast autolysate; 4 and 5 ⊙ blood + yeast ash; 6 and 7 × blood alone; ↑ indicates transfer of larvae from meat to blood.

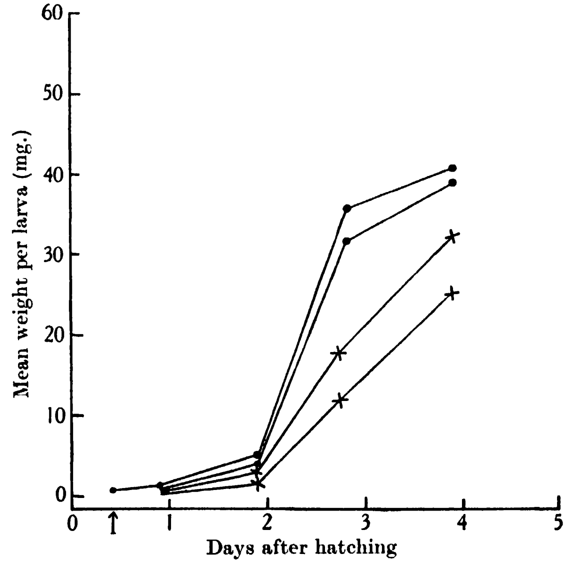

Fig. 2. Growth of blow-fly larvae on blood. • coagulated; × fluid. ↑ indicates transfer of larvae from meat to blood.

yeast ash was present, the larvae developed very slowly during the first day, growth later becoming almost normal. The period of slow growth was lengthened if the larvae were transferred each day to sterile blood. When aseptic larvae are fed on a diet which contains an insufficient amount of vitamin "B", growth is at first normal and later falls off, the reverse of what was found with infected larvae. In larvae reared without sterile precautions, the alimentary tract contains large numbers of bacteria; if this were the site of vitamin synthesis, a period of delayed growth would not follow the transference of larvae to a deficient diet. These results, therefore, suggest that the synthesis of vitamin "B" occurs in the food outside the body and not in the gut. This was confirmed by the observation that a change in the physical state of the food, heat-coagulation of the blood, resulted in improved growth (Fig. 2). This effect was not due to a difference in the bacterial flora as it will be shown later that coagulation of the blood has the same effect when pure cultures are used. Since the conditions in the gut are much the same whether the blood is fluid or coagulated, this result must be due to a difference in the growth of bacteria in the medium.

Growth-promoting effect of yeast ash.

Both muscle and yeast are rich in potassium and phosphorus, but blood contains relatively small amounts of these elements. Growth tests were, therefore, made with blood enriched with potash and phosphate; various salts were used, the amount being equivalent to 0·5 % sodium chloride. Before being mixed with blood, the salt solutions were neutralised with sodium hydroxide.

Table I. *Effect of mineral salts on the growth of larvae on blood.*

Substance added	Weight of larvae in mg. after two days' growth
1·1 % KH_2PO_4	34, 31
0·6 % KCl	10, 12
1·0 % NaH_2PO_4	35, 33
0·5 % NaCl	15, 9
1 % yeast ash	40, 34
2 % yeast ash	36, 33
Nil	12, 16

Table II. *Effect of mineral salts on the growth of larvae on serum.*

Substance added	Weight of larvae in mg.	
	3rd day	4th day
1·1 % KH_2PO_4	41, 46	—
1·0 % NaH_2PO_4	14, 16	25, 27
0·6 % KCl	—	4, 7
Nil	—	4, 5

The results given in Tables I and II show that the growth-promoting effect of yeast ash was entirely due to phosphate on a blood diet; in the case of serum, potash also improved growth. There appear to be two possible explanations of these results: (1) the amounts of phosphorus and potassium in blood and serum are insufficient for the requirements of the larvae; (2) the addition of potassium phosphate stimulates bacterial growth and synthesis of vitamin "B". Phosphorus analyses were, therefore, made on larvae and on the sample of blood used in these experiments. Organic matter was destroyed by oxidation with sulphuric and nitric acids, phosphorus being estimated colorimetrically by the Warren and Pugh [1930] modification of the method of Denigès [1920]. The results and calculations which follow are all expressed on a dry weight basis.

Table III shows the results of the phosphorus determinations. It was also necessary to know what proportion of blood is converted into larval tissue. An

Table III. *Phosphorus content of blow-fly larvae.*

	% P on dry weight
Larvae reared on meat	0·76
Larvae reared on meat	0·70
Larvae reared on blood	0·77
Blood sample	0·125

excessive number of larvae were, therefore, fed on a mixture of blood and sodium phosphate until the food was entirely consumed. 32 % of the original dry weight of the blood was recovered as dried larvae. Thus, 100 g. of the blood supplied enough food, other than phosphorus, for the formation of at least 32 g. of larval tissue, but only contained as much phosphorus as 16 g. of larvae. Blood is, therefore, deficient in phosphorus, supplying about half the amount required by *Lucilia* larvae for normal growth. This calculation agrees well with the results of growth tests carried out with different amounts of added phosphate.

Table IV. *Effect of phosphate on growth of larvae on blood.*

mg. PO_4 added per 1 ml. blood	% P in blood (dry weight)	Weight of larvae in mg. after 2 days' growth
0	0·125	12, 14
0·4	0·19	19, 23
0·8	0·26	29, 30
1·6	0·39	34, 35
3·2	0·66	33, 31

Table IV shows that doubling the amount of phosphorus in blood produced optimum growth. It is of interest to note that the phosphorus content of larvae does not fall on a diet of blood alone; presumably they concentrate this element by oxidising a larger proportion of their food than usual. Although blood is poor in phosphorus as compared with muscle, this result is surprising as many insects feed solely on blood throughout their whole life cycle. However, blow-fly larvae grow very rapidly and convert a high percentage of their food into tissue. Blood-sucking insects probably burn a larger proportion of their food, so obtaining more mineral matter per unit weight of tissue formed. It should be noted that the various basal diets used in the aseptic experiments on vitamin "B" [Hobson, 1933] all contained yeast fractions; these diets were not deficient in mineral salts as larvae grew well on them when bacteria were present.

Growth of larvae on blood infected with pure cultures.

In order to determine whether synthesis of vitamin "B" is due to a specific organism, sterile larvae were fed on blood infected with pure cultures of various organisms isolated from blow-fly larvae. The numbers assigned to the different types are the same as those used in the description of the bacterial flora [Hobson, 1932]; these are non-lactose-fermenting bacilli, which predominate in the gut of the larvae and in blown meat. Tests were also made with *B. coli*. The basal diet consisted of sterile blood mixed with an equal volume of 0·5 % sodium phosphate solution. The food was prepared with aseptic precautions; to ensure sterility, the tubes containing the blood were heated, either for 40 minutes at 75°, when coagulated blood was required, or twice at 50° for 30 minutes. The results (Table V) show the weights of the larvae after 3–4 days' growth. Each figure represents the mean weight of the larvae in one tube. It will be seen that with coagulated blood all the organisms tested produced good growth, the larvae

Table V. *Growth of larvae on blood infected with pure cultures. 1 °/₀ sodium phosphate added to blood.*

Organism used	Weight of 3-day old larvae (mg.)	
	Coagulated blood	Fluid blood
(1) Bacillus "A"	18, 22	2, 2·5
(4) "	34, 35	3, 6
(5) *Proteus vulgaris*	31, 35	—
(6) "	42, 44	16, 23
B. coli	38, 45	5, 6
Mixed infection; unsterilised eggs used	39, 43	30, 34
Aseptic	0·5, 1	—

developing at about the same rate as when the infection was mixed. However, the same organisms gave very poor results when the blood was not coagulated, the growth rate being distinctly inferior to that of unsterilised larvae. An attempt was made to isolate organisms able to promote larval growth on fluid blood. Single colonies were isolated from agar plates inoculated with blood on which larvae were feeding. One of these, No. 6, gave fair growth on uncoagulated blood.

These results show that, when larvae are growing on a deficient diet, synthesis of vitamin "B" is not due to a specific organism, but to various bacilli which develop in the gut and in the food. It was of interest to find that larvae grew well on coagulated blood when infected with *B. coli*. Since aseptic larvae respond to vitamin B_1 (Peters's antineuritic concentrate), when reared on sterile blood mixed with autoclaved yeast, this shows that *B. coli* can synthesise vitamin B_1 under the experimental conditions used. Previous workers have obtained conflicting results as to the ability of *B. coli* to synthesise this vitamin [see Peskett, 1933]. The marked effect of coagulating the blood appears puzzling at first sight. The explanation may be that bacteria would be concentrated on the surface of the blood coagulum. The larvae in this case feed by scraping at the surface, and would ingest a larger proportion of bacteria. Similarly; the stimulating effects of the larvae on bacterial growth, mechanical dispersion and excretion of trypsin [Hobson, 1931], would be more effective when larvae are feeding on the surface of a solid. Growth on a diet lacking in vitamin "B" is an autocatalytic reaction; bacterial action promotes larval growth, which, in turn, stimulates bacterial growth. Hence, the effect of any favourable factor tends to become exaggerated.

SUMMARY.

1. Blow-fly larvae are able to grow on blood when bacteria are present. Since aseptic larvae fail to develop on blood unless vitamin "B" is added, the natural flora must supply this vitamin.

2. The site of vitamin synthesis appears to be the food and not the intestine.

3. Blood contains insufficient amounts of phosphorus for the normal growth of larvae. Serum is deficient in both phosphorus and potassium.

4. When phosphate is added, larvae develop on unsterile blood at the usual rate except for a lag in the early stages.

5. Larvae can grow readily on blood infected with pure cultures of various bacilli isolated from the intestine and from blown meat. *B. coli* proved equally effective.

I wish to record my thanks to the Agricultural Research Council for a grant which entirely financed this work.

CLVI. ON A FAT-SOLUBLE GROWTH FACTOR REQUIRED BY BLOW-FLY LARVAE.

I. DISTRIBUTION AND PROPERTIES.

By RALPH PERCIVAL HOBSON[1].

From the Department of Entomology,
London School of Hygiene and Tropical Medicine.

(*Received April 11th, 1935.*)

Although there is good evidence that insects require vitamin B [see Uvarov, 1928; Hobson, 1933], little is known of their need for fat-soluble growth factors. The previous work will not be reviewed in detail at this stage, except to say that the suggestions of some workers that insects require vitamin A or E have little foundation. The present work arose from the observation that filtration of peptic digests of meat removes a substance which is essential for the growth of blow-fly larvae (*Lucilia sericata* Mg.) and which occurs in certain fats. An investigation was therefore made of the distribution and properties of the active substance.

Methods.

The basal diet used in this work was prepared as follows. Lean beef was digested with pepsin for 4 days at p_H 2, the digest being filtered through filter-paper and the solution concentrated on a water-bath. After a small amount of aqueous yeast extract had been added and the reaction adjusted to p_H 6 with

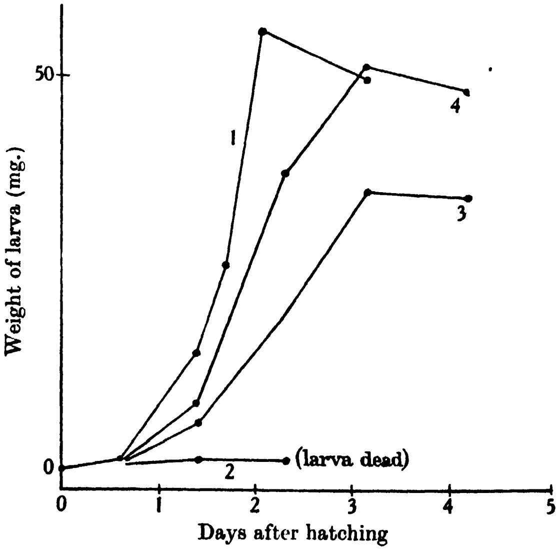

Fig. 1. Growth of blow-fly larvae on meat and peptone. 1, Meat; 2, peptone; 3, peptone + 2 mg. cod-liver oil; 4, peptone + 8 mg. cod-liver oil.

---

[1] Now at the School of Agriculture, University College of North Wales, Bangor.

sodium hydroxide, the mixture was diluted with water to make the concentration of peptone 15 % (based on a dry weight estimation made before the addition of yeast extract and alkali). This solution was stored in a refrigerator with chloroform as an antiseptic; before use samples were heated to remove the chloroform. Attempts to rear larvae on oil emulsions gave unsatisfactory results. Since the peptone solution could not be properly mixed with fat, one larva was used in each test. 0·3 ml. of peptone solution was absorbed on 60 mg. of cotton wool, pressed into a pellet, in a small test-tube. The oil was measured out with a platinum loop and smeared over the cotton wool; under standardised conditions, the loop delivered approximately 2 mg. of oil. One egg was placed in each tube, which was closed with fine muslin gauze, and the larvae were reared at 27° in a moist incubator. The amount of peptone supplied was equivalent to 180 mg. of fresh muscle; this provided sufficient food since a larva can grow to the full size (50 mg.) on 90 mg. of muscle.

Fig. 1 shows the growth of larvae on peptone and on muscle. On peptone alone, larvae fail to grow and usually die on the second day; however, they remain alive under aseptic conditions for 5 or 6 days without growing. When an active oil is given in excess, growth is almost normal and the larva reaches the full size in 70–80 hours; with an insufficient amount of the essential factor, growth is slower and the final weight less. Fig. 1 includes some results obtained with cod-liver oil. Since the rate of growth was not usually so uniform as this, the weight on the fourth day was taken as the criterion of growth.

Table 1. *The effect of various substances on the growth of blow-fly larvae on peptone diet.*

Substance	Dose (mg.)	Weights of larvae (mg.) on 4th day

Table II. *Distribution of the growth factor.*

Substance	Potency	Active dose mg.
Wool wax	+ + +	0·1
Beef muscle oil	+ + +	0·4
Ovolecithin (technical)	+	2
Wheat germ oil	+	3
Egg yolk	+	4
Cod-liver oil	+	6
Butter	+	8
Lard	−	>8
Olive oil	−	>8

Active dose = smallest amount required for normal growth of 1 larva on 0·3 ml. of peptone solution.

Effect of various fats and oils on growth.

In these experiments the fat-soluble substances were diluted with an inactive oil, olive oil, and tested at different concentrations, each larva receiving 8 mg. of oil. Tests were also made with egg yolk and commercial ovolecithin mixed with the peptone solution as suspensions. The mortality in these trials was high, especially with certain oils and at low concentrations; when the larva was dead or moribund on the fourth day, the experiment was repeated. The results of the successful tests are collected in Table I and summarised in Table II. The active dose was taken to be the smallest amount which produced a larva weighing more than 45 mg. on the fourth day from hatching.

Reference to Table II shows that cod-liver oil and butter fat proved relatively poor sources of the growth factor; wool wax and muscle oil were the most active of the substances tested, wheat germ oil and ovolecithin giving intermediate values. Lard and olive oil were almost inactive. These results show clearly that the active substance is not vitamin A, D or E. Vitamins A and D are present in large amounts in cod-liver oil and butter; also they are absent from wool wax [Drummond and Baker, 1929], the richest source of the larval factor. Since wheat germ oil proved less potent than muscle oil and wool grease, the larval factor is not vitamin E. It should be noted that the muscle oil was obtained from a sample of beef which yielded only 1·3 % of ether-soluble material, the extract being very rich in unsaponifiable matter.

Chemical properties of the growth factor.

In order to test the stability of the factor to oxidation, growth tests were carried out with cod-liver oil, which had been aerated for 24 hours at 90–95°. This product appeared to be toxic as a large proportion of the larvae died. However, since some grew tolerably well, it is concluded that the active substance is resistant to oxidation. It is also stable to alkaline hydrolysis and can be recovered quantitatively in the unsaponifiable residue. Lecithin was used for chemical fractionation since it is rich in the blow-fly factor; it also stimulates the growth of *Drosophila* on a synthetic peptone diet [Guyenot, 1917]. 40 g. of technical ovolecithin, hydrolysed with alcoholic potash on a boiling water-bath for 45 minutes, yielded 1·4 g. of unsaponifiable material. This was fractionated by recrystallisation from alcohol into colourless crystals of cholesterol and a dark-coloured gummy material which consisted largely of cholesterol. Growth tests with olive oil solutions showed that the unsaponifiable residue contained the whole of the original potency. The active dose, for 1 larva on 0·3 ml. of peptone solution, was 30–60γ, equivalent to 1–2 mg. lecithin; the minimum amount of lecithin which produced good growth was about 2 mg. (when emulsified in the same volume of peptone solution). Recrystallisation of the unsaponifiable residue from alcohol did not concentrate the activity, since both fractions proved equally potent. In order to determine whether the active substance is cholesterol itself or an impurity, further growth trials are being made with sterol samples from different sources.

DISCUSSION.

The results of the present experiments show that blow-fly larvae require a fat-soluble factor which is present in the unsaponifiable residue. This substance not only stimulates growth, but seems to possess, also, an "anti-infective" function. Under normal conditions *Lucilia* larvae are highly resistant to bacterial infection and grow readily on meat however badly decomposed. This immunity extends also to diets which are deficient in vitamin B and mineral salts; thus, although larvae grow extremely slowly on infected serum, they show no other ill effects. With the peptone diet alone, death always occurred after two or three days; also, larvae receiving small doses of the fat-soluble factor often died before the end of the experiment. The cause of death was excessive bacterial action since the mortality was reduced by sterile precautions and was not found in aseptic cultures. The fat-soluble factor seems, therefore, to play a part in the immunity of these larvae to infection.

The distribution of the growth factor shows clearly that it is not vitamin A, D or E; thus, wool grease proved more than ten times as potent as cod-liver oil or wheat germ oil. However, the results obtained with blow-fly larvae agree with the findings of previous workers on insects. Guyenot [1917] showed that *Drosophila* larvae require a growth factor which is supplied by yeast fat or egg lecithin, but not by triolein. Bacot and Harden [1922], when studying the response of this insect to vitamin B, found it necessary to include butter in the basal diet. Richardson [1926] showed that *Ephestia* larvae could not grow on wheat flour which had been extracted with fat solvents; wheat oil and egg yolk restored growth, olive oil and lard being ineffective. Although butter gave poor results, Richardson suggested that the active substance might be vitamin A. Moskalenko [1933] concluded that cockroaches require vitamin E and possibly other fat-soluble growth factors. Using an artificial diet, he found wheat-germ oil the most effective in stimulating growth; fish oil (?liver oil)[1] was also active, butter producing slow growth. Zabinski [1926; 1928], working with the same insect, obtained inconclusive results. Michelbacher *et al.* [1932] found that blow-fly larvae could not develop aseptically on a synthetic diet unless cod-liver oil or butter was included. Table III summarises the responses of various insects to fat-soluble growth factors.

The fat-soluble vitamin requirements of higher animals do not apparently differ in the same way as do their needs for water-soluble vitamins. It may be assumed, therefore, in the absence of evidence to the contrary, that the fat-soluble growth factors required by insects do not vary among different types. It will be seen from Table III that the results obtained with different insects bear a general resemblance. Since the blow-fly factor is not vitamin A, D or E, it is inferred that insects do not require the same fat-soluble growth factors as higher animals. Furthermore, the present results suggest a relationship between the blow-fly factor and sterol. Thus, the only substance which compared in activity

---

[1] I was unable to see the original paper, but was fortunate in borrowing an English translation. The fish oil was probably a liver oil since Moskalenko refers to it as well known to be rich in vitamin A.

with wool wax (mainly composed of sterol esters) was a sample of beef oil (Table II), which was undoubtedly rich in sterol. The other substances tested were relatively poor both in sterol and in the growth factor. Also, a sample of cholesterol obtained from ovolecithin proved highly active. The nature of the growth factor will be considered more fully in a later paper giving the results of tests with sterols from various sources.

SUMMARY.

1. Muscle oil contains a substance which is essential for the growth of blow-fly larvae. Other sources of the growth factor are, in order of decreasing potency: wool wax, wheat germ oil, egg yolk, cod-liver oil, butter. Olive oil and lard have little or no effect on growth.

2. These results agree with the observations of previous workers on insects, but the distribution of the blow-fly factor shows that it is not vitamin A, D or E.

3. The growth-promoting effects of various substances appear to run parallel with their sterol contents.

4. The active substance is present in the unsaponifiable residue after hydrolysis.

5. There was some evidence that the growth factor possesses also an "anti-infective" function.

I wish to record my thanks to the Agricultural Research Council for a grant which entirely financed this work.

CLVII. THE LIBERATION OF METHYL SULPHIDE BY SEAWEED.

By PAUL HAAS.

From the Botanical Department of University College, London.

(*Received April 12th, 1935.*)

THE smell given off from seaweed is of two kinds—that associated with decomposing weed and that evolved by the weed in its natural condition. It is the smell of decomposing weed which is usually the more noticeable by the seaside, being characterised as a rule by a more or less distinct odour of hydrogen sulphide which arises in part, presumably, from the putrefactive reduction of the organically combined sulphates which form a marked characteristic of so many marine algae [Haas, 1921; Haas and Russell-Wells, 1923]. There do not appear to be any recorded observations on the nature of volatile odoriferous principles given off by undecomposed seaweed, and it is with this aspect of the question that the present communication deals. The immediate incentive for this investigation was the peculiarly penetrating, somewhat sickly odour, suggestive of a volatile phosphorus compound, given off from *Polysiphonia fastigiata* on drying.

The persistent occurrence of this smell, no matter from what locality or at what season of the year the material had been collected, suggested that the smell was due to some change inherent in the weed, associated either with the drying process or with injury due to cutting, and not to accidental contamination or to bacterial action; the latter suggestion was moreover rendered improbable by the short interval elapsing between the time of collection of the weed and the appearance of the smell. The fact that material which had been killed by immersion in boiling water no longer gave the smell suggested that the production of the smell was in some way connected with a disturbance of the normal metabolism of the plant. The investigation of this matter is reserved for a future occasion.

EXPERIMENTAL.

With a view to identify the odoriferous principle concerned a five-litre flask was filled as rapidly as possible with freshly gathered cut up weed. The flask, fitted with a cork through which passed a long tube reaching to the bottom and a short delivery tube, was placed in a large water-bath kept at 30°. By means of a filter-pump a current of air charged with the evolved gas was then drawn through a series of different solvents such as water, alcohol or acetone; in each of these the gas was soluble, imparting a strong smell to the solution. On passing the gas previously dried by quicklime and calcium chloride into concentrated sulphuric acid it was likewise absorbed, but the resulting solution was odourless, though on dilution with water the odour at once reappeared. This circumstance rendered possible the collection of a reserve of gas for subsequent examination; it was found, in fact, that the gas could be recovered unchanged from this solution after six months by dropping it carefully into ice-cold water.

On passing the dried gas into a dilute solution of bromine in carbon tetrachloride the colour of the bromine was rapidly discharged with the simultaneous formation of clusters of lemon-yellow glistening crystals. Pressed on a porous porcelain tile these crystals were found to be both volatile and deliquescent, and even when placed in a desiccator over phosphorus pentoxide they tended to disappear in the course of a short time. This substance was readily soluble in water, alcohol, ether and chloroform, but could be recrystallised from hot carbon tetrachloride, though not without some loss due to volatilisation, and melted with evolution of gas at 93–94°.

A small quantity of this substance, heated in a Carius tube for six hours to 300° with pure concentrated nitric acid, free from sulphuric acid, yielded a considerable quantity of sulphuric acid but not a trace of phosphoric acid, thus showing that it contained sulphur. A search in the literature for a bromine derivative of an alkyl sulphide having the melting-point above quoted proved unavailing, and being unfamiliar with the smell of alkyl sulphides I consulted Prof. Challenger who suggested that the smell of an aqueous solution of the gas evolved from the weed resembled that of methyl sulphide. I therefore procured from Messrs British Drug Houses an authentic sample of methyl sulphide and dissolved a little of it in water; on drawing air through the solution, drying the issuing gas with calcium chloride and passing it into a dilute solution of bromine in carbon tetrachloride as before, the same lemon-yellow crystals appeared; these crystals likewise melted at 93–94°, and when mixed with some of the crystals obtained from the natural source still melted at the same temperature, thus establishing the identity of the material prepared from the two sources. This circumstance could leave no doubt that the gas given off from *Polysiphonia* was in fact methyl sulphide.

On referring to the literature it was found that Cahours [1875] had obtained by the action of bromine on methyl sulphide in the presence of water a solution which on evaporation over sulphuric acid deposited amber-yellow transparent glistening octahedral crystals; he stated that the crystals were deliquescent but did not mention that they were volatile or that they had a melting-point. On repeating this preparation according to his description it was found that his crystals were in fact identical with these produced in carbon tetrachloride, in the absence of water, and had the same melting-point, 93–94°, which was not depressed by admixture with some of the crystals prepared from the *Polysiphonia* gas. It seems desirable therefore to put these facts on record and so amplify the data furnished by Cahours concerning this compound which he was the first to prepare.

With a view still further to confirm the identity of the substance evolved from *Polysiphonia fastigiata* the dried gas was passed into a saturated alcoholic solution of mercuric chloride and into an aqueous solution of potassium chloroplatinite. The precipitates obtained in each case were proved by their appearance and by their melting-points and mixed melting-points to be identical with the corresponding compounds prepared under identical conditions from the authentic sample of methyl sulphide.

DISCUSSION.

So far as I have been able to ascertain this is the first recorded case of the evolution of methyl sulphide in appreciable quantity from a plant. Traces of this substance have been found in the first runnings of the distillation of certain essential oils, such as American peppermint oil and the oils distilled from species of *Pelargonium* of African origin and from *Brassica juncea* seeds. In all these examples however the methyl sulphide occurs only in very small quantity and is not the sole or even the major constituent of the essential oil, and certainly cannot be detected in the smell of the original plant, as in the case of *Polysiphonia*.

It is worthy of note that the only other natural source of methyl sulphide recorded is a petroleum oil from Ohio described by Mabery and Smith [1891]. While the occurrence of the same substance in two such widely different materials as seaweed and mineral oil may be no more than a coincidence, it may at least be said that the finding of detectable quantities of methyl sulphide in a seaweed is not inconsistent with the theory of algal origin which has been suggested for some oil fields.

SUMMARY.

1. Methyl sulphide has been identified as the odoriferous principle evolved from *Polysiphonia fastigiata*.

2. The melting-point of the bromine derivative of methyl sulphide, originally prepared by Cahours, is recorded for the first time.

3. Attention is drawn to the other recorded natural occurrences of methyl sulphide.

I should like to express my acknowledgment for help both in collecting material and in some of the preliminary experimental work which was given by Mr W. K. H. Karstens during his tenure here of a grant from the Vollenhoven foundation of Leyden University.

CLVIII. STUDIES IN THE BIOCHEMISTRY OF MICRO-ORGANISMS.

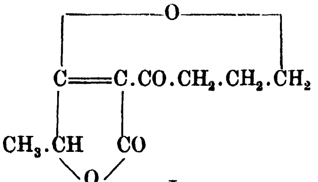
XLV. THE METABOLIC PRODUCTS OF *PENICILLIUM CHARLESII* G. SMITH. IV. *l*-γ-METHYLTETRONIC ACID, WITH OBSERVATIONS ON THE FORMATION AND STRUCTURE OF RAMIGENIC AND VERTICILLIC ACIDS.

By PERCIVAL WALTER CLUTTERBUCK, HAROLD RAISTRICK AND FRITZ REUTER.

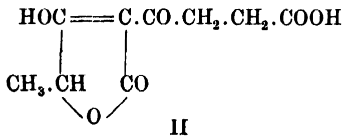
From the Division of Biochemistry, London School of Hygiene and Tropical Medicine, University of London.

(*Received April 13th, 1935.*)

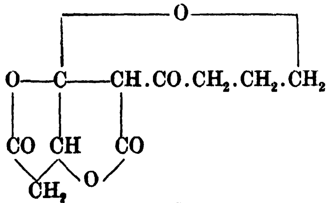
It was recently shown [Clutterbuck *et al.*, 1934] that *Penicillium Charlesii* G. Smith, when grown on nutrient solutions containing glucose, produces two new polysaccharides, mannocarolose [Haworth *et al.*, 1935] and galactocarolose, together with a number of new organic acids. The polysaccharides were isolated by precipitation from the evaporated metabolism solution with acetone, and the acids by solvent extraction of the filtrate from the polysaccharides, after removal of the acetone. Of these acids, carolic acid $C_9H_{10}O_4$ (I), carolinic acid $C_9H_{10}O_6$ (II), carlic acid $C_{10}H_{10}O_6$ (III), and carlosic acid $C_{10}H_{12}O_6$ (IV) have been shown [Clutterbuck *et al.*, 1935, 1, 2] to have the following molecular constitutions:



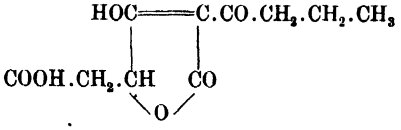
I



II



III

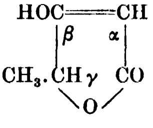


IV

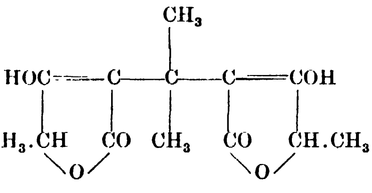
In addition to these four acids, two further acids, ramigenic acid $C_{16}H_{20}O_6$ and verticillic acid $C_{26}H_{32}O_{12}$ ($C_{26}H_{30}O_{11}.H_2O$), were also isolated in small amounts from the ether and chloroform extracts, using both Czapek-Dox and Raulin-Thom media.

During our investigation of the constitutions of carolic and carolinic acids, it was found that both acids on bromination gave *d*-α-bromo-γ-methyltetronic acid $C_5H_5O_3Br$, which on catalytic reduction gave *l*-γ-methyltetronic acid

$C_5H_6O_3$ (V). We have found that one of the most characteristic properties of *l*-γ-methyltetronic acid is the ease of its condensation with acetone. Thus on keeping a mixture of *l*-γ-methyltetronic acid and acetone in dilute aqueous solution at the ordinary temperature for 2–3 hours, especially in presence of HCl, or on boiling the mixture for a few minutes in absolute alcoholic solution, a practically quantitative yield of *iso*propylidene-bis-γ-methyltetronic acid (VI) is obtained.

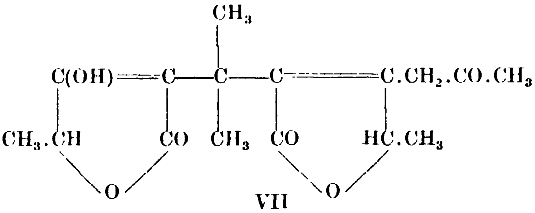


V



VI

If either of the above experiments is allowed to proceed for a longer time, a second molecule of acetone undergoes condensation and a beautifully crystalline acid, acetonyl*iso*propylidene-bis-γ-methyltetronic acid (VII) is formed. This acid has now been shown to be identical with ramigenic acid.



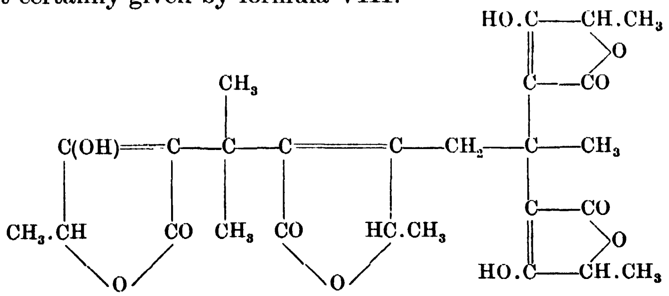
VII

Both of the above condensation reactions are strictly analogous to those obtained by Wolff and Schimpff [1901] with tetronic acid and acetone.

Further, we have found that verticillic acid (1 mol.) on standing overnight in dilute HCl, or more rapidly in acetic acid solution at room temperature is hydrolysed and gives 1 mol. of ramigenic acid and 2 mols. of *l*-γ-methyltetronic acid:

$$C_{26}H_{30}O_{11}.H_2O \longrightarrow C_{16}H_{20}O_6 + 2C_5H_6O_3$$

From its general properties, the structure of anhydrous verticillic acid is therefore almost certainly given by formula VIII.



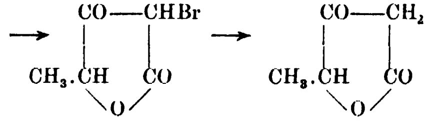
VIII

In view of the fact that in the early work the polysaccharide fraction had been separated by precipitation with acetone (alcohol had been avoided because slight esterification of the metabolic acids occurred) it appeared a reasonable supposition that verticillic and ramigenic acids were artefacts arising from *l*-γ-methyltetronic acid by reaction with acetone during the separation of the polysaccharide fraction. That this view is correct has now been proved by repeating the metabolism experiments exactly as in our first experiments but replacing acetone with alcohol as a means of precipitation of the polysaccharide fraction. The combined ether extracts of the alcohol- and polysaccharide-free metabolism fluid then gave an oil from which *l*-γ-methyltetronic acid was isolated in a yield of the same order as would be expected from the previously obtained yields of ramigenic and verticillic acids, assuming that these acids were formed by reaction of 2 and 4 mols. respectively of *l*-γ-methyltetronic acid with acetone. Further, ramigenic and verticillic acids were entirely absent, while, on the other hand, carolic, carolinic, carlic and carlosic acids were isolated from the ether and chloroform extracts of the metabolism solution by methods similar to those previously employed, and in comparable yields.

Carolic, carolinic, carlic, carlosic and *l*-γ-methyltetronic acids should therefore be regarded as true metabolism products, whilst the ramigenic and verticillic acids of our earlier experiments must now be regarded as artefacts arising from *l*-γ-methyltetronic acid by condensation with the acetone used for precipitation of the polysaccharide fraction.

During this work a small amount of synthetic γ-methyltetronic acid was required for comparison with our natural product. In our earlier paper, the method of Benary [1911] was used for its synthesis. This method, although repeated several times under varying conditions, always gave only a very small yield of γ-methyltetronic acid and a new synthesis was therefore elaborated. Ethyl propionylacetate was first synthesised by a Grignard condensation of ethyl iodide and ethyl cyanoacetate with subsequent hydrolysis and was then brominated under conditions which gave the αγ-dibromo-derivative of this ester. This compound on heating *in vacuo* readily lost ethyl bromide with ring closure and formation of α-bromo-γ-methyltetronic acid, $C_5H_5O_3Br$, which on catalytic reduction was converted into *dl*-γ-methyltetronic acid, $C_5H_6O_3$:

$$CH_3.CH_2.CO.CH_2.COOEt \longrightarrow CH_3.CHBr.CO.CHBr.COOEt$$



The acid obtained was in every way identical with the acid synthesised by Benary's method. Like the latter it did, however, give a slight depression of M.P. with the *l*-variety of this acid, M.P. 115° obtained by degradation of carolic and carolinic acids.

EXPERIMENTAL.

Earlier experiments.

In our previously described experiments, the polysaccharide fraction was separated from the evaporated metabolism solution by precipitation with acetone, the mother-liquors from which were concentrated to 600 ml., acidified with concentrated HCl and extracted several times first with ether and subsequently with $CHCl_3$.

The material extracted with ether, on grinding with a small volume of $CHCl_3$, filtering and washing with $CHCl_3$, gave a crystalline powder consisting in the

Czapek-Dox experiments of carlosic and carolinic acids, and in the Raulin-Thom experiments of carolinic and verticillic acids. The $CHCl_3$ filtrates from these acids, after removal of solvent, gave syrups which in both cases were ground with water. The fraction soluble in water was extracted with $CHCl_3$ and gave a yellow oil which slowly crystallised and consisted chiefly of carolic acid, whilst the material insoluble in water gave, on standing, crystals of ramigenic acid, and the residual syrups on neutralising with NaOH and adding $HgCl_2$ gave a precipitate of the mercuric salt of verticillic acid.

The material extracted with $CHCl_3$ was in the first extract almost pure carolic acid and in the remaining extracts carlic acid.

Present experiments.

In the present experiments the initial procedure was the same as described above except that absolute alcohol replaced acetone as the polysaccharide precipitant. After filtering off the polysaccharide fraction and concentrating *in vacuo* at 40–45° to remove alcohol, the mother-liquors were extracted as before with ether and chloroform.

The yellow syrups obtained by ether extraction of the concentrated metabolism solutions using Raulin-Thom and Czapek-Dox medium respectively should (according to our earlier work) contain carolinic acid, some carolic acid ramigenic and verticillic acids, and from Czapek-Dox medium carlosic acid in addition. This fraction also should contain most of the *l*-γ-methyltetronic acid if this acid were present. Of all these acids only *l*-γ-methyltetronic, ramigenic and verticillic acids give insoluble mercuric salts. In the present series of experiments therefore the ether-extracted material was divided in the case of each medium into two equal portions. One portion was neutralised with NaOH and treated with a large excess of saturated $HgCl_2$. The precipitate consisted almost entirely of the mercuric salt of *l*-γ-methyltetronic acid, ramigenic and verticillic acids being entirely absent. The second portion of the ether-extracted material was examined exactly as in our earlier experiments for the presence of carolinic, carlosic and carolic acids.

The material extracted with $CHCl_3$ was separated, as in our earlier experiments, into carolic and carlic acids.

Isolation of the products of metabolism of Penicillium Charlesii *G. Smith using ethyl alcohol as carbohydrate precipitant.*

One hundred 1-litre conical flasks containing 350 ml. Czapek-Dox solution and a similar number of flasks of Raulin-Thom solution were sterilised and sown as in our earlier paper [Clutterbuck *et al.*, 1934] with a spore suspension of *P. Charlesii* and incubated at 24° until the glucose had just disappeared. This occupied about 7 weeks with Czapek-Dox and about 4 weeks with Raulin-Thom medium. The metabolism solution was filtered from the mycelium and the latter well pressed and washed with water. The filtrate and washings were evaporated *in vacuo* at 45–50° to about 800 ml. and kept for 1 day at 0°. A small amount of amorphous material was filtered off and to the filtrate were added 4 volumes of absolute alcohol, the mixture being well stirred and allowed to stand until the precipitated polysaccharide mixture had completely settled. The clear liquid was then decanted and evaporated *in vacuo* to about 600 ml. to remove the alcohol. To the concentrate 125 ml. concentrated HCl were added, the fluid was extracted 10 times with an equal volume of ether, the combined ethereal extracts evaporated and the extracted material dried *in vacuo*. In this way were obtained, using Czapek-Dox medium, 153·2 g. and with Raulin-Thom medium 87·2 g. of a yellow oil.

The ether-extracted solution was then re-extracted with chloroform for the separation of carolic and carlic acids. The number of extracts was increased to 25 and this, together with the fact that a larger amount of HCl had been employed for acidification, led to the isolation of almost twice as much carlic acid as had been previously recorded. It was noticed in our earlier experiments that even after protracted extraction with ether and chloroform the mother-liquors still retained a small negative rotation, and this is now shown undoubtedly to be due to the incomplete extraction of carlic acid. The weights, after drying, of the first $CHCl_3$ extract were, on Czapek-Dox medium, 29·8 g. and on Raulin-Thom medium 24·9 g., whilst the remaining 24 extracts of the former medium weighed 17·5 g. and of the latter 20·0 g.

The ether extract was next divided into two equal portions, half being examined by the mercury salt method (*a*) for the presence of *l*-γ-methyltetronic, verticillic and ramigenic acids, and the remaining half being worked up (*b*) for carolic, carolinic and carlosic acids as in our earlier experiments.

(*a*) *Isolation of* l-γ-*methyltetronic acid as a product of metabolism of* P. Charlesii. The half-portions of ether-extracted material from experiments on each medium were first neutralised with NaOH using litmus paper as an external indicator, treated with a large excess of aqueous $HgCl_2$ and kept overnight. The resultant precipitate was separated by centrifuging, washed in the centrifuge pots, suspended in water and saturated with H_2S. The HgS was filtered off, H_2S removed from the filtrate in a stream of air and the free acids extracted with ether. On removing the ether a product was obtained which immediately crystallised but contained a little yellow oil. The total weight of this crude product with Czapek-Dox medium was 6·9 g. and with Raulin-Thom medium 12·6 g. The products were rubbed up with a little ether, transferred to a filter and washed with ether. The yellow oil was thus completely removed and dry crystalline powders, weights 4·5 and 9·2 g. respectively, remained. The material in both cases melted at 114° and consisted of almost pure *l*-γ-methyltetronic acid. No ramigenic or verticillic acid was present. After sublimation the *l*-γ-methyltetronic acid melted at 115°. (Found (Schoeller): C, 52·63, 52·61; H, 5·27, 5·28 %. $C_5H_6O_3$ requires C, 52·61; H, 5·30 %.)

0·066 g. required 5·80 ml. $N/10$ NaOH for neutralisation to phenolphthalein, corresponding to an equivalent of 114 ($C_5H_6O_3$ titrating as a monobasic acid requires 114). The free acid in water ($c=0·526$) had $[\alpha]_{5461} - 21°$. The rotation was therefore identical with that of the acid obtained from carolic and carolinic acids by bromination followed by catalytic reduction of the resultant *d*-α-bromo-γ-methyltetronic acid.

The acid obtained both from Czapek-Dox and Raulin-Thom media did not depress the M.P. of a sample of *l*-γ-methyltetronic acid obtained from carolic acid, and gave red $FeCl_3$ and violet $NaNO_2$ colours and a mono-2:4-dinitrophenylhydrazone, M.P. 235°, not depressed by mixing with the corresponding dinitrophenylhydrazone of synthetic *dl*-γ-methyltetronic acid. A neutral solution of the acid gave with $FeCl_3$ a very intense brownish red colour similar to that noted in our earlier paper with a neutral solution of verticillic acid.

It is certain therefore that when alcohol is used to precipitate the polysaccharide fraction, *l*-γ-methyltetronic acid can be isolated as a true metabolism product, whilst the ramigenic and verticillic acids of our earlier experiments are entirely absent and have probably arisen as artefacts by condensation of *l*-γ-methyltetronic acid with the acetone then used as polysaccharide precipitant.

(*b*) *Isolation of carolic, carolinic and carlosic acids from the ether extract.* This material, which after standing was for the most part crystalline, was ground in a glass mortar with a small amount (20 ml.) of chloroform, filtered and washed with chloroform. In this way the ether extract from each medium was separated into a quantity of light brown crystalline material and a chloroform mother-liquor which, after removal of solvent, was dried down to a syrup.

Using Czapek-Dox medium, the crystalline fraction consisted of a mixture of carlosic and carolinic acids. These acids were separated by boiling with a large volume of benzene and filtering, when carlosic acid immediately separated on cooling, whilst carolinic acid remained for the most part in solution and was again obtained by concentrating the benzene solution, adding a little light petroleum and setting aside to crystallise. Carlosic acid after several recrystallisations from boiling benzene had M.P. 181°, not depressed by admixture with an authentic specimen. The carolinic acid fraction was recrystallised once from a small volume of water and then several times from acetone-light petroleum and melted at 123°, not depressed by admixture with an authentic specimen.

Using Raulin-Thom medium, the crystalline fraction consisted almost entirely of carolinic acid, which after one recrystallisation from a small volume of water and then from acetone-light petroleum had M.P. 123°, not depressed by admixture with an authentic specimen. It will be noted that in our earlier experiments verticillic acid accompanied carolinic acid in this fraction but was now absent.

The syrups remaining after drying down the chloroform washings from the crystalline fractions referred to above contained in addition to a reddish brown oil both carolic and *l*-γ-methyltetronic acids. Thus on grinding half of this syrup with water, extracting the aqueous phase once with chloroform and removing the chloroform, a pale yellow oil remained which on standing slowly crystallised. This material was rubbed up with a small volume of alcohol, filtered, washed with a small volume of alcohol and finally recrystallised from this solvent. It had M.P. 132°, not depressed on admixture with an authentic specimen of carolic acid. The presence of *l*-γ-methyltetronic acid in the remaining portion of the syrup was shown by the mercury salt method used above in its isolation.

(*c*) *Isolation of carolic and carlic acids from the chloroform extract.* The isolation of carolic and carlic acids from the material extracted by $CHCl_3$ from the ether-extracted, carbohydrate-free metabolism solution was carried out exactly as in our earlier paper. Thus the semi-crystalline extracts were ground with a small amount (20 ml.) of absolute ethyl alcohol, filtered and washed with a little alcohol. In this way the first $CHCl_3$ extract using both Czapek-Dox and Raulin-Thom media gave almost pure carolic acid which after recrystallisation from alcohol had M.P. 132°, not depressed by admixture with an authentic specimen. The material from the remaining 24 $CHCl_3$ extracts on the other hand gave almost pure carlic acid, which after recrystallisation from a small volume of ethyl alcohol had M.P. 176°, not depressed by admixture with an authentic specimen.

The total yields in g. of the almost pure crystalline acids obtained from 100 flasks are given in the following table. The yields of *l*-γ-methyltetronic,

Medium	Carolic acid $C_9H_{10}O_4$	Carolinic acid $C_9H_{10}O_6$	Carlic acid $C_{10}H_{10}O_6$	Carlosic acid $C_{10}H_{12}O_6$	*l*-γ-Methyltetronic acid $C_5H_6O_3$
Czapek-Dox	27·2	6·5	19·3	6·3	4·5
Raulin-Thom	17·2	14·7	5·1	None	9·2

carlosic, carolinic and carolic acids actually isolated from half of the ether extracts have been doubled so as to refer to the total ether extract.

These figures are of the same order as in our earlier experiments except that the yield of carlic acid on Czapek-Dox medium is higher, owing to more thorough extraction, whilst the yields of verticillic and ramigenic acids obtained in the earlier experiments are replaced by a yield of *l*-γ-methyltetronic acid roughly corresponding to the combined weights of these two acids.

Hydrolysis of verticillic acid to give ramigenic and l-*γ-methyltetronic acids.*

This hydrolysis occurs only slowly in dilute HCl solution at room temperature because of the extremely small solubility of verticillic acid. The reaction was readily effected in the following way. Verticillic acid hydrate (VIII) (2 g.) was dissolved in 64 ml. 8 % aqueous sodium acetate solution, diluted to 100 ml. and 2*N* HCl added to faint turbidity (14 ml.). The solution was kept overnight. Large colourless prisms (1·12 g., M.P. 166–7°) separated, were filtered off and shown to be the hydrate of ramigenic acid (VII). Thus after recrystallisation from acetone-light petroleum the acid had M.P. 171°, not depressed on admixture with an authentic specimen of ramigenic acid, but depressed 10–12° on admixture with verticillic acid (M.P. 171°). It gave the characteristic rotation values of ramigenic acid, the anhydrous free acid in alcohol having $[\alpha]_{5461}+28°$ and the sodium salt $[\alpha]_{5461}+85°$. (Found (Schoeller) on anhydrous material: C, 62·34, 62·27; H, 6·47, 6·59 %. $C_{16}H_{20}O_6$ requires C, 62·30; H, 6·54 %.) The acid also gave on methylation the characteristic monomethyl derivative of ramigenic acid. Thus on suspending the finely powdered acid in ether and adding an ethereal solution of diazomethane there was an immediate and vigorous reaction and a methyl derivative separated, M.P. 192°. On dissolving in a larger volume of boiling ether, filtering and adding an equal volume of boiling light petroleum, the methyl derivative separated in long colourless needles, M.P. 199°. (Found: C, 63·41, 63·47; H, 6·91, 6·93; OMe, 9·60, 9·78 %; Mol. wt. (cryoscopic in camphor) 332, 340. $C_{16}H_{19}O_5OCH_3$ requires: C, 63·31; H, 6·88; OMe, 9·62 %. Mol. wt. 322.)

The mother-liquors from which ramigenic acid had been separated were continuously extracted with ether, and the extracted material, which contained some acetic acid, was rapidly dried over sticks of KOH at very low pressure. A solid remained (0·90 g.) which contained a trace of yellow oil but consisted essentially of colourless crystalline material. This sublimed with great ease and after two sublimations had M.P. 115°, not depressed by admixture with a sample of *l*-γ-methyltetronic acid from carolic acid. (Found: C, 52·82, 52·80; H, 5·37, 5·37 %. $C_5H_6O_3$ requires C, 52·61; H, 5·30 %.) 0·052 g. required 4·60 ml. *N*/10 NaOH for neutralisation to phenolphthalein, corresponding to an equivalent of 113. ($C_5H_6O_3$ titrating as a monobasic acid requires 114.) This acid gave red $FeCl_3$ and violet $NaNO_2$ colours and a mono-dinitrophenylhydrazone, M.P. 235°, not depressed by mixing with the corresponding dinitrophenylhydrazone of synthetic *dl*-γ-methyltetronic acid. (Found: C, 45·03, 45·18; H, 3·47, 3·57; N, 19·04, 19·01 %. $C_{11}H_{10}O_6N_4$ requires C, 44·89; H, 3·43; N, 19·04 %.)

The theoretical yield from 2 g. of verticillic acid hydrate is 1·22 g. of ramigenic acid $C_{16}H_{20}O_6.H_2O$ (assumed 1 mol.), and of *l*-γ-methyltetronic acid (assumed 2 mols.) is 0·85 g. It appears therefore that verticillic acid (1 mol) on mild hydrolysis gives rise to 1 mol. of ramigenic acid and 2 mols. of *l*-γ-methyltetronic acid. This fact fixes the empirical formula of verticillic acid hydrate as $C_{26}H_{32}O_{12}$, and confirms the formula previously assigned to this substance.

Synthesis of ramigenic acid and iso*propylidene-bis-γ-methyltetronic acid.*

For this purpose the natural *l*-γ-methyltetronic acid obtained as a metabolic product of *P. Charlesii* and also a sample of the same acid prepared from carolic acid by bromination and reduction of the so-formed α-bromo-γ-methyltetronic acid were used.

l-γ-Methyltetronic acid on standing in dilute aqueous solution with acetone for 2–3 hours readily deposits crystals of *iso*propylidene-bis-γ-methyltetronic acid (VI). After filtering off this compound, the mother-liquors on keeping for 48 hours deposit crystals of ramigenic acid (VII). Both of these reactions proceed somewhat more quickly in presence of HCl. The reactions can be best carried out by boiling a solution of *l*-γ-methyltetronic acid (0·25 g.) in absolute alcohol (5 ml.) containing acetone (5 ml.) on the water-bath under reflux. If the reaction is stopped after 30 minutes, the acetone distilled off and water added, *iso*propylidene-bis-γ-methyltetronic acid crystallises out. If boiling is continued for 4–5 hours, the product is pure ramigenic acid. An exact analogy for both of these reactions is given by Wolff and Schimpff [1901] in their reactions of tetronic acid and acetone which give *iso*propylidene-bis-tetronic acid and acetonyl-*iso*propylidene-bis-tetronic acid respectively.

Iso*propylidene-bis-γ-methyltetronic acid* (VI) crystallises from water with $2H_2O$, which is readily lost on heating at 63° *in vacuo*. The anhydrous acid melts at 172°. (Found (Schoeller): C, 58·09, 58·18; H, 6·09, 6·00 %. $C_{13}H_{16}O_6$ requires C, 58·19: H, 6·02 %.) The acid in alcohol ($c=0{\cdot}513$) had $[\alpha]_{5461} - 39°$.

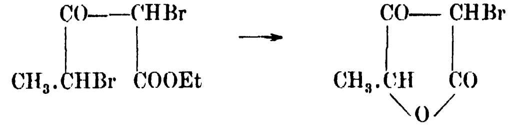
0·0298 g. required 2·19 ml. *N*/10 NaOH for neutralisation to phenolphthalein corresponding to an equivalent of 136 ($C_{13}H_{16}O_6$, titrating as a dibasic acid requires 134). The acid gives a red $FeCl_3$ colour in aqueous alcohol but does not give an immediate colour with $NaNO_2$.

*Acetonyl*iso*propylidene-bis-γ-methyltetronic acid* (ramigenic acid, VII) synthesised as described above showed exactly the same properties as those of ramigenic acid as described in our earlier paper. Both acids crystallised in the same characteristically well-formed prisms, M.P. 171°, the mixed M.P. showing no depression. Both acids can be crystallised both in the anhydrous form $C_{16}H_{20}O_6$ and as the monohydrate. Both acids show the same abnormality in rotation. Thus in each case the free acid in absolute alcohol ($c=0{\cdot}22$) had $[\alpha]_{5461} + 28°$ whereas the sodium salt (calculated as monosodium salt) in water ($c=0{\cdot}27$) had $[\alpha]_{5461} + 85°$. Both acids when suspended in ether in finely powdered condition reacted immediately with an ethereal solution of diazomethane and gave the same monomethyl derivative, which after recrystallising from ether-light petroleum melted at 199°, the mixed M.P. showing no depression. The synthetic acid showed the same solubilities and behaviour on titration and gave the same reactions with salt solutions as were described in our earlier paper for ramigenic acid. It is certain therefore that the synthetic acetonyl*iso*propylidene-bis-γ-methyltetronic acid (VII) is identical with the ramigenic acid isolated in earlier experiments from the metabolism fluid and the ease of its formation in dilute aqueous solutions containing *l*-γ-methyltetronic acid and acetone makes it certain that the ramigenic acid of our earlier experiments was an artefact arising from these substances during the separation of the polysaccharide fraction with acetone.

A new synthesis of dl-*γ-methyltetronic acid.*

In our earlier paper [Clutterbuck *et al.*, 1935, 1] this acid was synthesised by the method of Benary [1911] by condensation of bromopropionylbromide with ethyl sodiomalonate with the usual ring closure by loss of ethyl bromide on heating and subsequent hydrolytic decarboxylation. With this method however the yield we obtained was always very small and a better method was desirable.

In our new method, ethyl propionylacetate was first synthesised by the Grignard reaction of Blaise [1901] as modified by Willstätter and Clarke [1914]. This ester was then brominated under conditions, which by analogy with the work of Wolff [1896] should result in the formation of ethyl $\alpha\gamma$-dibromopropionylacetate. Ring closure was then effected by heating as usual giving α-bromo-γ-methyltetronic acid,



which on catalytic reduction with palladium-charcoal-hydrogen readily gave *dl*-γ-methyltetronic acid.

Ethyl propionylacetate (11 g.) was dissolved in ether (100 ml.) and 7·8 ml. bromine ($\equiv$4 atoms Br) were slowly added, the flask being cooled in running water. The reaction was immediate. The ether layer was washed with water until free from HBr, dried over $MgSO_4$ and the ether removed *in vacuo*. The resulting dibromoester was highly lachrymatory and had a very disagreeable odour. It was not therefore isolated in the pure state but was immediately heated at reduced pressure (about 30 mm.) for 3 hours in an oil-bath, temperature 130–140°. In this way ring closure with loss of ethyl bromide was effected. On cooling the product set to a semi-crystalline mass and was kept overnight in the cold room. On filtering and washing with benzene 3·35 g. of crystalline α-bromo-γ-methyltetronic acid remained. The filtrate, which on adding benzene deposited a small amount of tar, was filtered and evaporated and the residue heated for a further period as above. On standing in the cold room overnight, filtering and washing with benzene, a second crop of the bromide (0·62 g.) was obtained. The total yield of α-bromo-γ-methyltetronic acid was thus 3·97 g. or 26·8 % of theory. The product melted at 173° and gave red $FeCl_3$ and violet $NaNO_2$ colour reactions. It was reduced catalytically with palladium-charcoal-hydrogen in the same way as were the bromides from carolic and carolinic acids in our earlier work, and gave quantitatively *dl*-γ-methyltetronic acid $C_5H_6O_3$, which crystallised from benzene-light petroleum in curved feathery needles, M.P. 117°. It readily sublimed *in vacuo* and the sublimate melted at 117°. (Found (Weiler): C, 52·94; H, 5·69 %. $C_5H_6O_3$ requires C, 52·61; H, 5·30 %.) 0·0745 g. required 6·60 ml. $N/10$ NaOH for neutralisation to phenolphthalein corresponding to an equivalent of 113 ($C_5H_6O_3$ titrating as a monobasic acid requires 114).

With Brady's reagent it readily gave a crystalline mono-dinitrophenylhydrazone, M.P. 235°, unchanged by recrystallisation from nitrobenzene-toluene and not depressed by admixture with the dinitrophenylhydrazone from the acid prepared by earlier methods. The acid on boiling with $2N$ H_2SO_4 was readily hydrolysed giving CO_2, and the hydrolysate slowly, after the manner of acetoin, gave the bis-dinitrophenylhydrazone of diacetyl, M.P. 318°, not depressed by admixture with an authentic specimen.

The acid $C_5H_6O_3$ is therefore undoubtedly the *dl*-variety of γ-methyltetronic acid.

SUMMARY.

It is shown that *l*-γ-methyltetronic acid $C_5H_6O_3$ is formed as a metabolic product of *Penicillium Charlesii* G. Smith when this mould is grown on synthetic solutions containing glucose. A new synthesis of the *dl*-form of this acid is described.

Ramigenic acid, $C_{16}H_{20}O_6$, and verticillic acid, $C_{26}H_{32}O_{12}$, previously reported as metabolic products of *P. Charlesii*, are now shown to be artefacts arising by condensation of *l*-γ-methyltetronic acid with the acetone previously used for precipitation of the polysaccharide fraction from the evaporated metabolism solution. Ramigenic acid has been synthesised from *l*-γ-methyltetronic acid and acetone and shown to be acetonyl*iso*propylidene-bis-γ-methyltetronic acid. Verticillic acid has been shown to be the bis-γ-methyltetronic acid derivative of ramigenic acid.

CLIX. PHOSPHATE AND CREATINE METABOLISM IN FEVER.

BY WILFRID WALTER PAYNE.

From the Biochemical Department, The Hospital for Sick Children, Great Ormond Street, W.C. 1.

(*Received April 5th, 1935.*)

WHILE making some observations in a case of juvenile G.P.I. undergoing malaria treatment it was noted that some urine specimens were practically devoid of phosphate. A search through recent text books and articles failing to give any reference to this phenomenon it was decided to study the problem further.

METHOD.

When the children had been infected with malaria by mosquitoes there was an incubation period of from 10–21 days. During this period observations on the blood and urine were made. The total urinary output was collected in three daily periods 7 a.m.–1 p.m., 1 p.m.–7 p.m., 7 p.m.–7 a.m. (the times arranged to suit the convenience of nursing), and the various estimations performed daily. This was continued until the pyrexia developed. From this point the whole of every specimen of urine passed was collected separately by the nurse and the time noted. Blood examinations were made at suitable times. This was continued until the attack was terminated by quinine administration. The collection of urine was continued until more or less normal figures were obtained. A further blood examination was then made. In no single case however was it possible for the complete programme to be carried out.

The analytical methods used were: urea—McLean; phosphate (blood and urine)—Briggs; creatine and creatinine (blood and urine)—Folin; blood sugar—micro-Folin-Wu. By simple adaptations of the blood methods it was found possible to do most of the investigations on about 1–1·5 ml. blood which was obtained from a single puncture of a finger. It was found that this disturbed the children far less than puncture of a vein. Even so it was not considered advisable to take as frequent specimens as could have been desired.

RESULTS.

Urine. Two sets of changes were observed—a gradual alteration of the total daily output of phosphate and creatine as the malaria infection increased in intensity and a rapid alteration during the pyrexial bouts. These changes are shown in Figs. 1 and 2. In Fig. 2 the relation between the hourly excretion of phosphate and creatine is obscured on a few occasions by a profuse polyuria which produced high excretion values for all the urinary constituents.

Phosphate. The daily phosphate excretion diminishes with the duration of the fever until the termination either spontaneously or after quinine. Also during each bout of temperature the phosphate excreted diminishes, the maximum fall occurring at the time of the peak temperature. When the fever is well established the phosphate in the urine completely disappears. (No colour was

formed with Briggs's reagents even with much extra urine.) Immediately after the peak the phosphate rises often to quite high values.

Creatine. The general level of creatine excretion falls somewhat with the full onset of the fever and then returns to normal. After quinine the creatine again

falls. The creatine varies with the temperature. At the time of the rise of temperature there is a rise in the creatine output. A fall starts just after the peak and the creatine output reaches its lowest level at the time when the temperature has just returned to normal. When this coincides with the general low level of excretion no creatine is found in the urine. A similar absence of creatine from the urine occurs after quinine. During the febrile period the minimum values of phosphate and creatine in the urine never coincide, but after quinine they may occur together.

Creatinine. The changes in creatinine excretion are less clear cut. The excretion often runs more or less parallel with that of creatine but at a higher level. There is a tendency for a rise above normal to occur with the rise of temperature but the fall which occurs in the intervals is only slightly below the normal level.

Blood. The changes in the blood are shown in Figs. 1 and 2 and in tabular form in Table I, A, B and C.

Inorganic phosphorus. The blood phosphorus falls to quite low values by the time the peak temperature is reached. The fall starts at the same time as the rise of temperature. There is a corresponding rise in the phosphorus when the peak is passed. The exact time of this rise varies in different cases from the peak to 2 hours after the peak. After quinine low values were obtained.

Creatinine and creatine. The creatine content of the blood rises as the temperature rises. After the peak there is an abrupt fall. The post-critical rise of the blood phosphate does not occur until this fall is complete. Figures are not available for the values in the interval, several days elapsing in every case before another set of observations was made. After quinine all values obtained were somewhat lower than the pre-febrile ones.

Blood sugar. Although the blood sugar was estimated frequently no correlation could be observed between the fever and the blood sugar. The added variable of food which was taken irregularly in relation to the pyrexia and absorbed probably equally irregularly would be sufficient to obscure any underlying relationship unless it were very marked.

These changes are not found solely in malaria since other conditions in which similar bouts of pyrexia alternate with periods of normal temperature also show similar changes. They were shown in a boy suffering from streptococcal septicaemia and to less extent in a child in whom pyrexia was being produced by repeated T.A.B. injections intravenously.

Discussion.

These very striking changes in the phosphate of the urine have been reported as far back as 1860 in malaria by Haxthausen [1860] and many others. A survey of the literature up till 1900 has been made by Garratt [1904]. The findings of all the observers when dealing with malaria were uniform and identical with those reported here. In dealing with non-malarial cases no uniformity of results was obtained, there being no periodic swing to reveal such changes as occur in malaria. The daily output was either slightly increased or diminished at the start and suffered far less variation than did the urea.

No conclusions as to the cause of the changes were advanced by Garratt, but in his discussion he suggests that the phosphorus may have been stored in the muscles and glands of the body. Indeed, no adequate answer could have been given until the recent work on muscle metabolism culminated in the simultaneous discovery of phosphocreatine by Eggleton and Eggleton [1927], and by Fiske and Subbarow [1927].

The precritical period is marked by a rapid rise of temperature and by muscular tremors or rigors which should produce effects similar to muscular work. The effect of work is somewhat different according to its duration and to the degree of fatigue. Short sharp exercise (10 secs.) produces only a fall of blood phosphorus after a few minutes' interval [Gemmill and Ribeiro, 1933], but after exercise of a longer duration (20 mins.) causing exhaustion there is a rise of blood phosphorus followed by a fall. Corresponding but less marked changes occur in the urine, the rise being greater than the fall [Havard and Reay, 1926; Planet and Cardoso, 1933]. There is also a rise in the blood creatine [Kael, 1932; Planet and Cardoso, 1933]. Tetanic stimulation of excised muscle increases the hexosephosphate, but this increase rapidly disappears on cessation of the stimulus [Cori and Cori, 1931; 1933].

Apart from work, adrenaline brings about certain changes. There is an increase of muscle hexosephosphate with no change in the phosphocreatine or adenosinetriphosphate content coupled with a reduction of plasma phosphate and a drop of the urinary phosphate so marked that at times none can be detected [Allan *et al.*, 1924; Cori and Cori, 1931; Bell, 1932].

Another interesting observation is that creatine given by mouth to dogs causes a fall of the blood phosphate and a marked decrease or even complete absence of urinary phosphate [Brown and Imrie, 1931]. Clarkson [1932] has shown that creatine by mouth in man produces a similar diminution of phosphate excretion.

It will be seen that changes detected in the isolated muscle are of such magnitude that in the intact organism considerable changes in the composition of the blood and urine are produced.

In dealing with the febrile cycle of malaria the observation of Borchardt [1928] that the production of experimental fever is considerably modified in the absence of the suprarenal suggests that the secretion of adrenaline occurs in that part of the malarial cycle terminating in the peak. In the same period rigors or severe muscular tremors occur. There is therefore in this phase tetanic muscular contraction superimposed on adrenaline stimulation, which as shown by Cori and Cori [1933] produces a maximum deposition of hexosephosphate. The phosphocreatine broken down by muscular contraction is rapidly reconstituted but when fatigue ensues there is some reduction in its amount, the creatine escaping into the blood and being lost. This is the time at which maximum output of creatine in the urine was found. The phosphate presumably is retained as hexosephosphate. Morais [1932] has shown that in fever produced by dinitro-α-naphthol the phosphocreatine in the muscles of pigeons is reduced from an average of 29·6 mg. to an average of 5·4 mg. per 100 g. muscle.

At the end of this phase, which presumably coincides with the maximum temperature and cessation of rigors, the hexosephosphate due to tetanisation is dissociated, and since the phosphocreatine has been reduced there is ample opportunity for its reconstruction since there is a slight increase in the creatine of the blood and an increase in the available phosphate. This is probably the same type of reaction as occurs when creatine is given by mouth, *i.e.* an increased phosphocreatine formation when the materials are available. The exact time at which the blood phosphate will commence to rise is a resultant of two factors—the rate of breakdown of the hexosephosphate formed by tetanisation and the rate of re-formation of phosphocreatine. At this point there occurs therefore a fall of the blood creatine and a variable response of the blood phosphate. Later on the balance is shifted in favour of a rise in phosphate by the addition of the breakdown products of the extra hexosemonophosphate formed in response to the adrenaline liberated in the previous phase, this disappearing more slowly according to Cori and Cori [1931]. A reduction in the rate of phosphocreatine formation due to a reduction of the available creatine together with an increase in the phosphocreatine already formed is also a possible factor. It is at this point that the low values for blood and urine creatine were found.

In the early days of the malaria the phosphate of the blood is plentiful and is not completely spent by the time of the peak. All the available creatine can be used to reform phosphocreatine and so minimum values for creatine in the urine are obtained. In the later period the phosphates have decreased in amount and the available phosphate is exhausted by the time the peak is reached. At this point the urine is found to contain little or no phosphate. The amount of phosphate available is now not enough to produce so big a reduction of the creatine in the blood and urine. Why the blood phosphate falls is not clear. It is stated by many authors that the phosphates are excreted in excessive amounts in fever, but in actual fact in these cases there was no increased loss of phosphate compared with the preceding non-febrile period. In many, indeed, less phosphate was lost in the urine. No attempt to determine the loss in the faeces was made and it is therefore possible that the loss occurred there and the results of von Moraczewski [1900] lend some support to this. At the same time there was a variable but definite decrease in the food intake and thus a lessened phosphorus intake.

The increase of nitrogenous output has long been recognised and it has been observed by many [*e.g.* von Moraczewski, 1900] that the ratio P/N falls in fever indicating a retention of phosphorus produced from protein destruction. On the other hand creatinine has been found to be excreted in excess in fever, and since it seems certain that creatine is the precursor to the urinary creatinine there should be no shortage of available creatine. This is borne out by the results obtained here.

The early low creatine values in the urine and the later low phosphate values can thus be accounted for. It is not so easy to account for the simultaneous low values occurring in the days immediately following the administration of quinine and the return of the temperature to normal. These low figures differ from the preceding ones in that they coincide in time and it is only in this period that a specimen of urine was obtained containing neither detectable creatine nor phosphate. These low values did not occur throughout the whole day but occurred on the whole in the period 5 a.m. to noon. The easiest explanation is to suppose that during and at the end of the sleep period there is a regeneration of the phosphocreatine content of the muscles which in all probability were depleted during the attack.

The significance of the absence of creatine and phosphate from the urine is of interest. According to Wigglesworth and Woodrow [1923], Brain *et al.* [1928] and Walker [1932] the kidney has a threshold for phosphate about 2–3 mg. per 100 ml. calculated from the slope of the curve relating urinary and blood phosphate concentration. Walker indeed states that no example in man of reaching this hypothetical threshold has been recorded. It will be seen from Table II that the values of the blood phosphate obtained at times when no phosphate was being excreted agree well with the calculated value but show a fairly wide variation. This variation might be increased by the unavoidable use of whole blood. In the rapid fall which occurs the red cells might lag behind the plasma in regard to the phosphate content and thus misleading high values would occur. If the rate of diffusion were the limiting factor, however, equilibrium would be established almost instantaneously.

Table II. *The level of the blood phosphate in relation to the urine phosphate.*

Phosphate in urine	Blood phosphate (mg./100 ml.)						
	Case L. S.	S. S.	F. F.	E. S.	J. W.	G. R.	E. G.
None	2·8	3·2, 3·3	2·0	—	—	1·9, 1·7	2·0
Trace	3·2	4·6	—	1·8, 1·9	2·7	2·5	—

In the case of creatine the question is more complex. In the adult no creatine escapes into the urine although it appears in the blood in the same (or even greater) amounts as are found in children actually excreting creatine. Examination of the values obtained here gives no support for a rigid threshold although not enough figures are available to be dogmatic with so rapid a variation of the blood creatine.

Case E. C. Lowest value of creatine 4·5, 6·5, 4·5. Urine +
,, ,, 5·2 ,, 0
,, ,, 6·1 ,, Trace
Case E. G. ,, 4·2 ,, +

It is quite possible that all the chromogenic substance formed after hydrolysis is not creatine, or again the creatine may be in part combined with some larger molecule in its transition from muscle creatine to urinary creatinine, or as suggested by Hunter and Campbell [1918], the greater part of the creatine is in the red cells and only small amounts are present in the plasma. It is probable however that in the rapid variations in the creatine values the excess creatine is in the plasma since it is assumed that the variations are due to the muscles.

SUMMARY.

1. The phosphate, creatine and creatinine in blood and urine have been studied in cases of malaria produced in children.

2. There is a fall of the phosphate in the blood during the rise of the temperature followed by a rise starting about the time the temperature begins to fall. The fall may be so great as to cause the phosphate to disappear from the urine.

3. There is a rise of the creatine in the blood with the temperature followed by a fall as the temperature falls. The creatinine follows the same course only somewhat delayed in time. As with phosphate the fall is great enough to cause the normal creatinuria of children to disappear.

4. When the fever is stopped by giving quinine there is a simultaneous fall of both phosphate and creatine.

5. Evidence for a threshold for renal excretion of phosphate is put forward. The threshold value in these children lies between 1·8 and 3·2 mg. per 100 ml., the lower values being more probable. No evidence of a threshold for creatine could be found.

6. An explanation has been sought on the basis of a rapid breakdown of phosphocreatine and formation of hexosemonophosphate in the muscles by the combined action of adrenaline and muscular action, followed by an equally rapid reversal when the temperature peak is passed.

I wish to thank Dr D. Nabarro for permitting me to investigate the children under his care and for the helpful interest he has taken in the work. My especial thanks are due to Nurse Irving, without whose unremitting care the many specimens of urine required could never have been obtained, and to Miss Dora Ham on whose shoulders the greater part of the analytical work has fallen and who, as well, has shared in the collection of the blood at the various inconvenient hours that have been necessary. I also wish to thank Dr P. Eggleton for helpful criticism of the work.

CLX. THE CHEMISTRY OF THE WHITE ROTS OF WOOD.

IV. THE EFFECT ON WOOD SUBSTANCE OF *USTULINA VULGARIS* TUL.

By WILLIAM GEORGE CAMPBELL AND JAN WIERTELAK.

From the Section of Chemistry, Forest Products Research Laboratory, Princes Risborough, Aylesbury, Bucks.

(*Received April 17th, 1935.*)

In connection with his studies of the parasitism of the genus *Ustulina* on the timbers of temperate regions Wilkins [1934, and in the press] identified *U. vulgaris* Tul. as the causal organism of a disease of lime (*Tilia vulgaris* Hayne). In view of the facts that this constituted the first experimental evidence of the parasitism of this particular fungus on lime wood in temperate climates and that doubt has frequently been expressed with regard to its injurious effect on trees, it seemed desirable to supplement the mycological study by determining the ultimate chemical effect of the fungus on the wood substance. This has now been carried out on material supplied by Mr W. H. Wilkins of the Mycology Laboratory, University Department of Botany, Oxford; and also on a sample of freshly felled beech wood, which is the usual host of the fungus.

EXPERIMENTAL.

(1) *Lime wood decayed by* U. vulgaris.

The material consisted of a 6-in. disc cut from the bole of the diseased tree. Three distinct zones were clearly discernible in the sample as follows: (1) Outer sound wood. (2) Intermediate "red wood", a dark brown-coloured zone. (3) Inner decayed wood. The appearance of the specimen suggested that the causal fungus was of the white rot type.

The wood from each of the three zones was air-dried to a moisture content of approximately 6 % and converted into a series of more or less regularly shaped pieces measuring approximately 4 × $1\frac{1}{4}$ × $1\frac{1}{4}$ in. The volume of each piece was determined by the method described in previous work [Campbell, 1932] and each piece was weighed after oven-drying at 105°. Accepting the outermost zone as sound wood the approximate percentage loss in weight sustained by the inner zones during decay was calculated by comparing the average ratio $\frac{\text{oven-dry weight}}{\text{air-dry volume}}$ for each group of decayed specimens with that for the group of sound specimens. Each group of specimens was now converted to sawdust and ground to pass a 60-mesh screen. In each case the portion remaining on the 80-mesh screen was reserved for analysis (Table I).

Table I. *The effect of* Ustulina vulgaris *on the chemical composition of lime wood* (Tilia vulgaris *Hayne*).

Results expressed as % by weight of oven-dry material.

		Intermediate "red wood"		Decayed wood			
				I		II

Pentosans not in cellulose	8·07	9·21	8·79	9·25	7·20	7·66	5·26

(2) *Beech wood decayed by* U. vulgaris *in pure culture.*

A sample of freshly felled beech wood (*Fagus sylvatica* L.) was converted to sawdust and air-dried. A sample of 60–80 mesh material prepared from this was sterilised by steaming at 100° for 30 minutes on each of three consecutive days, inoculated with a pure culture of *U. vulgaris* and incubated at 20°. The authors are indebted to Mr W. P. K. Findlay for carrying out the inoculation. After 14 months the decayed wood was washed free from acid with cold water, dried at 105°, weighed and analysed (Table II).

Table II. *Analysis of 60–80 mesh beech wood decayed by* Ustulina vulgaris.

Results expressed as % by weight of oven-dry sound wood.

	Sound wood	Decayed wood
Duration of decay	—	14 months
Loss in wt.	—	3·17
Cold water-soluble	0·32	0·75
Hot water-soluble	1·23	0·72
1 % NaOH-soluble	14·88	15·12
Cellulose	59·89	55·26
Lignin	21·38	21·14

Pentosans not in cellulose	10·15	10·60
Total methoxyl	6·48	6·28
Methoxyl in lignin	4·73	4·50

DISCUSSION.

The results in Table I indicate that in the living tree *U. vulgaris* produces a typical white rot. Both lignin and carbohydrates are attacked and the alkali-solubility, when calculated as a percentage of sound wood, decreases steadily as decay proceeds.

The results for the intermediate zone of so-called "red wood" are of considerable interest. From a visual examination it was doubtful whether the fungus had penetrated into this zone to any appreciable extent although the wood was stained a reddish brown colour, which suggested that at least part had undergone chemical change. The analytical data make it abundantly clear that the wood substance in question was in an early stage of decay. A loss in weight of approximately 4·6 % was sustained and this is almost wholly accounted for by depletion of the Cross and Bevan cellulose. The furfuraldehyde-yielding complexes associated with the cellulose only exhibit the faintest indication of decomposition. At this early stage of decay the lignin is also attacked to a slight extent. Both the methoxyl groups and the main portion of the lignin complex would appear to be involved. With regard to extractives it is noteworthy that the decayed wood contains less water- and alkali-soluble material than sound wood when the results are all expressed on the same basis. At the same time the fraction soluble in alcohol:benzene is greater in the decayed than in the sound wood. It is therefore suggested that the increment to the alcohol:benzene-soluble fraction is derived from transition products in the break-down of the wood substance. The red-brown colour of the intermediate zone may thereby be explained.

As the decay becomes more advanced the nature of the ultimate chemical changes is in all respects similar to certain other white rots which have been studied [Campbell, 1932; Wiertelak, 1932]. At the most advanced stage examined approximately one-third of the cellulose and one-quarter of the lignin were decomposed. Depletion of the furfuraldehyde-yielding complexes was also well marked. It is therefore apparent that the fungus derives the greater part of its nourishment from the carbohydrates of the cell wall substance of the wood. It is observed that as decay proceeds the solubility of the wood in alcohol: benzene exhibits a decline. This would appear to indicate that the by-products formed in the early stages of decay are ultimately decomposed.

Turning now to the data in Table II it can be seen that although the saprophytic attack of *U. vulgaris* on wood substance is slow it closely resembles, in its early stages at least, the parasitic action (Table I).

As before, attack is concentrated on the cellulose from the outset. In this case there is more definite indication of early attack on the furfuraldehyde-yielding complexes associated with the cellulose, and the attack on lignin at this stage has been confined to methoxyl groups.

SUMMARY.

Ustulina vulgaris Tul. as a parasite on lime wood (*Tilia vulgaris* Hayne) produces a type of decomposition which must be characterised as a white rot. The chief source of fungal nourishment, however, is the carbohydrate portion of the cell wall. Lignin is also decomposed but not to the same extent as the Cross and Bevan cellulose.

The saprophytic action of the fungus on beech wood, although slow, is chemically of the same order as the parasitic action.

The experimental data obtained from decayed lime wood suggest that this fungus must have a pronounced detrimental effect on the mechanical properties of the wood.

We wish to express our indebtedness to the Polish Fund of National Culture for financial assistance and to the Department of Scientific and Industrial

The precipitate from pancreatin treated with NaOH constituted about 3·1 % of the total pancreatin and could be separated into an active and an inactive fraction. The former was a denatured protein containing 13·6 % N, and the active portion could be recrystallised from alcohol to give a substance of M.P. 59°. The latter possessed the properties of a mixture of saturated fatty acids such as palmitic acid and constituted 14·7 % of the precipitate.

It was indeed found possible to prepare a mixture of fatty acid and caseinogen which reproduces the surface active properties of pancreatin. Thus a mixture of sodium oleate and caseinogen in the proportions of 1:2 by weight gave the same p_H optimum for displacement of both protein and tripalmitin films as did the same quantity of pancreatin. Further, the action of sodium fluoride on such a synthetic mixture was to cause visible flocculation of protein and with it much adsorbed fatty acid, thus accounting for the observed inhibitions of surface activity by sodium fluoride. It is worthy of note that some species of complex between the sodium oleate and caseinogen must exist in solution for the action on films of sodium oleate alone is not affected by the addition of sodium fluoride; and as already noted the fatty acids are only extractable with hot alcohol.

Specific enzymes.

In previous publications experiments have been described showing the progressive attack of monolayers of caseinogen by specific proteolytic ferments, the reaction proceeding in stages according to the particular enzyme fraction employed. The following newly available preparations have been studied.

(1) *Chymotrypsin.* This possesses negligible lipolytic and considerable proteolytic properties corresponding to a more extensive breakdown than the original crystalline trypsin. On injection beneath films of tripalmitin and of caseinogen, the latter was digested much further (a further 35 mv. as measured by the method of surface potentials) than by crystalline trypsin. The tripalmitin was scarcely attacked at all.

0·123 g. chymotrypsin dissolved in 300 ml. $M/25$ phosphate buffer at p_H 8 (25°) reduced the surface potential of a caseinogen monolayer from 280 mv. to a final constant value of 225 mv. in 15 minutes. This corresponds to the bulk activity of chymotrypsin. Treatment with NaOH or incubation with crystalline pepsin caused rapid inactivation for bulk and surface activity. Like crystalline trypsin, chymotrypsin solutions give a gelatinous rigid film at the air/liquid interface; thus one observes the caseinogen film turn from gelatinous to liquid during the reaction, while the free surface of the enzyme solution remains gelatinous. The chymotrypsin can neither digest itself nor displace the partially digested caseinogen film.

(2) *Chymotrypsinogen.* This material, from which chymotrypsin is prepared by activation with crystalline trypsin, is completely inactive for surface reactions as it is in bulk. The free surface potential value of chymotrypsinogen solutions is much higher than that of its active form.

(3) *Crystalline pepsin.* This shows no lipolytic activity either in bulk or towards tripalmitin films, but digests caseinogen films at p_H 2·0, with a reduction in the potential of the protein film from 380–315 mv. in 20 minutes, at a concentration of 0·1 ml. pepsin soln./200 ml. The same phenomenon is apparent here as in the case of chymotrypsin, namely that during the reaction the caseinogen film, initially a rigid two-dimensional gel, becomes perfectly fluid owing to digestion, while the free surface of the enzyme solution remains gelatinous throughout. Crystalline pepsin possesses no surface activity at p_H 8·0.

(4) *Enzymes separated by alumina.* Pancreatin freed from lipase by progressive adsorption with alumina *B* gave proteolytic solutions which digested caseinogen films in a manner similar to Northrop's chymotrypsin. Treatment with NaOH completely inactivated these preparations in respect to surface as well as bulk activity, and on acidifying the solution a precipitate was obtained at p_H 4·6 which on redissolving was completely inactive. Thus adsorption on alumina effects the removal of all fatty acids as well as of lipase from pancreatin.

The above specific enzyme preparations on injection beneath unimolecular films of long chain alcohols or amines gave no evidence of any complex formation.

The limitations of the surface technique in this field are now clear. It is seen that a fatty acid-protein complex can simulate the expected behaviour of a lipolytic enzyme in respect to p_H optimum and fluoride inhibition and in replacing for example a tripalmitin film by a film of fatty acid. Further, these complexes are obtained from pancreatin by processes such as boiling or alkali treatment which destroy the true enzymes. It is only specific ferments such as are obtained by less drastic treatment, *e.g.* ammonium sulphate precipitation or adsorption on alumina which can be examined with safety. It is of interest, however, that it appears to be impossible to separate the lipase fraction of pancreatin from lipoids, including fatty acids.

In regard to the protein-fatty acid complex, evidence of such adsorption complexes was obtained by du Noüy [1926] from measurements of the surface tension of mixtures of varying preparations of sodium oleate and albumin. Roughly 200 molecules of the soap can be adsorbed to a protein molecule of molecular weight about 35,000, *i.e.* about one molecule per side-chain. In the light of the present work there must be an equilibrium between such a complex and free fatty acid or soap. Thus a film of tripalmitin spread on a solution of the soap-protein or fatty acid-protein complex is replaced by a film of soap or fatty acid, according to the p_H, possessing a surface potential some 100 mv. higher than that of the soap-protein complex accumulating at the free surface. The simplest interpretation is that the close-packed film of tripalmitin cannot be penetrated by the large molecules of protein or of protein-fatty acid complex, but that the free fatty acid or soap molecules can penetrate and displace the tripalmitin over a wide range of p_H. The displacement of films of tripalmitin and of protein by fatty acid or soap alone is closely related to the surface tension as dependent on p_H. Fig. 4 shows the surface tension-time curve at various p_H values for sodium oleate as measured by the ring method. The maximum and most rapid surface tension lowering occurs around p_H 7. With increasing acidity the rate of reaching the maximum surface tension lowering decreases markedly and the effects are complicated by the formation of oleic acid emulsions with somewhat variable properties. On the alkaline side the rate of surface tension lowering increases, so that at p_H 12 the maximum value is reached instantaneously, but this maximum lowering is very much smaller, namely 7 dynes/cm. as compared with 25 dynes/cm. at p_H 7·8 for the same concentration of sodium oleate, 0·0005 %.

Now in the neighbourhood of neutrality soap displaces both tripalmitin and protein films very rapidly; at p_H 2 tripalmitin films are slowly displaced by fatty acid and protein films only very slowly. At p_H 12 the tripalmitin film is displaced very slowly and the protein films very rapidly. The inactivity in the acid solution is due to the actual emulsion formation referred to, and in the alkaline solution the explanation in the case of the displacement of protein is that the surface tension lowering of the soap solution is sufficiently great and rapid to displace the protein films, which have a still smaller surface tension

Research for the Laboratory accommodation afforded to one of us (J. W.), as well as to the Director of Forest Products Research for permission to communicate these results.

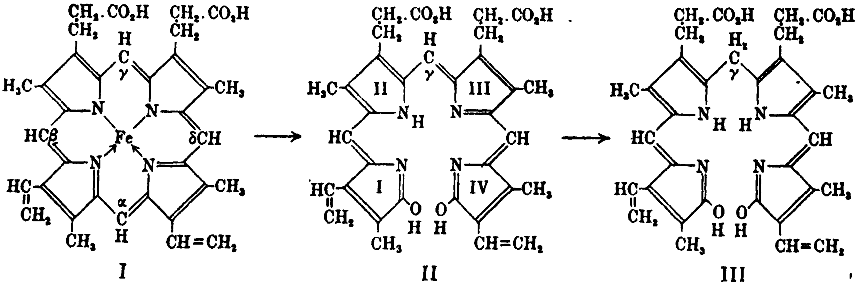
CLXI. TRANSFORMATION OF HAEMINS INTO BILE PIGMENTS.

By RUDOLF LEMBERG.

From the Biochemical Laboratory, Cambridge.

(*Received April 17th, 1935.*)

That bile pigment arises in the body by decomposition of haemoglobin is generally accepted. The work of Fischer and collaborators has confirmed the close chemical relationship between bilirubin and the colour component of haemoglobin. Hitherto nothing was known about the chemical mechanism of this transformation, nor has the formation of a bile pigment from haemoglobin or haemin *in vitro* been demonstrated with certainty. Mesobilinogen[1] has been transformed into mesoporphyrin [Fischer and Lindner, 1926, 2]; the reverse reaction however has not been accomplished. From a chemical point of view the formation of bile pigments from haemin would mean their total synthesis, since haemin has been synthesised by Fischer and Zeile [1929]. Several mesobilirubins (with a symmetrical arrangement of the side-chains) are now obtainable by direct synthesis, but the natural bile pigments which have unsymmetrically arranged and unsaturated side-chains, like bilirubin and biliverdin, cannot be synthesised in this way. A glance at the formula now established for bilirubin (III) by the investigations of Fischer since 1931 shows that it must arise from the porphyrin nucleus of haemoglobin by oxidative scission. The α CH-group is removed and replaced by two hydroxyl groups, and the porphyrin ring is thus opened. If this reaction leads to bilirubin (I → III), the γ CH-group is reduced to CH_2. Although an oxidative-reductive process is not impossible, another alternative suggests itself, *viz.* that the reaction leads at first to biliverdin [dehydrobilirubin, *cf.* Lemberg, 1934, 1] which is subsequently reduced. It has been reported by Barry and Levine [1924] that the liver reduces biliverdin to bilirubin. Moreover the bile of a number of animals (*e.g.* of the frog) contains biliverdin and not bilirubin[2].



---

[1] The writer proposes to use the shorter term "mesobilinogen" instead of "mesobilirubinogen". The first name is also more logical, since mesobilinogen is the leuco-compound of mesobiliverdin *etc.* as it is of mesobilirubin.

[2] Unlike the product of autoxidation of bilirubin in alkaline solution and like uteroverdin the biliverdin of frog's bile is free from products of secondary alteration. This disproves Fischer's view that there is a genuine difference between biliverdin and dehydrobilirubin.

Several references occur in the literature to the formation of green pigments from haemoglobin or from haemin. In fact, the bile pigment nature of some of these compounds has been claimed, although the evidence has been very scanty. With the exception of Warburg and Negelein [1930] no investigator has obtained a pure substance. Moreover, the work of these authors pointed in a different direction, since they obtained substances containing iron ("green haemin").

A closer study of the literature reveals that the processes observed by the different authors leading to the formation of green pigment from haemin or haemoglobin have more in common than appears at a first glance.

From the description given by Lewin [1901] of the dichroic green-brown substance (or more likely mixture of substances), obtained from the blood of animals poisoned with phenylhydrazine and termed haemoverdin, it remains doubtful whether it belongs to the series of pigments discussed in this paper. This does not seem improbable in view of the existence of oxidative systems produced in erythrocytes by phenylhydrazine [Warburg *et al.*, 1931, 1, 2] and in consideration of the power of this compound to produce jaundice.

Parisot [1911] prepared a green pigment by incubation of haemolysed blood with adrenaline and ammonium sulphide or sodium hydrosulphite. He considered the substance to be biliverdin, since it gave the Gmelin test. This test cannot however be considered as sufficient evidence for the bile pigment nature of a substance, unless the typical absorption bands appearing at some stages of the reaction are observed. Brugsch and Pollack [1924] contested the bile pigment nature of Parisot's substance on the grounds that it did not give the diazo-test. Since biliverdin in contrast to bilirubin does not give this test, the failure of Brugsch and Pollack to obtain it is no evidence against Parisot's assumption.

Fischer and Lindner [1926, 1] observed that (proto-)haemin and also other haemins, dissolved in pyridine, were transformed at 40–50° into green pigments in the combined presence of oxygen and of reducing substances (*e.g.* polyhydric phenols, SH-compounds). Instead of these reductants yeast (which was used in the first experiments by these authors), minced plants or animal tissue (particularly liver) could be used. The authors mention the possibility that the amorphous green pigment might be a bile pigment, but their results do not harmonise in several points with this assumption. They found the green product to contain iron and to show distinct absorption bands different from those of any known bile pigment. From the description of the bands there can be no doubt that they were of the type of those given by the "green haemin" of Warburg and Negelein [1930].

By the action of molecular oxygen at 50° on pyridine-haemochromogen in the presence of hydrazine as reductant, Warburg and Negelein [1930] obtained a "green haemin" showing typical absorption bands, Warburg [1932] considered such "green haemins" as somewhat related to the green haemins of phaeophorbides and brought forward the hypothesis that the "Atmungsferment"-haemin (a green-red haemin) might stand between the red (porphyrin-)haemins and the green (chlorophyll-)haemins, the latter being oxidation products, the former reduction products of the Atmungsferment-haemin, from which they arose in the course of development. The results of the present paper show that the "green haemins" obtainable by oxidation have nothing to do with chlorophyll haemins. Warburg and Negelein did not obtain the "green haemin" itself in a pure state, but they were able to transform it by methyl alcoholic hydrochloric acid into a crystalline ester $C_{36}H_{40}O_6N_4FeCl_4$ which contained chlorine in contrast to the green haemin itself.

Schottmüller [1903] recognised that streptococci (*S. viridans*, *Pneumococcus*) produce a green pigment from haemoglobin when grown aerobically on the surface of blood agar plates or in blood broth. This process has been investigated in detail by Hart and Anderson [1933] and earlier literature on the subject has been reviewed in their paper. The pigment (which in fact is a mixture) shows in addition to other absorption bands a band in the red part of the spectrum resembling that of Warburg's green haemin. With the pigment produced by bacteria from haemoglobin Rich and Bumstead [1925] observed an atypical Gmelin reaction only. A pigment of the same properties as that produced by bacteria was prepared by Anderson and Hart [1934] by the action of non-bacterial reducing systems on haemoglobin in the presence of oxygen, and a similar mechanism was assumed to work in the formation of the pigment by bacteria.

The essential similarity of all the processes described above is that the simultaneous action of a reducing system and of oxygen on either haemochromogen or haemoglobin is necessary for the green formation.

Recently Schreuss and Carrié [1934] reported that a green pigment showing the properties of a biliverdin (it was soluble in ether and passed from it into hydrochloric acid) can be obtained in very small amounts if haemoglobin or haematin is incubated with liver "brei" or liver extract at 70° and p_H 7–8. The authors do not give any details of their method and the pigment was not isolated in the pure state. The formation of biliverdin was regarded by them as an oxidation of bilirubin during the extraction process.

It appeared particularly important to me to make a closer study of the "green haemin ester" of Warburg and Negelein, not only because it was the only pure product obtained but also for important structural implications. This ester contained four chlorine atoms and one iron atom. The results of Warburg and Negelein made it improbable that the substance was a haemin ester of a chloroporphyrin, since unlike the known tetrachloroporphyrins it could not be reduced to a normal red porphyrin. Biliverdins however form ferrichlorides, as has been shown by Fischer *et al.* [1932] and by Lemberg [1932], and it seemed not impossible that the substance in question was such a ferrichloride of a biliverdin.

EXPERIMENTAL.

For the preparation of the "green haemin" the procedure of Warburg and Negelein was used with slight alterations. It is essential to complete the transformation of haemin into green haemin as fast as possible to avoid formation of brown by-products. This could be attained more easily if only small amounts of haemin were used in each experiment; the products of several experiments were then worked up together.

In a 500 ml. wide-necked Erlenmeyer flask with almost vertical sides 0·4 g. of haemin was dissolved in a mixture of 100 ml. pyridine and 250 ml. water. This solution was kept at 50° in a water-bath and was aerated with a violent current of oxygen accompanied by vigorous mechanical stirring. A solution of 1·3 g. hydrazine sulphate in 32 ml. $N/2$ NaOH was then added. The colour changed soon to green and after 3–4 minutes the first band of haemochromogen at 557 $m\mu$ had disappeared and the spectrum of the green haemin (*cf.* below) was seen. At this point the reaction was stopped immediately and the solution cooled with ice. The filtered solutions of several successive experiments were combined and extracted without delay with ether and chloroform as described by Warburg. The black precipitate which appeared during the extraction of the brown by-products with ether included a considerable part of the "green haemin". This was extracted by an aqueous pyridine solution containing some hydrazine hydrate and some acetic acid. This part of the product however was kept separate; it yielded a considerable amount of "green haemin" but did not give crystalline ester. The main bulk of the chloroform solution was concentrated *in vacuo* at 40° to a few ml. and precipitated with light petroleum (B.P. 50–60°).

The precipitate was transformed into the "green ester" by boiling in methyl alcoholic hydrochloric acid. From 2 g. haemin 50 mg. pure crystalline ester were obtained with the following crystal properties.

Elongated platelets pointed at the ends. Extinction slightly oblique. Pleochroism: light blue-green, if long axis of platelets parallel to plane of polarisation, dark green in perpendicular orientation. Blue and green colours between crossed nicols. The substance did not melt. The solution of the compound does not show distinct absorption bands but a general absorption of the red part of the spectrum.

A few mg. of the ester were dissolved in chloroform. The dark green solution turned blue when shaken with water (colour of neutral biliverdin). The aqueous solution was found to contain ferric iron as indicated by the thiocyanate reaction. This experiment is proof that iron is not present in complex combination in the ester, but as a ferric chloride double salt.

One mg. of the ester was dissolved in 1 ml. methyl alcohol and this solution was poured into a mixture of ether and sodium tartrate solution. Biliverdin ester passed into the ether layer colouring it blue, whereas iron was found in the tartrate solution. With 1 % hydrochloric acid the pigment passed into the acid aqueous solution with green colour.

With zinc acetate and iodine biliverdins like bilirubins [Auché, 1908] are transformed into the complex zinc salts of biliviolins. Biliviolins contain two hydrogen atoms less than biliverdins [Lemberg, 1934, 2]. Their zinc complex salts are characterised by typical absorption bands and extremely strong red fluorescence. The "green ester" reacted immediately with zinc acetate to give a yellow-green solution with an absorption band in the extreme red part of the spectrum (biliverdin zinc salt); on addition of a drop of iodine the solution turned green-blue and displayed a striking red fluorescence and absorption bands at 635·0 $m\mu$ and (less strong) 582·0 $m\mu$. These bands are the same within experimental error as those of biliviolin ester zinc salt, prepared in the same way from biliverdin (634·1 and 580·8 $m\mu$) and distinctly different from those of the corresponding mesobiliviolin compound (*cf.* below). This experiment confirmed the finding that the iron is not bound in complex combination in the green ester, and made its identity with the ferrichloride of biliverdin ester very probable.

The formula of *biliverdin dimethyl ester ferrichloride* is $C_{35}H_{38}O_6N_4.HCl.FeCl_3$. (Found: C, 51·86; H, 4·80; Fe, 6·68; OCH_3, 7·60, 7·47 %. $C_{35}H_{39}O_6N_4FeCl_4$ requires C, 51·91; H, 4·86; Fe, 6·90; OCH_3, 7·67 %.) The analyses reported by Warburg and Negelein are in better agreement with this formula than with the formula $C_{36}H_{40}O_6N_4FeCl_4$ which the authors ascribed to the substance. (Found: C, 51·92, 51·79; H, 4·90, 4·82; N, 6·47, 6·46; Fe, 6·85, 7·13, 6·78, 6·64; Cl, 17·93, 17·66; OCH_3, 8·29, 7·64, 7·83 %. $C_{35}H_{39}O_6N_4FeCl_4$ requires C, 51·91; H, 4·86; N, 6·93; Fe, 6·90; Cl, 17·53; OCH_3, 7·67 %.)

Since the compound has no melting-point it was transformed into *biliverdin dimethyl ester* for identification. 40 mg. were dissolved in methyl alcohol, containing some sodium acetate, and this solution was poured into a mixture of chloroform with a dilute solution of sodium carbonate and sodium tartrate. The blue chloroform solution was washed with water, filtered, dried with Na_2SO_4 and evaporated *in vacuo*. The residue was recrystallised from methyl alcohol. It was free from iron and chlorine and melted at 208° (uncorr.). Mixing with purest biliverdin ester (M.P. 215°) gave no depression of the melting-point.

From the mother-liquor of the crude "green ester" a second small yield of crystals of the same properties was obtained. The mother-liquor of these however contained a different biliverdin which in the violin reaction with zinc acetate and iodine gave absorption bands of mesobiliviolin zinc salt (623·6, 572·2 $m\mu$). It is not however suggested that the compound in the mother-liquor was mesobiliverdin ferrichloride. The neutral iron-free ester obtained from it was easily soluble in methyl alcohol and did not crystallise completely. The following observations indicate that it might be haematobiliverdin (with two $CH(OH).CH_3$ groups).

21·39 mg. of this biliverdin were heated for 1·5 hours over P_2O_5 in a flask at 150° in a high vacuum (of the mercury pump). The substance lost 0·91 mg. (calculated loss of two mols. of water, corresponding to a transformation of two hydroxyethyl side-chains into vinyl groups: 1·19 mg.). The product had however been altered more fundamentally; it was no longer soluble in methyl alcohol, but soluble in chloroform and did not give the violin reaction. Hence a second sample was heated at 105° in the vacuum of the mercury pump. Under these conditions haematoporphyrin is transformed into protoporphyrin. After half an hour 14·54 mg. had lost no more than 0·12 mg. The heating was continued for three more hours; now the substance gave a violin reaction like biliverdin (protobiliverdin): absorption bands of the zinc salt at 632·3 and 578·7 $m\mu$. Whereas biliverdin dissolved in concentrated sulphuric acid is destroyed by heating for a quarter of an hour on a steam-bath and mesobiliverdin is not attacked at all and remains blue-green, the biliverdin of the mother liquor is changed into a blackish blue-green.

This partial alteration of the side-chains occurs in the preparation of the "green haemin" and not in the succeeding esterification, since biliverdin ferrichloride is completely stable under the conditions of the esterification, and since the amount of by-product formed varies according to the purity of the green haemin.

Preparation of mesobiliverdin ester from mesohaemin.

Since the corresponding mesobiliverdin compounds are well-characterised substances, and since it was interesting to investigate whether or not the reaction mechanism of the formation of "green haemin" is bound up with the vinyl side-chains I subjected mesohaemin to the same process as haemin above. Like haemin, mesohaemin was transformed into a green haemin and the latter into a green ester, containing iron and chlorine. The oxidation time extended for 6 minutes. From 0·8 g. mesohaemin 60 mg. of well crystallised green ester were obtained. The substance decomposed at 261° (uncorr.) under the following conditions. The paraffin-bath was brought to 100°, before the thermometer with the substance was inserted, and then the temperature slowly raised. Under the same conditions mesobiliverdin dimethyl ester ferrichloride ("ferrobilin ester" of Fischer) decomposed at 265° (uncorr.). With more rapid heating higher decomposition points are found. (Found: C, 51·44, 51·97; H, 4·99, 5·25; Fe, 6·77, 6·10; Cl, 18·42 %. $C_{35}H_{43}O_6N_4FeCl_4$ requires C, 51·66; H, 5·33; Fe, 6·87; Cl, 17·45 %.)

With zinc acetate and iodine the solution of the green ester turned blue exhibiting a striking red fluorescence and absorption bands at 623·2 and 572·3 $m\mu$ characteristic for mesobiliviolin zinc salt. Mesobiliverdin ester prepared from bilirubin showed absorption bands at 623·7 and 573·3 $m\mu$, if treated with zinc acetate and iodine[1].

40 mg. of the ferrichloride were dissolved in chloroform and freed from iron and HCl by washing with dilute sodium carbonate solution containing some tartrate. The residue of the dried evaporated chloroform solution was crystallised from methyl alcohol; 20 mg. of characteristic well-formed prisms crystallised out; M.P. 218–219° (uncorr.), no depression with mesobiliverdin dimethyl ester (M.P. 220° uncorr.). (Found: C, 67·39; H, 6·85 %. $C_{35}H_{42}O_6N_4$ requires C, 68·34; H, 6·89 %.)

From the mother-liquor of the ferrichloride 25 mg. of a biliverdin ester (according to the violin reaction of the meso-type) were prepared which did not crystallise as well, were more easily soluble in methyl alcohol and had a lower M.P. (179–180°). The ferrichloride of this ester was easily soluble in methyl alcohol in contrast to that of mesobiliverdin ester. From these observations it can be concluded that the product is not impure mesobiliverdin ester, but consists of a different biliverdin ester.

Verdohaemochromogen ("green haemin") and mesoverdohaemochromogen.

In contradistinction to the green esters which have now been recognised as ferrichlorides of biliverdins, the green haemins contain the iron still in complex combination. With zinc acetate and iodine they do not give the violin reaction. The iron cannot be removed by washing with water or with alkali. From the results of the investigation to be described below it will be seen that they are pyridine-haemochromogens. I propose to name the "green haemin" of Warburg verdohaemochromogen and the corresponding compound from mesohaemin mesoverdohaemochromogen.

The two compounds are very similar, but they can be distinguished from one another by the position of their absorption bands, those of the meso-compound lying nearer to the ultra-violet. This difference in the situation of the bands of proto- and meso-compounds is also true for the porphyrins, haemochromogens and biliviolins. Verdohaemochromogen dissolved in pyridine-water shows a sharp absorption band in the red with its centre at 662 $m\mu$ and two weaker bands in the green (533·1 and 500·8 $m\mu$). Mesoverdohaemochromogen under the same conditions shows the bands 644·2, 525·4 and 494·4 $m\mu$. In chloroform (containing pyridine) the first two bands lie more towards the infra-red, whereas the third has the same position as in water (verdohaemochromogen 663·5, 535·7 and 500·8 $m\mu$, mesoverdohaemochromogen 650·7, 527·8 and 495·1 $m\mu$).

If verdohaemochromogen in an aqueous solution containing much pyridine is shaken with air the type of the spectrum is little changed. The bands become less sharp, particularly that in the red, which becomes broader and is shifted towards the infra-red. Mesoverdohaemochromogen behaves in the same way. These aerated solutions contain parahaematins and have a bluish green colour rather than the yellowish green colour of verdohaemochromogen solutions. Parahaematins are also obtained if the verdohaemochromogens precipitated from the chloroform solution by light petroleum have stood some time exposed to the air. The fresh precipitate however consists, at least to a large extent, of the haemochromogen, as will be seen below. Verdohaemochromogens are evidently more stable towards atmospheric oxygen than haemochromogens.

---

[1] The situation of the absorption bands depends somewhat on the purity of the violin, admixture of much verdin causing a shift of the bands towards the infra-red. It depends also on the p_H of the mixture, alkali shifting the bands towards infra-red. The difference in the position of the biliviolin and mesobiliviolin bands is however so great that compounds of the proto and of the meso series can be clearly distinguished in this way.

If the verdohaemochromogens are shaken with air in a solution containing no great excess of pyridine, the absorption bands disappear and are replaced by diffuse absorption at both ends of the spectrum. On addition of sodium hydrosulphite the olive solution turns green and displays the bands of the haemochromogens (in the case of verdohaemochromogen it is essential to use only small amounts of reductant). We can conclude from this experiment that the affinity of verdohaematin for pyridine is much less than that of verdohaem. Pyridine-verdoparahaematin which is formed by the oxidation of the verdohaemochromogen decomposes in water into verdohaematin and pyridine, unless a great excess of pyridine is present. By $Na_2S_2O_4$ verdohaematin is reduced to verdohaem, and the latter, owing to its greater affinity for pyridine, recombines with it. This is a complete parallel with the behaviour of haematin and haem towards pyridine.

If sodium hydrosulphite is added to a solution of "green haemin" in pyridine-water the solution turns yellow. The two absorption bands in the green disappear and are replaced by general absorption in the blue part of the spectrum, whereas the band in the red remains but is shifted towards the ultra-violet (652 $m\mu$). On shaking with air the solution turns green again, the bands in the green reappear and that in the red returns to its previous place. A ready explanation for this reversible reduction with sodium hydrosulphite would be that the green colour and the bands in the green were properties of a parahaematin compound which is reduced by sodium hydrosulphite to the yellow haemochromogen. The "green haemin" would then be a parahaematin and not a haemochromogen. This is, however, not in accordance with the experiments described above and it can be proved that such an explanation is incorrect. The reaction with hydrosulphite is given by verdohaemochromogen only, mesoverdohaemochromogen remains green with hydrosulphite and the absorption bands in the green do not disappear. This shows that the unsaturated side-chains of the proto-compound are somehow involved in this reaction.

The behaviour of the "green haemin" towards alkali also gives evidence that the absorption bands in the green belong to the haemochromogen. If a solution of sodium carbonate is added to a solution of "green haemin" in pyridine-water the absorption bands disappear slowly and the olive-green solution obtained shows diffuse absorption in the red and blue parts of the spectrum. If now a small amount of hydrosulphite is added the solution turns green and displays the spectrum with the three bands of the green haemin; if more hydrosulphite is added the solution becomes yellow and the bands in the green disappear. This experiment can only be explained in the following way. Pyridine-verdoparahaematin, which arises by oxidation of verdohaemochromogen in atmospheric oxygen, is unstable in alkali: thus it dissociates into verdohaematin and pyridine. By the reduction verdohaem is formed which unites with pyridine to give verdohaemochromogen, which is stable towards alkali. Since we obtain the absorption bands in the green in this experiment by reduction with hydrosulphite these bands must be those of the haemochromogen, and the further reversible reduction must be explained in a different way. Here again we find the verdohaem compounds behaving like normal haem compounds: haemochromogens are stable towards alkali, parahaematins are not [Keilin, 1926].

It can be shown in this way that the green haemin precipitated from the concentrated chloroform solution with light petroleum still contains verdohaemochromogen. A few mg. of the freshly precipitated "green haemin" were dissolved in 2 ml. pyridine-water and put into a Thunberg tube the stopper of which contained 1 ml. 10 % sodium carbonate solution. The tube was at once repeatedly evacuated and filled with nitrogen. The alkali was then allowed to run into the solution. The colour turned slightly more olive, indicating that a part of the haemochromogen had been oxidised and split, but the three bands were still strongly visible. The pyridine used in this experiment did not reduce haemin to haemochromogen (as impure pyridine does). When the experiment was repeated with a preparation of "green haemin" which had been kept for some hours in contact with the air, the bands disappeared after the addition of the alkali.

The pyridine-free *verdohaematin* was obtained in the following way. A few mg. of green haemin were ground with water in a mortar and left in suspension for one hour. By the filtration of this suspension a black powder was obtained which was washed several times with water. Its solution in methyl alcohol showed only one diffuse absorption band at 700–680 $m\mu$, that of mesoverdohaematin a band at 690–655 $m\mu$ (in a Zeiss pocket spectroscope). Verdohaematin was dissolved in phosphate buffer p_H 7·5 giving an olive solution without distinct absorption bands. With hydrosulphite the solution became olive-green, but no distinct bands were seen (verdohaem). If CO were passed into this solution, it changed to olive-brown and displayed distinct bands at 665 and 610 $m\mu$ verdohaem-CO). Experiments with pyridine confirmed the results obtained above. A small amount of pyridine did not produce any alteration before reduction, a great excess of pyridine gave rise to bluish green parahaematin solutions with a rather diffuse band in the red and more distinct bands in the green. Unexpected however, was the behaviour towards ammonia. After addition of ammonia $Na_2S_2O_4$ did not give ammonia-verdohaemochromogen, as had been expected, but a brown ammonia-haemochromogen with a completely different spectrum, showing one absorption band at 567 $m\mu$. The same compound was obtained by direct action of ammonia on verdohaemochromogen. Pyridine now produced a dirty yellow solution with a reddish tint in artificial light and a sharp absorption band at 565·7 $m\mu$. A closer study of this interesting reaction has yet to be made. With the exception of its behaviour towards hydrosulphite mesoverdohaemochromogen behaved similarly in every respect.

These experiments prove that the "green haemins" are haemochromogens, containing bivalent iron in complex combination and pyridine bound to the iron atom. It is only by treatment with acid that the iron is removed from this combination. Since haemochromogens are more easily split by acids into the iron-free compounds and iron salt than the compounds with tervalent iron like haemin, the easy removal of the iron from the green haemins is understandable. Unlike haemins, however, verdohaematins are also unstable towards acids and apparently even more liable to alterations than the verdohaemochromogens. Verdohaematin is easily transformed by dilute hydrochloric acid in methyl alcoholic solution into a mixture of biliverdin and some biliviolin.

Verdohaem compounds as bile pigment complex salts.

The evidence thus far brought forward has not yet excluded with certainty the possibility that in the "green haemins" the porphyrin ring was still closed, and that the scission occurred only during the preparation of the "green esters". It was not quite impossible, although improbable, that the ring of the green haemins was closed by a CO-group instead of a CH-group, and that the CO-group was replaced by two OH-groups under the hydrolytic action of the acid.

The reduction of haemins by sodium amalgam leads to porphyrinogens which on reoxidation by atmospheric oxygen yield porphyrins. The reduction of verdohaematin, however, leads to mesobilinogen which is oxidised by atmospheric oxygen to a urobilinoid pigment. 50 mg. of verdohaematin were dissolved in 1 % sodium carbonate solution and shaken with sodium amalgam for 2 hours. The slightly yellow solution was separated from the mercury and extracted with ether containing glacial acetic acid. The ethereal solution gave a strong reaction with Ehrlich's aldehyde with absorption bands at 562 and 495 $m\mu$. With zinc acetate and iodine a strong "urobilin" reaction was obtained. On standing the colourless ethereal solution gradually turned yellow, containing now a typical urobilinoid pigment. The absorption band of the zinc salt was situated at 508·6 $m\mu$, that of the acid aqueous solution of the pigment itself at 494·5 $m\mu$. This is exactly the behaviour of mesobilinogen. I have recently shown [1934, 3] that mesobilinogen, unlike urobilinogen, is oxidised by ferric chloride to a mixture containing biliverdins and biliviolins. The bilinogen obtained from green haemin behaves in this reaction like mesobilinogen and yields a biliviolin which according to the spectrum of its zinc salt is mesobiliviolin. There can be little doubt that the substance in question is mesobilinogen. When haemin was treated in the same way, the ether solution of the chromogen gave only a very feeble Ehrlich reaction. After some standing the spectrum of protoporphyrin appeared. In the aqueous solution a small amount of a yellow substance was present which gave a green fluorescence with zinc acetate, the typical shift of the absorption band towards the red, characteristic for urobilinoid pigments, was not however observed. Like verdohaematin "green haemin" itself was reduced to mesobilinogen by sodium amalgam.

This experiment proves the presence of an open bile pigment chain in the "green haemins" which is maintained in ring form by the central iron atom. The following experiments give additional evidence that the iron-free part of the green haemin is a bile pigment closely related to biliverdin.

When copper acetate was added to a solution of mesoverdohaemochromogen in a mixture of methyl alcohol and pyridine the solution turned at first yellow-green. The two absorption bands in the green had disappeared and that in the red had been shifted towards infra-red (to about 680 $m\mu$). On standing the band in the red gets weaker and is replaced by two bands at 632 and at 578 $m\mu$. The latter spectrum is that of a copper complex salt of mesobiliviolin, the former that of mesobiliverdin-copper which is oxidised by bivalent copper to the latter [*cf.* Lemberg, 1934, 1]. Mesoverdohaematin treated with copper acetate yields the same products.

It has been said above that the verdohaemochromogens do not react with zinc acetate. When however the solution is kept exposed to the air after the addition of the zinc salt, the red fluorescence and the spectrum of the biliviolin zinc salt appear slowly. Even the replacement of iron by another metal is not necessary to form complex salts of biliviolins from green haemins. When a solution of mesoverdohaemochromogen in methyl alcohol containing a little ammonia was shaken with air an absorption band at 633·7 $m\mu$ was observed.

Since iron complex salts of biliverdins and biliviolins have not yet been described[1], I investigated the action of ferrous sulphate on mesobiliverdin in ammoniacal solution. The filtrate was olive-green and showed diffuse absorption in the red and blue. After addition of pyridine and sodium hydrosulphite the green solution displayed absorption bands at 627·2 and 576·4 $m\mu$. This behaviour does not correspond with that of mesoverdohaemochromogen but with that of a haemochromogen of mesobiliviolin. Shaking the solution with air produced a series of changes which have not yet been investigated in detail. Since bivalent copper oxidises the copper complex salt of mesobiliverdin to that of mesobiliviolin, it was easily understandable that the tervalent iron formed in the presence of oxygen would oxidise the mesobiliverdin iron salt to that of mesobiliviolin as well. For this reason I tried to introduce iron into mesobiliverdin by means of ferrous sulphate in ammoniacal solution in the absence of oxygen.

---

[1] The "ferrobilins" are not complex salts in this sense, but ferrichlorides.

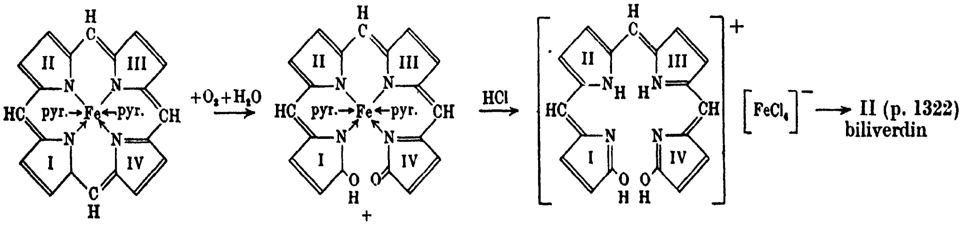
For this purpose an apparatus was used consisting of a tube containing a filter plate of porous glass with a tap below it; a small dropping funnel was fitted into the top of the tube, and the bottom was inserted into a small receiver with a tap in the side arm. Each of the three vessels was connected by means of three-way taps with the vacuum pump and with a nitrogen apparatus. Nitrogen, freed from oxygen by passage over heated copper, passed at first from the receiver, containing a little pyridine with some hydrazine hydrate as reductant, through the tap and the porous glass plate into the lumen of the tube containing mesobiliverdin in ammoniacal solution. To this solution ferrous sulphate solution, freed from oxygen by evacuation and saturation with nitrogen, was added from the dropping funnel, and after a few minutes the reaction mixture was sucked through the filter into the receiver. The two taps were then closed and the spectrum of the solution investigated. Under these conditions no complex salt is formed. The blue-green solution showed the general absorption of the red part of the spectrum characteristic of mesobiliverdin. Under the conditions of the experiment any complex iron salt formed would yield haemochromogen, the sharp absorption bands of which would not escape notice. As long as the solution was kept in nitrogen, no change was observed. When however air was allowed to enter the flask, the spectrum of biliviolin complex salt described above appeared. When hydrochloric acid was now added to this solution, mesobiliverdin ferrichloride was precipitated, leaving a blue-violet solution of mesobiliviolin (spectrum in acid solution: absorption bands with centres at 592·6 and 551·5$m\mu$, rather diffuse and connected by a shadow; main absorption band of the zinc salt: 624·9 $m\mu$). Mesobiliverdin itself apparently does not form haem compounds.

From these experiments it must be concluded that the "green haemins" are haemochromogens of bile pigments with an open ring. The iron-free compound is probably not identical with biliverdin, but unstable and easily transformed into biliverdin.

Discussion.

The reaction leading from haemins (or more exactly from pyridine-haemochromogens) to "green haemins" and from these to biliverdins can now be formulated as follows:

(The side-chains have been omitted.)



(pyr. = pyridine)
haemochromogen

verdohaemochromogen
("green haemin")

biliverdin ferrichloride

The first step leads from pyridine-haemochromogen by an oxidative process to verdohaemochromogen. The central part of the molecule remains unaltered, but the porphyrin ring is split open and transformed into a bile pigment nucleus. The usual way of writing the bile pigment formula in a straight chain is only a conventional mode of expression. Since there is free rotation around the single bonds combining pyrrole nuclei with carbon atoms the molecules of bile pigments may assume different shapes in space, *e.g.* that of a plane opened ring.

The identification of the "green esters" with derivatives of natural bilirubin (bilirubin IXα according to Fischer's nomenclature) proves that the scission occurs in the same place (α CH-group) as in the transformation of haemoglobin into bilirubin. It must be conceded that the yield of well-crystallised biliverdin ester is rather small and that isomerides with different position of the side-chains, resulting from scission of the ring at other CH-groups, might be present in the mother-liquor, but this applies also to natural bilirubin, a small fraction of which only is obtainable completely pure.

The ring having been opened at one point the stability of the complex salt becomes remarkably decreased. The central iron in its complex combination still holds the ring together, particularly as long as its six coordination places are filled, as they are in the haemochromogens. In contrast with normal haematins the verdohaematins are very unstable compounds.

The formula given above characterises the verdohaem compounds as iron salts of *iso*biliverdins. The latter are unstable and, if set free, are transformed into biliverdins (*cf.* formula II, p. 1322) by a migration of one hydrogen atom from the nitrogen of the pyrrole nucleus III to the α CO-group of ring IV.

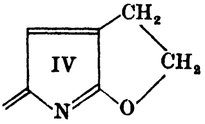
The reaction of verdohaemochromogen with hydrochloric acid consists of the following stages. The pyridine is removed and the verdohaem oxidised to verdohaemin, this is now split into ferric chloride and *iso*biliverdin which rearranges to give biliverdin. This isomerisation transforms the nitrogen in ring III into a basic tertiary nitrogen which adds a proton. There is in addition esterification of the two carboxyl groups in the side-chains by the methyl alcohol. $FeCl_4^-$ ions are always present in solutions of ferric chloride and since the ferrichloride is the least soluble salt, it crystallises out.

The fact that isomerisation of biliverdin is necessary for the formation of "green haemin" explains why this cannot be accomplished from biliverdin with ferrous salt. The zinc and copper compounds of biliverdin are probably complex salts of biliverdin itself and not of *iso*biliverdin, since unlike the iron salt they are obtained from biliverdin, and since they show an absorption spectrum very different from that of verdohaemochromogen. Both types of complex salts can however be transformed by oxidation into complex salts of biliviolins[1].

The transformation of haemin into biliverdin is also of interest for the question of the nature of the side-chains of bilirubin. It suggests that bilirubin and biliverdin contain two vinyl groups like haemin. Fischer has often discussed this question and has repeatedly altered his views. Quite recently Fischer and Haberland [1935] have come to the conclusion that bilirubin contains one vinyl group, whereas the second unsaturated side-chain is present in the form of a dihydrofuran nucleus (*cf.* formula on p. 1333). Although it is not quite impossible that such a ring is formed during the reaction leading from haemin to biliverdin by closing a ring between the vinyl group in position β and the hydroxyl group in position α at ring IV, it does not seem probable.

---

[1] H. Fischer who had previously confused the blue colour of the neutral biliverdins with the similar colour (although very different spectrum) of the acid biliviolins and assumed that the latter were isomerides of the former, has now [Fischer and Haberland, 1935] recognised his mistake and has arrived at the formula for biliviolins which I proposed in my paper before the Biochemical Society on November 16th, 1934, and which has been published in a short note [1934, 2]. Fischer has overlooked this note.



Moreover, the evidence brought forward by Fischer for the existence of this ring is unconvincing. It is based (1) on the fact that the behaviour of the unsaturated groups in bilirubin towards reagents is different from that of these groups in haemin; (2) on the isolation of a substance assumed to be a pyrrofuran compound, obtained in small yield by the action of nitrous acid on bilirubin; and (3) on the isolation of a dihydrobilirubin with one vinyl group and one ethyl group by catalytic hydrogenation of bilirubin.

As regards the first point, these differences concern both unsaturated groups in the same way; since only one can be present in form of a dihydrofuran ring (on account of the position of the unsaturated side-chain in ring I relative to the hydroxyl group), the observed differences of the bilirubin side-chains from those of haemin must be explained in a different way.

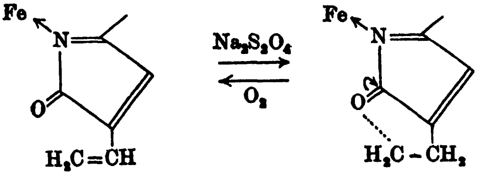
The existence of the pyrrofuran compound is very doubtful. In later experiments Fischer [1915] tried in vain to reproduce this substance, nor was Dr Mühlbauer (unpublished observation) able in my laboratory to obtain a substance of the properties described in the first paper by Fischer and Hahn [1914]. In a short note Fischer and Hess [1931] mentioned that the substance in question reacted with phenylhydrazine and possibly was methylhydroxyvinylmaleinimide (although this substance would yield analytical values quite different from those obtained by Fischer and Hahn). In spite of this uncertainty the substance is now again used as an argument in favour of the existence of a dihydrofuran ring. Previously Fischer had assumed a furan ring, although this was in evident disagreement with the amount of hydrogen necessary for the transformation of bilirubin into mesobilirubin and mesobilinogen.

The third argument of Fischer is the fact that one of the unsaturated groups of bilirubin is more easily reduced to an ethyl group by catalytic hydrogenation. The partially hydrogenated substance has an ethyl group in ring IV and a vinyl group in ring I. Provided that Fischer's hypothesis is correct, it would be necessary to assume that by catalytic hydrogenation the dihydrofuran ring is split open to ethyl and hydroxyl more readily than the vinyl group is saturated. This is very improbable, and Fischer's results are more easily explained by the simple assumption that the vinyl group in the neighbourhood of the α-hydroxyl reacts more rapidly. For these reasons it is suggested that bilirubin contains two vinyl groups like haemin.

The following observation may throw light upon the question why the vinyl group in the neighbourhood of the hydroxyl group[1] reacts more rapidly with catalytically activated hydrogen. Verdohaemochromogen is reversibly reduced by $Na_2S_2O_4$; since mesoverdohaemochromogen is not reduced, the unsaturated side-chain must play a rôle in this reversible reduction, which cannot involve the iron, since this is already in the bivalent form before the reduction. The yellow haemochromogen, obtained by reduction from verdohaemochromogen and reoxidisable to it, is probably a monohydroverdohaemochromogen in which one hydrogen atom is added to the vinyl group in ring IV. This radical is stabilised by the proximity of the α CO-group.

---

[1] Of the lactim form (—C(OH)=N—) or the CO-group of the lactam form (—CO—NH—) of bilirubin, which are probably in equilibrium.



(It is hardly necessary to mention that the cyclic structure suggested for the radical has nothing in common with a dihydrofuran ring, the linkage of the side-chain with the oxygen being a single electron.) This double oxidation-reduction system of verdohaemochromogen (in respect of the iron atom and the unsaturated-side chain) might be of interest with regard to the possible catalytic activities of the substance.

The mechanism of the reaction leading from haemin to verdohaemochromogen remains still to be investigated. Undoubtedly it is the haemochromogen which is oxidised, but whether oxygen performs this directly, or the tervalent iron of haematin, or whether oxygen and haematin are necessary for the reaction cannot yet be decided.

The action of H_2O_2 may be taken into consideration. McLeod and Gordon [1922] and Hart and Anderson [1933] have arrived at different conclusions with regard to the rôle played by H_2O_2 in the formation of the "green pigment" from haemoglobin. In this respect it is important to mention that other greenish haematins exist, and that they are present in the "green pigment" obtained from haemoglobin[1]. No definite conclusions as to the reaction mechanism of the formation of verdohaemochromogen can thus be drawn from the investigations of the different authors on the formation of "green pigment" from haemoglobin. Verdohaemochromogens are easily destroyed by H_2O_2 even in very dilute solution. The possibility that H_2O_2 in extremely small concentrations is the active agent, cannot be quite excluded, but it seems more probable that the formation of an unstable iron-peroxide of the haemochromogen itself may be the first step followed by transference of the oxygen to the porphyrin nucleus; or the reaction may be of a more complicated nature and require the presence of haematin compound with tervalent iron together with haemochromogen; the former may either oxidise haemochromogen directly or by the way of a chain reaction. However that may be, it is certain that the reaction is essentially a process in which the catalytic activity of the haem compound is applied to its own molecule.

It is suggested that the formation of bile pigment in the body may be caused by a similar process. The system of Warburg and Negelein studied above is of course only a model of the system responsible for bile pigment formation in the body. It differs in that the compound oxidised in the body is haemoglobin and not pyridine-haemochromogen, so that the resulting verdohaem compound would be either verdohaemoglobin or globin-verdohaemochromogen. Instead of hydrazine we have reducing systems. It is unnecessary to assume the action of a special enzyme for the oxidation of haemoglobin, the haem of the molecule itself or of cytochrome working as catalyst. Enzymes may play a rôle, however, in the process in so far as they provide the reducing systems [*cf.* Hart and Anderson, 1933; Anderson and Hart, 1934]. The transformation of the verdohaem compound into biliverdin cannot be brought about in the animal body by any of the reactions described above; here further research is necessary. It is evident however from the ease with which this transformation proceeds that its occurrence under physiological conditions is likely.

---

[1] I am indebted to Anderson and Hart for sending me samples of green pigment produced by pneumococcus and by non-bacterial reducing systems from haemoglobin. In confirmation of the spectroscopic investigation published in their paper I found that both pigments give the same absorption spectrum in pyridine solution with hydrosulphite. The spectrum is that of a mixture of haemochromogens, *i.e.* of a good deal of unaltered protohaemochromogen, of a haemochromogen with an absorption band at 620 mμ, and of a rather small amount of verdohaemochromogen. The second haemochromogen belongs to a haematin type which can be produced by autoxidation of haematin in alkaline solution (without reductant) and which is also of greenish colour ("cryptohaemin" of Negelein).

Apart from these differences the essential process is probably the same. Hitherto only teleological explanations have been offered for the formation of bile pigments from haemoglobin, such as the unconvincing hypothesis of Asher [1924] that the decomposition of haemoglobin is necessary for providing the cells with Atmungsferment-iron. In consideration of the results brought forward in this paper the formation of bile pigments in the animal body is the natural consequence of the catalytic activity of the haem iron working on its own molecule. A similar explanation probably holds for the complexity of the cytochrome spectrum [Keilin, 1926].

From the physiological point of view a great deal remains to be done, but it is believed that the model now worked out will provide a good guide to further research.

SUMMARY.

"Green haemin" is prepared according to Warburg and Negelein by action of oxygen on pyridine-haemochromogen in presence of hydrazine. A corresponding compound is obtained from mesohaemin.

The "green haemins" are characterised as pyridine-haemochromogens of *iso*biliverdins. The name "verdohaemochromogens" is proposed. Their formation is due to oxidative scission of the porphyrin nucleus of the haemochromogen, catalysed by haem iron.

The "green ester", obtained by Warburg and Negelein by action of methyl alcoholic hydrochloric acid on green haemin, is identified with the ferrichloride of biliverdin ester. From mesohaemin the ferrichloride of mesobiliverdin is obtained in the same way.

The ferrichlorides can be transformed into the biliverdin esters and these can be identified with products prepared from bilirubin of gall stones. Since haemin has been synthesised, its transformation into biliverdin means the total synthesis of the latter.

It is suggested that the formation of bile pigments in the animal body proceeds in a similar way yielding biliverdin (dehydrobilirubin) which is afterwards reduced to bilirubin.

The nature of the unsaturated side-chains of bilirubin and biliverdin is discussed and it is suggested that they are vinyl groups like those of haemin.

CLXII. THE TECHNIQUE TO BE SELECTED FOR DETERMINATION OF BILIRUBIN IN BLOOD BY THE DIAZO-METHOD.

BY EMANUEL GERARD GODFRIED.

From the Laboratory of Chemical Pathology, St Bartholomew's Hospital, London.

(Received April 27th, 1935.)

IN the present communication an attempt is made to decide which is the most practical method for estimating the total bilirubin in serum or plasma. To-day there are several modifications of Van den Bergh's test in use in different laboratories, and these different techniques give results which may vary quite widely, so that the findings reported by one laboratory are not comparable with those from another. Van den Bergh's direct reaction and its particular problems will not be considered now; the estimation of all the bilirubin involving treatment of the serum with alcohol, or, in other words, the "indirect quantitative test" alone will be studied.

In Van den Bergh's original description 1 volume of plasma or serum and 2 volumes of absolute alcohol are mixed and centrifuged. To 1 ml. of supernatant fluid 0·25 ml. of diazo-reagent and 0·5 ml. of absolute alcohol are added. The dilution factor is 5. The colour is compared with a standard solution of ferric thiocyanate in ether. Later on this ethereal standard was replaced by 2 % anhydrous cobaltous sulphate in water.

It was then shown that in some sera bilirubin is lost by adsorption on the protein precipitated by alcohol; this is largely prevented if the bilirubin is converted into azobilirubin before the precipitation of the proteins by alcohol, because azobilirubin is less strongly adsorbed than bilirubin itself; even more azobilirubin may be kept in solution in the alcohol if saturated ammonium sulphate is also added [Thannhauser and Andersen, 1921].

At this stage McNee and Keefer [1925] summarised the technique which might be universally adopted as follows. To 1 ml. of serum (or plasma) 0·5 ml. of diazo-reagent is added. After the maximum colour has developed 2·5 ml. of absolute alcohol and 1 ml. of saturated ammonium sulphate are added. The contents are mixed and centrifuged. The dilution factor is 4. The colour is compared with a standard solution of cobaltous sulphate (2·161 %).

Hunter [1930] then suggested that ammonium sulphate was unnecessary, and that the cobalt standard should be altered to 1·9 %, thus increasing the bilirubin estimates by some 14 %. His method simply consists in adding 0·5 ml. of diazo-reagent to 1 ml. of serum or plasma. After a short interval 2·8 ml. of absolute alcohol are added and the mixture is centrifuged, the dilution factor being about 4.

White [1932] dissolves 1·3 g. of anhydrous cobaltous sulphate in 50 ml. of distilled water, adds 40 ml. of conc. HCl (sp. gr. 1·19), mixes and cools. The volume is made up to 100 ml. and the mixture is ready for use in 24 hours.

It is more or less generally accepted that the aqueous cobalt standard is more satisfactory than the ethereal ferric thiocyanate standard; also that more accurate results are obtained if the bilirubin is azotised before the addition of alcohol. This is again clearly demonstrated by the results reported in the table below; if alcohol is added before the diazo-reagent (original method, column 2 of table) the results are nearly always lower, and may be very seriously low as compared with those where azotisation precedes the addition of alcohol (Thannhauser and Andersen's method, column 3 of table); Hunter's method gives results (column 5 of table) which are either the same as those yielded by Thannhauser and Andersen's method, or a little lower (significantly higher on one occasion only in this series), provided that the same standard is used for the two methods. Naturally the results (column 4 of table) are higher with the more dilute standard (1·9 %) recommended by Hunter. Those findings in column 5 which are a little lower than those in column 3 may be accounted for by the omission of ammonium sulphate in Hunter's modification.

No.	Original method. Cobalt standard 2·161 %	Thannhauser-Andersen method. Cobalt standard 2·161 %	Hunter's method. Cobalt standard 1·9 %	Hunter's method. Cobalt standard 2·161 %
1	1·0	6·0	11·4	10·0
2	0·5	1·2	1·8	1·6
3	4·0	14·0	16·0	14·0
4	2·5	6·4	7·3	6·4
5	0·7	2·8	2·3	2·0
6	12·0	18·0	17·0	15·0
7	—	8·0	7·4	6·5
8	20·0	25·0	27·4	24·0
9	2·0	6·0	6·8	6·0
10	2·0	6·4	7·3	6·4
11	0·7	1·8	1·7	1·5
12	—	6·0	6·3	5·5
13	—	12·0	11·5	10·0
14	—	5·8	5·7	5·0
15	—	4·5	5·1	4·5
16	—	8·5	8·2	7·2
17	0·6	2·0	2·1	1·8
18	—	22·0	20·5	18·0
19	—	8·4	9·6	8·4
20	1·2	1·2	1·4	1·2
21	2·0	2·1	2·4	2·1
22	1·0	1·2	1·4	1·2
23	1·5	2·4	2·7	2·4
24	0·5	3·5	4·1	3·6
25	0·8	2·1	2·4	2·1
26	0·7	1·0	1·1	1·0
27	0·6	0·8	0·8	0·7
28	0·7	1·8	2·1	1·8
29	0·8	1·3	1·6	1·4
30	1·3	2·2	—	—
31	0·6	2·0	2·1	1·8
32	4·2	4·2	4·1	3·6

All values are in Van den Bergh units. The first 19 cases showed a "direct positive reaction", *i.e.* a red colour developed within a few minutes after the addition of diazo-solution to the plasma.

White's standard again gives different results. A few comparisons were made, but the standard shows no advantage.

The following table indicates that when the same final solution of azobilirubin is compared with the 2·161 % cobalt standard and with White's standard the latter will give a result some 25 % higher than the former.

Cobalt standard 2·161 %	White's standard	Cobalt standard 2·161 %	White's standard	Cobalt standard 2·161 %	White's standard
2·0	2·5	8·5	11·0	14·0	19·0
2·1	2·7	14·0	17·0	2·5	3·0
1·0	1·3	1·5	2·0	6·4	8·0
1·2	1·5	2·4	3·0	1·8	2·3
6·0	8·0	0·5	0·6	2·4	3·0
1·2	1·5	3·5	4·5	0·7	0·9
1·6	2·0	4·0	4·8	2·8	3·5

The writer concludes therefore that Hunter's and White's modifications are no improvement and suggests the universal adoption of Thannhauser and Andersen's technique as outlined by McNee and Keefer, unless and until further work results in the introduction of an undeniably more accurate method.

As pointed out by Harrison [1930] however the Thannhauser and Andersen technique is unsatisfactory if there is gross haemolysis, because the haemoglobin is not completely precipitated by the addition of alcohol and ammonium sulphate. In that case it is best to repeat the test with fresh non-haemolysed serum; alternatively the original Van den Bergh's method may be used, in which the 2 volumes of added alcohol do precipitate the haemoglobin, but, as has been shown, such results may be seriously low.

SUMMARY.

Out of the several procedures suggested for Van den Bergh's estimation of bilirubin in blood the method described by Thannhauser and Andersen and the concentration of cobalt sulphate (2·161 %) used by McNee and Keefer are selected as the most suitable for clinical purposes.

I am indebted to Dr G. A. Harrison for his suggestions, his help in compiling this paper and for the facilities provided in his laboratory. The work was done with the aid of the Prof. Stokvis' funds, University of Amsterdam, and with a grant from the Cassel Foundation.

CLXIII. AN INVESTIGATION OF PROTEIN-FREE URINES GIVING A BIURET-LIKE REACTION.

BY EMANUEL GERARD GODFRIED.

From the Laboratory of Chemical Pathology, St Bartholomew's Hospital, London.

(*Received April 27th, 1935.*)

OCCASIONALLY when urine is added to Benedict's qualitative or to Fehling's solution the treated copper reagent becomes a deeper blue at room temperature. If the urine is superimposed carefully a reddish-purple ring is observed; it is this reaction, and not the violet colour due to a biuret reaction with urine containing protein, that has been studied.

When the fresh urines of healthy and diseased persons are examined carefully by this ring test, it is found that a large minority of both groups give positive reactions of varying intensity. It is important that the urine shall be relatively fresh, for the reaction diminishes in intensity in a few hours and in most cases becomes negative overnight.

This, though not generally known, is an old observation; Ralfe [1883] stated that the urine should be recently passed, for if kept overnight the reaction became negative, a fact which he suggested might be due to putrefactive changes. Ralfe and the older workers of course used Fehling's reagent which tends to give a slightly less marked test than Benedict's solution, but otherwise it is immaterial which of the two is employed; both copper reagents have been used in the present work, but Benedict's much the more frequently. This being understood, for convenience in subsequent description the test will be referred to as the "cold Benedict reaction".

For a long time peptone was believed to be the cause of the urinary "biuret test"; it will be shown that the substance cannot be peptone, and that, as Salkowski [1897] and Stokvis [1897] clearly recognised, the reaction should not be mistaken for a biuret test. The alternative suggestion of the above investigators, that urobilin was responsible, likewise cannot be supported.

Preliminary observations on the "cold Benedict reaction".

That a positive test cannot be due to peptone is shown by the following observations. When a positive urine is heated at 100° for 5 minutes and cooled, the reaction becomes negative. If now a few drops of tincture of iodine are added a reddish-purple ring does appear (see below under "Dybbuc test"). Saturating the urine with ammonium sulphate does not precipitate the substance responsible for the above tests.

If the biuret test is performed in the ordinary way (*e.g.* 3 parts urine, 1 part 40 % NaOH and 1 % $CuSO_4$ drop by drop) it is negative; only when a weaker alkali is employed is the reaction positive (see later). In other words the reaction is not a biuret test in the sense that this is employed for testing for proteins, proteoses or peptones.

That a positive test cannot be due to urobilin is shown by the following observations. Many urines giving positive cold Benedict reactions do not contain urobilin as judged from spectroscopical examination and Schlesinger's test, and conversely many urines which do contain urobilin give negative cold Benedict reactions. The reddish purple colour of the developed reaction is not extracted by amyl alcohol, benzene, carbon tetrachloride, chloroform, ether, ethyl acetate, toluene or xylene; spectroscopically the solution shows an ill-defined absorption of the green stretching from about its centre up to the E line and not a definite band in the position of that of the copper-urobilin compound. Many positively reacting urines give a negative result with Ehrlich's reagent (*p*-dimethylamino-benzaldehyde) for urobilinogen.

Positive cold Benedict reactions were obtained in some urines of both sexes, of both children and adults, in health and in a miscellaneous group of diseases. Positive results were not obtained in the urines of rabbits, guinea-pigs, rats or cats, though animals' urines have not been extensively studied.

No parallelism was established between the intensity of urinary tests for indican, or uroerythrin and the cold Benedict reaction. Solutions of pure creatine in water gave negative results.

The impression was gained that urine which has been stored in the urinary bladder for a short time only gives stronger reactions than urine which has been stored there for relatively long periods. One of the assistants in the laboratory usually passed urine giving a marked reaction; a specimen collected over a period of say 15 minutes gave a far stronger reaction than one collected over a period of say 2–3 hours; the effect of polyuria due to drinking and the possible influence of meals were carefully excluded.

Substitution of $CuSO_4$ and Na_2CO_3 solutions for the copper reagent.

The initial observations were made with Fehling's or Benedict's solutions; it was clearly desirable to simplify the reagents essential for the colour development. Neither copper sulphate solutions alone nor alkalis alone produced the colour on addition to the urine; both were necessary, and the colour development was better if the $CuSO_4$ were added before the alkali. After many experiments the following proportions appeared to be about optimum, *viz.* urine 5 ml., 1 % crystalline $CuSO_4$ 1 ml. and 5 % anhydrous Na_2CO_3 1 ml. On mixing these in the order given a rose or purplish red colour develops in a few seconds. If ammonia solution (sp. gr. 0·880) is employed as alkali, the colour is a deeper blue, but care has to be taken to avoid excess of ammonia. NaOH or KOH likewise can be substituted, but even greater care has to be taken to avoid excess, otherwise, as previously mentioned, the characteristic colour change does not occur at all.

Relation of "cold Benedict reaction" to "Dybbuc test".

Whilst working in Prof. Snapper's clinic in Amsterdam the following reaction was frequently performed by several of the pupils, including the writer, during routine chemical examination of urines. The cause of the reaction was not known, and the test was nicknamed "Dybbuc" (Hebrew for ghost or evil spirit). To about 5 ml. of urine 1 drop of ammonia solution (sp. gr. 0·880) is added, followed by tincture of iodine drop by drop until the colour is definitely reddish. One half treated with a solution of a zinc salt (*e.g.* 1 drop of 1 % $ZnSO_4$) becomes slightly more red. The other half treated with dilute $CuSO_4$ solution (*e.g.* 1 drop of 5 %) becomes reddish violet.

It naturally occurred to the writer that possibly the substance responsible for the cold Benedict reaction was the same as, or closely related to, the substance responsible for the "Dybbuc" test. Stokvis [1897] observed that the addition of iodine improved the colour obtained by treating urine with dilute solutions of KOH and $CuSO_4$.

In several hundred tests on the urines of more than 20 individuals a positive cold Benedict reaction has always been accompanied by a positive Dybbuc test. When urine which, initially positive, gives a negative cold Benedict reaction owing to keeping, heating at 100°, treatment with a small proportion of adsorbent charcoal or saturation with ammonium sulphate, it nevertheless still gives a positive "Dybbuc" test. On the other hand the cold Benedict reaction can again be made positive by adding a little iodine solution either before or after the addition of the urine to the Benedict's solution. This suggests that the substance responsible for the cold Benedict reaction may be a precursor of the substance responsible for the "Dybbuc" test.

In the hope of deciding whether the iodine merely causes oxidation other oxidising agents were substituted. Negative results were obtained employing in varying proportions solutions of each of the following: H_2O_2, $NaNO_2$, $KMnO_4$, $KClO_3$, $FeCl_3$ and Cl_2. Positive results could be obtained, but with less ease than with iodine, by using bromine water or potassium persulphate. It therefore looks as though it is not purely a question of simple oxidation.

The three tests, the cold Benedict reaction, treatment of the urine with $CuSO_4$ and Na_2CO_3, and the "Dybbuc" test were all used at the different stages in the subsequent attempt to decide the nature of the substance responsible for the colour development. The pigment is essentially red when extracted, the purple or violet tints in tests on urine being due to excess of $CuSO_4$. Further it is believed that the red pigments of the three tests are the same or closely allied; certainly in each case the same ill-defined absorption of the half of the green nearest the blue end of the spectrum is observed, and the red colour is unstable, fading slowly on standing, immediately upon acidifying or heating. The red pigment can be separated and concentrated by saturating the urine with ammonium sulphate and extracting with ethyl alcohol (*e.g.* 1/5 volume).

Further observations on the substance, X, responsible for the above tests.

X is destroyed by strong acids, and by H_2S in a few minutes. Strong alkali destroys it slowly, especially on heating. The other properties observed for X closely resemble those reported in the literature for substances in the urochrome group and may be summarised as follows.

(1) X is not extracted from urine by amyl alcohol, benzene, chloroform, ether or light petroleum.

(2) When a positively reacting urine is concentrated *in vacuo* below 50° to a syrup, both urochrome and X are extracted by ethyl alcohol. X therefore belongs to the "Extraktivstoffe" of Berzelius [Dombrowski, 1907–08, 1, 2].

(3) X is not adsorbed on the precipitate formed by treating urine with lead acetate at an acid reaction. Urochrome behaves similarly [Weisz, 1911; 1920, 1, 2; 1922; 1923; 1930]. $(NH_4)_2SO_4$, Na_2CO_3 or NaCl should be used for subsequent removal of the lead before testing the filtrate for X. The main bulk of the filtrate is precipitated by NH_4OH or NaOH because both urochrome [Weisz, 1920, 1, 2; 1930] and X are adsorbed on the alkaline lead precipitate. Both may be separated from the precipitate by adding the latter to a saturated solution of $(NH_4)_2SO_4$, followed by alcohol, when they pass into the alcohol layer; the strong alkali however soon destroys X.

(4) Saturation of the urine with ammonium sulphate precipitates urobilin which is removed by filtration. On treating the filtrate with ethyl alcohol urochrome is extracted [Garrod, 1894] and likewise X. The alcoholic extract is washed with saturated ammonium sulphate and evaporated to dryness *in vacuo.*

On extracting the residue with ethyl alcohol both urochrome [Garrod, 1894] and X are removed.

(5) Addition of mercuric acetate to the urine gives a precipitate on which urochrome [Thudichum, 1864; Garrod, 1894] and X are adsorbed. Both may be removed from the mercury precipitate in the same way as from the $Pb(OH)_2$ precipitate (see above).

(6) The urine is concentrated to a small volume *in vacuo* and dialysed. Neither urochrome [Fischer and Zerweck, 1924] nor X passes the membrane.

(7) Saturation with $(NH_4)_2SO_4$ followed by extraction with butyl alcohol removes urochrome [Drabkin, 1930, 1, 2] and X.

(8) Amyl alcohol extraction of acid urine removes substances of the urobilin group, but neither urochrome [Weisz, 1930] nor X.

(9) Butyl alcohol extracts urochrome [Drabkin, 1930, 1, 2] and X from acidified fresh urine. Drabkin washed his butyl alcoholic extracts and concentrated them *in vacuo*. In the writer's opinion this changes the nature of the urochrome for the following reasons: on standing the colour of the concentrated extract deepens considerably as Drabkin also noted; the final pigment appears to be no longer soluble in water but may be made so by simple washing with ether, which however must be carefully done for, as noted also by Drabkin, too long a contact with ether results in changes in the solubility of the pigment. The writer is doubtful whether unchanged urochrome is soluble in anhydrous butyl alcohol, though "urochrome" prepared by Drabkin's method is.

Butyl alcoholic extracts of X similarly washed and concentrated *in vacuo* yield material which no longer gives the tests for X.

(10) Alcoholic solutions of urochrome, prepared as described in either (2) or (4), yield a precipitate of pigment on addition of ether, but this "urochrome" precipitate has changed chemically for it is either insoluble or only partially soluble in ethyl alcohol [Garrod, 1894]. Likewise alcoholic solutions of X, similarly prepared, after treatment with ether no longer give the tests for X; neither the precipitate, nor the filtrate nor the two combined give a positive reaction.

(11) Charcoal adsorbs urochrome from urine [Hohlweg, 1908; Salomonsen, 1908; Mancini, 1908; Klemperer, 1903; 1904] and also X. Both can be extracted from the charcoal by 10 % NH_4OH in 50 % ethyl alcohol; mere traces are extracted by ethyl alcohol or methyl alcohol alone. Alternate washings with large volumes of acetone and of water remove urochrome partially and X completely.

Attempts to isolate X.

After the above study of its properties, the following procedure was employed in attempts to isolate X. The quantities of reagents given below are for 1000 ml. portions of urine.

The acid urine was treated with 250 ml. of saturated normal lead acetate and filtered. Lead was removed from the filtrate by excess of saturated ammonium sulphate. The second filtrate was shaken with about 50 g. of charcoal for 5 minutes. The precipitate was collected on a Büchner funnel and washed with large volumes of distilled water (filtrate and washings contained no X) and was then washed alternately five times with about 100 ml. portions each of acetone and of water, about 1000 ml. in all. The aqueous acetone solution was refiltered and concentrated to a small volume (about 20 ml.) below 40° under reduced pressure. The concentrate was submitted to one of the two following procedures.

(*a*) When the concentrate was submitted to chromatographic analysis in a column of $CaCO_3$, adsorption of pigment occurred in one layer only, and this layer gave strong reactions for X. In a series of experiments the deeper the pigmentation the stronger were these reactions. $BaCO_3$ and kaolin give less satisfactory adsorption.

(*b*) The concentrate was taken to dryness in a vacuum desiccator over $CaCl_2$. The yellow-brown residue was repeatedly submitted to prolonged extraction with anhydrous butyl alcohol in which a portion slowly dissolved. The butyl alcoholic extract gave with water, NH_4OH and iodine a beautiful red colour, and the usual subsequent colour changes with zinc and copper salts. The insoluble residue on solution in water gave negative tests for X. All attempts to concentrate the butyl alcoholic extract, or to separate X from it, resulted in partial or complete destruction of X.

The above procedure has been carried out on more than ten occasions. It has also been tried on urines which initially gave negative tests for X, when the final butyl alcoholic extract, if faintly yellow gave definite but weak reactions for X, but if colourless gave negative reactions.

It looks therefore as though X is either a pigment of the urochrome group or a substance associated with urochromes throughout the process of separation.

Opinions differ as to whether urochrome is a chemical entity or embraces a group of unknown substances [Weisz, 1920, 1, 2]. In the literature a number of pigments have been described which are supposed to be identical with urochrome because they are not precipitated by saturation with ammonium sulphate, and after such treatment are extracted from the filtrate by ethyl alcohol. The author has prepared "urochrome" from faeces [Garrod, 1903], "lactochrome" from milk [Palmer and Coolidge, 1914] and "protochrome" from peptone [Pelkan, 1920]. All these preparations gave negative tests for X.

SUMMARY.

1. The biuret-like reaction in protein-free urines which for many years has been regarded as due either to peptones or to urobilin has been further studied.

2. In agreement with certain authorities it is recognised that the reaction is not a biuret test in the usual sense.

3. It is shown that the reaction is not due to peptones or urobilin.

4. It is concluded that the substance responsible for the reaction is either a pigment of the urochrome group, or is associated with urochromes throughout the processes of separation.

I am greatly indebted to Dr G. A. Harrison for suggesting this investigation in which he himself had made a few preliminary observations, for the facilities provided in his laboratory and for his help in writing this paper. The work was undertaken with the aid of the Prof. Stokvis' funds, University of Amsterdam, and with a grant from the Cassel Foundation.

CLXIV. CONSTITUENTS OF HUMAN SEMINAL PLASMA.

By MAURICE WALTER GOLDBLATT.

From the Sherrington School of Physiology, St Thomas's Hospital, London.

(*Received April 20th, 1935.*)

The chemical description of human seminal fluid is far from complete, and except for isolated observations few quantitative data were available until recently. Landois and Stirling [1891] describe it as being neutral or alkaline and containing, in addition to 82 % water and 2 % salts (phosphates, sulphates, carbonates and chlorides), serum albumin, alkali albuminate, nuclein, lecithin, cholesterol and phosphorised fat. Slowtzoff [1916], cited by Roger, gives 90·3 % water, 0·9 % ash, 8·8 % organic matter, 2·58 % protein and 0·21 % lipoids. The ash is stated to contain K, Na, Ca, Mg, P, Fe and S; Ca and P being most abundant. The protein is described as albumin, globulin, nucleoprotein, nuclein and albumose. Cholesterol, choline and spermine are also stated to be present. McCarthy *et al.* [1928] made an extensive series of analyses of fluid obtained by massage of the seminal vesicles and prostate. It is certain that the fluid thus obtained contains a much greater proportion of prostatic secretion than the fluid normally ejaculated. Some of the analytical figures given by these authors are so widely different from those obtained with seminal fluid that this statement seems justified.

In a recent publication Huggins and Johnson [1933] have presented the results of analyses of various fluids obtained from the male genital tract: spermatocele fluid, semen, semen after vasotomy and seminal vesicle fluid. As we are here interested only in the seminal fluid, we shall refer to the results of these workers only in so far as they affect our knowledge of this fluid. They found that the volume and composition of semen from vasotomised men were not very different from those of semen from normal men, thus indicating that the contribution of fluid from the testes and epididymis is not considerable. They also found that whereas semen and seminal vesicle fluid are very rich in glucose and inorganic phosphorus, prostatic fluid contained no glucose at all and very little inorganic phosphorus. The fluid from the seminal vesicles possessed a composition not greatly different from that of semen itself, so that the authors conclude that the main contribution to semen is from the seminal vesicles. The average values for the constituents of semen calculated from the figures given by these workers are: p_H 7·26, non-protein N 66·3 mg./100 ml., CO_2 14·6 mM, Cl 42·6 mM, glucose 295 mg./100 ml., inorganic P 65·6 mg./100 ml., calcium 20·8 mg./100 ml. There are certain difficulties in making some of these analyses to which we shall refer later. It is of interest to compare these findings with the statement made by Marshall [1922] that the amount of calcium in one ejaculation is 0·01 g., *i.e.* the amount of calcium in 50 ml. semen according to the results of Huggins and Johnson. Unless the seminal fluid contains forms of calcium which cannot be precipitated by ammonium oxalate, the figure given by Marshall is 10 times too high.

The question of the nature of the proteins in seminal fluid has presented certain difficulties because of the presence of non-coagulable protein.

It has been stated by several workers that choline is present in seminal fluid. Evidence against this statement is given in a paper on the pharmacological properties of seminal plasma by the writer [Goldblatt, 1935].

EXPERIMENTAL.

The specimens placed at our disposal were the results of normal coitus and were received in the laboratory at various times up to 12 hours after ejaculation. In all the specimens motile spermatozoa were very abundant and in no case was there evidence of bacterial decomposition.

Having regard to the variable content of cells and other microscopically visible material, it was decided to work only with seminal plasma, *i.e.* the fluid obtained after centrifuging the semen for 10 min. or so at about 6000 r.p.m. and decanting or pipetting the supernatant fluid. Plasma thus obtained is almost free from cells and suspended particles. Seminal plasma is stable for long periods and appears rather like a milky blood serum; it is opalescent and often of a pale yellow colour; it is not very viscid and it gives no deposit on standing; sometimes it is very turbid; it possesses the peculiar odour of semen, which becomes more intense on warming.

Reaction. The p_H of seminal plasma, determined colorimetrically, varied in different specimens from 7·5 to 7·8, but this range is certainly more alkaline than at the time of ejaculation. Huggins and Johnson [1933] used semen immediately after emission and at once covered with oil and found the p_H to be 7·26, great care having been taken to prevent contamination with urinary residues. Such a low p_H compared with blood is in accord with the high amino-acid, phosphate and lactic acid contents.

It is generally stated that in physiological conditions the alkalinity of the seminal fluid is necessary to prevent immobilisation of the sperm cells by the acid secretion of the vagina. It must be remembered that the vagina itself is free from glands and that it is supplied with mucus from the glands of the cervix. The production of acid in the vagina is due to the action of organisms on the glycogen of the vaginal epithelium. It seems probable also that the spermatozoa on entering the vagina produce a considerable amount of lactic acid between the period of ejaculation and complete loss of motility. The necessity for a powerful buffering mechanism in semen is therefore obvious and even a rough titration with $N/10$ HCl shows how efficient its buffering capacity really is. Being, compared with blood, relatively poor in protein it owes its high buffering capacity to bicarbonate and to an enormous inorganic phosphate content. It seems that from the point of view of p_H regulation the seminal fluid stands intermediate between blood and urine, the mechanisms of both being utilised.

Bicarbonate. If seminal plasma be treated with a little mineral acid carbon dioxide is liberated. Experiments with the Van Slyke constant pressure apparatus show that seminal plasma loses half its bound CO_2 on exposure to a vacuum, from which we may conclude that the bound CO_2 is all present as HCO_3^-, as was to be expected. The average value obtained for our series of specimens was 22 millimols CO_2 per litre; this value is rather higher than that given by Huggins and Johnson, *viz.* 14·6.

Chloride. Chloride was estimated by Van Slyke's method for blood. The values obtained with three specimens were 0·209, 0·187 and 0·193 g./100 ml., expressed as NaCl, thus giving an average of 0·197 g./100 ml. The closeness of these results suggests that the salt content of seminal plasma may be normally maintained between as narrow limits as is the blood plasma chloride.

For prostato-vesicular secretion McCarthy *et al.* [1928] find 0·231 g./100 ml. for the chloride as NaCl whilst Huggins and Johnson [1933] give 0·164 for seminal vesicle fluid, 0·164 for semen after vasotomy and 0·355 for prostatic fluid. If we apply the figures of the latter workers to those of McCarthy *et al.* we find that the prostato-vesicular fluid obtained by the latter consisted of two parts vesicle fluid and one part prostatic fluid. The figures of Huggins and Johnson lead to the conclusion that, on the average, semen after vasotomy did not contain any prostatic fluid at all. An interesting possibility is thus presented that vasotomy may lead to an inhibition of the release of prostatic secretion. This is also suggested by the average figures of these authors for glucose and inorganic phosphorus.

Phosphate. Seminal plasma is very rich in phosphorus compounds. Attempts to use the technique of Briggs for the estimation of inorganic phosphorus led to unexpected difficulties; these were soon traced to the fact that the trichloroacetic acid filtrates were not protein-free. The same difficulty in obtaining protein-free filtrates is met with in each of the following methods of deproteinisation: Folin's tungstic acid, acidified sodium sulphate and colloidal ferric hydroxide, sodium hydroxide and zinc sulphate, 80 % alcohol. The soluble protein is proteose. In addition to this difficulty there is also the matter of the presence of spermine phosphate which is readily soluble in trichloroacetic acid. We shall consider the latter question first.

Behaviour of spermine phosphate towards Briggs's reagents.

In the first experiments we used spermine phosphate (kindly supplied by Messrs Hofmann La Roche) dissolved in dilute alkali. On adding the reagents in the proportions used for blood plasma a yellow crystalline precipitate was formed and a blue colour gradually developed in the turbid mixture. Removal of the precipitate and comparison of the blue colour with standards of KH_2PO_4 showed that from 1·35 and 0·68 mg. spermine phosphate (*i.e.* 0·16 mg. and 0·08 mg. P) only 0·07 and 0·04 mg. "inorganic" P was estimated. It was quite clear that the Briggs technique precipitated a great deal of the spermine as a molybdate insoluble in the conditions of the estimation.

Now the structure of spermine phosphate leads us to expect it to behave like an inorganic phosphate, so the following experiments were carried out to determine the proper conditions, using quantities of spermine of the same order as that found in seminal plasma. For these experiments we used a specimen of spermine diphosphate kindly supplied by Dr G. A. Harrison of St Bartholomew's Hospital and prepared by him from human tissues [1931].

A solution of this salt in 4 % trichloroacetic acid was prepared containing 1 mg. per ml. The formula for spermine diphosphate is $C_{10}H_{26}N_4 . 2H_3PO_4, 6H_2O$, *i.e.* it contains 21·3 % water of crystallisation and 12·25 % total P. Hence 1 mg. spermine diphosphate should yield 0·123 mg. "inorganic" P if it behaves as an inorganic phosphate.

(*a*) 2 ml. of the solution were wet-ashed and the total phosphorus determined by Briggs's method was found to be 0·256 mg. (theoretical 0·245).

(*b*) To determine the proportions of acid molybdate which, for quantities of spermine phosphate likely to be met with in human seminal plasma, would not produce either a turbidity or a precipitate, the following mixtures were prepared.

Spermine phosphate solution ml.	4 % trichloro-acetic acid ml.	Briggs's acid molybdate ml.	Water ml.	Remarks
2·0	—	2·0	3·0	Precipitate
2·0	3·0	2·0	—	Precipitate
2·0	—	2·0	—	Turbidity
0·5	1·5	2·0	—	Turbidity
0·25	1·75	2·0	—	Turbidity
1·0	—	2·0	—	No turbidity
2·0	—	4·0	—	No turbidity

It is clear, therefore, that the use of Briggs's molybdate in trichloroacetic acid filtrates of human seminal plasma containing spermine will produce precipitates if the 2 : 7 proportion of molybdate be used as it is for blood plasma filtrates. If, however, two parts of molybdate be added to one part of the spermine-containing filtrate no precipitate or turbidity due to the spermine will be produced.

On mixing 1 ml. of the above spermine diphosphate solution with 2 ml. molybdate solution and then adding 1 ml. of the quinol (0·5 %) and 1 ml. of the sodium sulphite (20 %), a pure clear blue gradually developed which corresponded to an inorganic phosphorus content of 0·125 mg. (theoretical 0·123 mg.). Similarly 2 ml. of the solution of spermine diphosphate and 4 ml. of the molybdate followed by 1 ml. of the quinol and sulphite gave a blue corresponding to 0·227 mg. inorganic phosphorus (theoretical 0·245 mg.). The development of the colour ran exactly parallel with that of the standard KH_2PO_4, so that it is justifiable to suppose that spermine phosphate acts towards the Briggs reagents as an inorganic phosphate. If we take 3 mg. per ml. as the upper limit of the spermine phosphate content of seminal plasma, the above proportions of molybdate should obviate any difficulties from the formation of insoluble spermine phosphomolybdate, provided we take volumes of trichloroacetic acid filtrates equivalent to 2/3 ml. of seminal plasma. But when dealing with seminal plasma complications still arise from the presence of protein in the trichloroacetic acid filtrate. Huggins and Johnson [1933] refer shortly to a turbidity on adding acid molybdate to the trichloroacetic acid filtrate and state that they removed it by ultrafiltration through a collodion sac under a negative pressure of 150 mm. Hg. We must therefore consider what effect the presence of soluble protein (proteose) has upon the estimation of inorganic phosphorus.

Effect of proteose on the estimation of inorganic phosphorus.

A series of mixtures of 1 % Witte's peptone (filtered and shown to contain proteose and peptone) and KH_2PO_4 were prepared so that 2 ml. contained 0·1 mg. P and 0, 2, 4, 6, 8 and 10 mg. of the protein. To 2 ml. of these mixtures were added 10 ml. 20 % trichloroacetic acid. The protein precipitates were filtered and refiltered until the filtrate was as clear as possible. To 5 ml. of the filtrates were added 2 ml. acid molybdate, 1 ml. of quinol and 1 ml. of sulphite. In all except the first tube turbidities of increasing intensity appeared according to the amount of protein in the original tubes. After about 30 mins. the contents of each tube were filtered and the clear blue filtrates compared with the blue of the first filtrate. The following figures give the amounts of inorganic phosphate in the filtrates: 0·042 (no protein), 0·040, 0·035, 0·035, 0·030, 0·028 mg. It is clear that the losses were due to the formation of insoluble phosphomolybdate of protein. If acid molybdate be added to a solution of Witte's peptone a precipitate is formed which readily dissolves in excess of the reagent; but if a trace of phosphorus be added to the protein solution before addition of the molybdate there is formed a precipitate which does not dissolve in excess of the reagent. In the 5 ml. portions of the trichloroacetic acid filtrates used in the above experiment there were increasing amounts of dissolved protein and so we expect increasing amounts of the phosphate to be lost. If the losses in inorganic phosphorus be plotted against the original concentration of protein the points fall approximately on a straight line. It is clear, therefore, that unless we know the amount of proteose in the filtrates obtained with seminal plasma an undetermined amount of inorganic phosphate will be lost in removing the precipitate formed on adding the acid molybdate. We have no data on the amount of proteose in seminal fluid but we suspect it to be present in very considerable amount. There is no doubt that the values obtained by other workers and ourselves for inorganic phosphorus in seminal fluid are considerably lower than the actual content. We proceed as follows: 10 ml. 20 % trichloroacetic acid are added to 2 ml. seminal plasma and after vigorous shaking allowed to stand for an hour. The mixture is now filtered and refiltered until a clear filtrate is obtained. This filtrate invariably gives a positive biuret reaction. To 2 ml. of the filtrate are added 4 ml. of the acid molybdate; a heavy yellowish turbidity forms at once and gradually settles out as an amorphous precipitate. Repeated filtration will usually yield a protein-free filtrate but sometimes we find it necessary to add a little $CaCl_2$ (anhydrous) and re-filter. Addition of the Briggs reagent to an aliquot part of the filtrate now gives a clear blue which can be compared with standards in the usual way.

In this way we obtain values for "inorganic" phosphorus which include all the spermine phosphate, but, as we have pointed out, these values are too low. The averages of our series of specimens were:

Total acid-soluble phosphorus	95 mg./100 ml.
"Inorganic phosphorus"	70 mg./100 ml.

If we take Harrison's figures for the spermine phosphate content of human semen, *viz.* 112–268 mg./100 ml., then it is not excessive to attribute some 15 to 30 mg./100 ml. P of the "inorganic" phosphorus to this substance. This leaves 40–50 mg./100 ml. as the true inorganic phosphate subject to the reservations considered above.

Huggins and Johnson [1933] found that prostatic fluid contained only 3·4 mg./100 ml. inorganic phosphorus. Harrison [1933] has shown that the prostate is richer in spermine than any other organ in the body; the average figure given was 583 mg. spermine phosphate per 100 g. wet weight. It is not unlikely that most of the phosphate in prostatic secretion is in the form of spermine phosphate. Now we have seen above that some 15–30 mg. of the "inorganic" phosphate of seminal fluid are due to spermine phosphate and there is no doubt that the prostatic contribution to seminal fluid is small in proportion to that of the seminal vesicles; hence we must conclude that the vesicles contain (secrete) spermine phosphate. The facts that the testes and epididymis contribute very little fluid to seminal fluid, that the testes are relatively poor in spermine (only 60 mg. per 100 g. wet weight according to Harrison [1933]) and that spermatocele fluid is free from spermine lead us to the conclusion that the major part of the spermine in seminal fluid arises from the seminal vesicles. Fluid from the distended seminal vesicles of young men was obtained by Huggins and Johnson [1933] and found to contain 45 mg./100 ml. inorganic phosphorus, but they did not consider the spermine content.

There is no direct evidence as to the function of all this phosphorus but it seems reasonable to consider the great change in chemical environment experienced by the sperm on ejaculation as related to the necessity for active movement in the female genital tract and that the phosphates ensure a very efficient buffering action. As to the function of spermine phosphate nothing is known.

Calcium. The only other inorganic constituent of seminal plasma we examined was calcium. Using the ordinary technique of Kramer and Tisdall for serum calcium we found an average value of 24·5 mg./100 ml. This agrees well with the finding by Huggins and Johnson of 20·8 mg./100 ml. The origin of this very high concentration of calcium is most probably the prostate. This is supported by the finding of McCarthy *et al.* [1928] of 66 mg./100 ml. calcium in prostato-vesicular secretion. The former authors, however, give only 23·3 mg./100 ml. as the calcium content of seminal fluid after vasotomy, a result due probably to the small fluid contribution made by the prostate.

The forms in which the calcium exists in seminal fluid are probably calcium hydrogen phosphate, calcium bicarbonate and a combination with protein. The low phosphate content of prostatic secretion indicates that very little calcium can come from this source as the hydrogen phosphate but we have no certain data as to the partition of calcium among the three possible combinations.

Urea. It is not surprising to find urea in seminal fluid having regard to its ready diffusibility into all tissues but its function here, if any, is not easily understood. The great concentration of other blood constituents in the seminal plasma may involve urea more or less accidentally. Be that as it may, the concentration of urea in this fluid is roughly twice that in blood. The average value in our series was 72 mg./100 ml., estimated by hydrolysis with soya bean and aeration into standard acid. Of course very small contaminations with urine would give false values but the evidence is against such contamination since similar values are obtained even when the urethra was washed with dilute boric acid before ejaculation [McCarthy *et al.*, 1928].

Reducing substances. In estimating the reducing power of seminal plasma the difficulty of deproteinising, already referred to, at once introduces complications. We have used MacLean's method (a Cu method) and that of Hagedorn and Jensen (ferricyanide method). The latter method gives values which are certainly unreliable owing to the much greater proportion of protein which escapes precipitation. The former method gives filtrates which contain only a faint trace of protein and, provided a "blank" determination be made in the cold, reliable values are obtainable. The following values were obtained with the seminal plasma of normal and diabetic subjects.

Normal, 206, 277, 226, 211, 282, 380, 291 mg./100 ml. as glucose.
Diabetic, 628, 569, 576, 669, 681 mg./100 ml. as glucose.

Thus normal seminal plasma contains between two and three times the amount of reducing substances found in normal blood. The values for the diabetic subjects are probably more or less misleading, since traces of glucose are always to be found in the urethra of the glycosuric. There can be no reasonable doubt that the sugar in the seminal fluid must be regarded as a nutrient for the spermatozoa and it is easy to demonstrate the utilisation of the sugar if the sperm cells are kept alive. If the sperm cells are killed by heat, dilution or by the addition of a drop of toluene no fall occurs in the reducing power of the fluid. Nor does the reducing power change in the seminal plasma if it is kept sterile. In the following experiment a fresh specimen of human seminal fluid was obtained in a sterile tube, divided into three parts: one part was heated to kill the sperm, another part incubated in a water-bath at 38° and the remaining part centrifuged and the supernatant plasma used. Estimations of reducing substances were made in each part at once and after 20 hours' incubation.

	Heated fluid	Plasma	Unheated fluid
At once	291	280	291 mg./100 ml. as glucose
After 20 hours' incubation	289	280	72

McCarthy *et al.* [1928] also recorded glycolytic activity in incubated seminal fluid and found that there was a large increase in lactic acid but that this increase did not account for the loss in sugar. This production of lactic acid is probably an important factor in the poor survival of spermatozoa in natural seminal fluid *in vitro* however carefully sterility, temperature and oxygen supply are controlled. Failure of the buffering capacity comes about sooner or later but generally within 12 hours.

The source of the sugar in the seminal fluid seems to be the seminal vesicles, for the prostatic fluid has no reducing power at all.

Lactic acid. Seminal fluid contains lactic acid in large amounts. The acid is present in the freshly ejaculated fluid and increases on incubation. We used the method of Friedemann, Cotonio and Shaffer for the determination of this substance in the tungstic acid filtrate after treatment with copper sulphate and calcium hydroxide. The following values were obtained with different specimens of fresh seminal fluid, the spermatozoa having been killed soon after ejaculation:

92, 80, 104, 87, 103 mg./100 ml.

The increase in lactic acid during incubation of seminal fluid containing living sperm cells is shown in the following:

	Reducing power as glucose mg./100 ml.	Lactic acid mg./100 ml.
At beginning	291	80
After 20 hours' incubation at 38°	72	140

There is clearly a great discrepancy between the lactic acid production and the lost glucose. How the lactic acid is produced in the vesicles it is hard to say. The few spermatozoa which may be present in this situation do not appear to be sufficient to account for so high a lactic acid value nor can we attribute it to an enzymic action on the glucose, for the seminal plasma, freed from spermatozoa, does not show any increased lactic acid content after incubation. Nor can we suppose that it is formed in the prostate (because prostatic secretion is free from reducing substances) unless we consider that it may arise from a non-carbohydrate source (*e.g.* amino-acid). If it derives directly from the blood we must attribute remarkable powers of selective concentration to the seminal vesicles. Teleologically it appears useless to produce large quantities of lactic acid in a medium where its presence later will be inimical to the survival of the sperm cells. There are, of course, considerable numbers of leucocytes and other cells in seminal fluid and these, as in blood, may be partly responsible for the glucose-lactic acid reaction. The matter is not easy to investigate and is in a state of obscurity.

Cholesterol. This substance can be readily estimated in seminal plasma by the usual methods for serum cholesterol. Sometimes other substances are extracted by the chloroform and may interfere with the purity of the colour obtained with the acetic anhydride. The average value for our series was 82 mg./100 ml.

In the following table we give a comparison of the composition of blood plasma and seminal plasma.

Composition of blood and seminal plasma.

	Blood plasma 100 ml.	Seminal plasma 100 ml.
p_H	7·4	7·2–7·3
NaCl (g.)	0·59–0·60	0·20
CO_2 as ml./100 ml.	50– 70	50
Inorganic P (mg.)	3– 4	40– 50
Acid-soluble P (mg.)	3– 4	95
Spermine P (mg.)	—	15– 30
Calcium (mg.)	10	24– 25
Glucose (mg.)	100	200–300
Urea (mg.)	30	72
Lactic acid (mg.)	15– 20	90–100
Cholesterol (mg.)	150–200	80

Proteins. Seminal plasma gives all the protein colour reactions. When slightly acidified with 1 % acetic acid it gives a slight precipitate; this probably indicates the presence of a small amount of nucleoprotein. It must be remembered that the mucinous matter secreted by the accessory glands is removed in a stringy mass when the semen is centrifuged. On dilution of seminal plasma with a large excess of water a slight precipitate of globulin is formed. On filtering off the globulin a considerable amount of coagulable protein is readily demonstrable in the filtrate; this we take to be albumin.

The reaction at which maximum coagulation is obtained is about p_H 5·5 but the amount of coagulable protein seems to vary a great deal in different specimens. Removal of the coagulable protein always yields a richly proteinous filtrate. This non-coagulable protein is referred to in the older literature as propeptone and sometimes as hemialbumose. Marshall [1922] refers to an albumose-like substance and remarks that "the statement that this protein is an albumose is probably not correct, since albumoses have never been found to occur in the living cell". Posner [1892] refers to the non-coagulable protein of human seminal fluid as propeptone and finds that it is absent from spermatocele fluid which contains enormous numbers of fully developed but non-motile spermatozoa; he concludes that the propeptone is elaborated in the accessory glands and not in the testes. Vertun [1899] also analysed spermatocele fluid; in his case actively motile spermatozoa were present; the fluid contained albumin and a trace of globulin but a variety of tests showed that it was free from albumose, from which he concluded that the presence of albumose was of no importance in the maintenance of the motility of the spermatozoa.

Our own findings with every specimen of seminal plasma support the view that there is proteose present. On removing the coagulable protein by boiling at p_H 5·5 and filtering, the filtrate gives a pink biuret reaction; half-saturation of the filtrate with ammonium sulphate gives a considerable precipitate the filtrate from which gives another precipitate on full saturation with ammonium sulphate. The filtrate after full saturation gives no protein reactions. We were able partly to separate the primary and secondary proteoses by ultrafiltration. Human seminal plasma was ultrafiltered through a collodion membrane under a pressure of 50 mm. Hg. A yellowish clear filtrate was obtained which was alkaline to litmus, contained no coagulable protein, gave a pink biuret reaction, a positive salicylsulphonic acid reaction, a precipitate with nitric acid which disappeared on warming and reappeared on cooling but no precipitate with copper sulphate. The ultrafiltrate on half-saturation with ammonium sulphate gave a copious precipitate the filtrate from which still contained protein; all the protein was removed on full saturation of the filtrate. The ultrafiltrate, therefore, contained both primary and secondary proteoses. The fluid left in the collodion sac was acidified and boiled to remove the coagulable proteins; the filtrate from this was rich in protein but gave no precipitate on half-saturation with ammonium sulphate but a copious one on full saturation. It seems, therefore, that the primary proteose had all passed through the collodion filter but the secondary proteose had done so only in part. Some specimens of seminal fluid contain no primary proteose at all but there is never any doubt about the secondary proteose. At least two secondary proteoses are present which can be demonstrated as follows. Remove the coagulable proteins by boiling at p_H 5·5; filter and half-saturate the filtrate with ammonium sulphate; filter and add a half-volume of saturated ammonium sulphate; a copious precipitate is produced. This precipitate can readily be filtered off, dissolved in water and precipitated with two volumes of absolute alcohol (the alcohol precipitates the ammonium sulphate as well as the protein but a pink biuret reaction is readily obtained if excess of alkali is used). These facts show the presence of thioalbumose or a substance closely resembling it. On removing the thioalbumose we obtain a water-clear filtrate which gives a slight turbidity or precipitate on full saturation with ammonium sulphate, removal of which yields a non-protein filtrate. The protein nature of the last precipitate is readily established by dissolving in water and obtaining a pink biuret reaction. We did not further identify this substance but it seems likely that it is synalbumose.

We conclude that the following proteins are present in seminal fluid: mucin, nucleoprotein, albumin, globulin (traces), proteoses but no peptone. The proteoses may be both primary and secondary but in some specimens primary proteose may be absent. Secondary proteoses are always present and consist of thioalbumose and synalbumose or bodies closely resembling them.

It is now clear why the usual methods of protein precipitation used in blood analysis do not yield non-protein filtrates when applied to seminal plasma. These methods if applied to a solution of Witte's peptone, containing proteose and peptone, always yield filtrates giving the reactions of proteose. The same remarks apply if the precipitation is carried out in 80 % alcohol.

Alcohol-soluble material in seminal plasma.

One volume of seminal plasma is mixed with four volumes of absolute alcohol and well shaken. The copious white precipitate is removed by filtration and the alcohol removed from the filtrate by distillation at 42° under reduced pressure. The whitish residue when taken up in water yields a turbid suspension and gives the following reactions: it is alkaline (sometimes neutral), biuret—pink, Millon—weakly positive, xanthoproteic—no precipitate but turns yellow on heating and orange on adding ammonia, Molisch and glyoxylic—negative, ammonia does not give a precipitate, the Pauly, Sakaguchi and ninhydrin reactions are all strongly positive. The intensities of the last three reactions are so out of proportion to that of the biuret reaction that it seems possible that there are free iminazole and guanidine compounds present. This possibility has not as yet been followed up but it is suggestive that all these reactions become negative in the extract after a relatively short period of dialysis and that after precipitation of all the proteins of seminal plasma by full saturation with ammonium sulphate the filtrate still gives these reactions. We have already referred to the results of other workers that seminal fluid is very rich in amino-acids and this may explain our findings. We conclude, therefore, that the alcohol extract contains proteose and probably a considerable amount of amino-acids.

The presence of proteose in seminal plasma suggests that a proteolytic enzyme may be present or that the spermatozoa may have the power of splitting proteins. The latter seems improbable in view of the absence of proteose from spermatocele fluid containing motile sperm. The absence of peptone argues against any ordinary peptic activity but the matter requires further investigation. Tested upon calcified milk seminal plasma gives no evidence of the presence of a proteolytic ferment.

Diastase. Karassik [1927] reports the presence of diastase in human prostatic fluid and McCarthy *et al.* [1928] found it in prostato-vesicular fluid. The wide distribution of this enzyme renders its presence in seminal plasma not unexpected. We studied the diastatic power of fresh seminal plasma in buffered solution as follows:

Tube no.	1	2	3
0·1 % starch (ml.)	5	5	5
1·0 % NaCl (ml.)	2	2	2
KH_2PO_4-NaOH buffer (ml.)	2	2	2
p_H	6·6	5·8	8·0
Seminal plasma (ml.)	0·4	0·4	0·4
Time for complete digestion at 38° (min.)	45	65	No change in 2 hours

It appears, therefore, that a diastase is present which is active at reactions between p_H 6 and 7. A simple calculation shows that the diastatic activity of 3 or 4 ml. of seminal plasma is sufficient to produce an amount of simpler sugars from polysaccharide (*e.g.* glycogen from the vagina and cervix) more than sufficient to supply the needs of the spermatozoa for a considerable time.

Glycolytic activity. Seminal plasma has no glycolytic activity if all the sperm cells have been removed.

Thrombokinase. Coagulating agents have been stated to be present in the seminal secretions of rats, mice and guinea-pigs by Walker [1910] and others. A special gland exists in these animals which secretes a substance which coagulates the contents of the seminal vesicles and so brings about the vaginal plug formation well known in these animals. Walker could not find these glands in rabbits or bullocks. In human seminal fluid particles or aggregations are seen which suggest some sort of coagulation to this author but he does not state what is coagulated. Any close analogy to the fibrinogen-fibrin change in blood seems improbable but, although the amount of globulin in seminal plasma is small, we cannot say with certainty that something akin to fibrinogen is not present. One factor in the mechanism of blood coagulation can readily be demonstrated in seminal plasma, *viz.* thrombokinase. This was done as follows: to 4·5 ml. seminal plasma were added 27 ml. absolute alcohol; the mixture was well shaken and allowed to stand for an hour or so; the filtrate from this was freed from alcohol by distillation at 42° under reduced pressure and the residue taken up into 10 ml. water. A solution of prothrombase (Mellanby) containing 0·5 mg./ml. was prepared. The presence of thrombokinase was tested by the power to activate prothrombase to thrombase in the presence of $CaCl_2$; the thrombase activity was tested by the power to coagulate oxalated ox plasma. The prothrombase was first shown to be inactive. A mixture of 2 ml. prothrombase solution, 1 drop $N/5$ $CaCl_2$ and 1 drop of seminal plasma extract was placed in a water-bath at 38° for 2 mins. 0·1 ml. of the prothrombase solution thus treated added to 1 ml. oxalated plasma at 38° produced complete coagulation in 15 secs. An exactly similar experiment with a freshly prepared aqueous extract of bull's testis gave a coagulation time of 12 secs. An acetone extract of seminal plasma was also used in a similar experiment and gave a coagulation time of 45 secs.

It is thus clear that a thrombokinase of considerable activity is present in seminal plasma. The origin of this kinase may be the testis but we think its more likely origin is the broken down cells of several kinds which are always found in the seminal fluid. As to the function of kinase in seminal fluid we make no suggestion.

Miscellaneous observations.

(*a*) It seemed possible that seminal fluid might contain hormones having an influence on the female genital tract. Injection of 1 ml. fresh seminal fluid intravenously into young virgin rabbits did not, however, produce any changes in the uterus or ovaries during periods up to 48 hours after the injections. The animals showed no toxic effects but invariably the injections were followed by an almost immediate defaecation; for the effect on intestinal muscle see Goldblatt [1935].

(*b*) Successive intravenous injections of seminal fluid or alcoholic extracts thereof into rabbits had no effect on blood sugar.

(*c*) Seminal fluid does not give the nitroprusside reaction for glutathione or related bodies.

SUMMARY.

1. Human seminal plasma has been quantitatively analysed for certain constituents. The ratios of the concentrations of these in seminal plasma to their concentrations in blood plasma are as follows: chloride and cholesterol, 0·3–0·5; bicarbonate, 0·7–1·0; calcium, glucose, urea, 2·0–3·0; lactic acid, 5·0–6·0; acid-soluble phosphorus (inorganic, 50 %, spermine, 30 %, undetermined 20 %), 30.

2. The proteins of seminal plasma include: mucin (traces), nucleoprotein, albumin, globulin (traces), proteoses. The proteoses may be both primary and secondary; secondary proteose is always present. The secondary proteose, it is suggested, consists of thioalbumose and synalbumose or bodies closely resembling them. Peptone is never present in seminal plasma. The presence of proteoses interferes with several estimations.

Protamines and histones have not been found in seminal plasma.

3. Glycolysis can be demonstrated in seminal plasma only if active sperm cells are present. This is associated with a large increase in lactic acid but the latter is not sufficient to account for all the lost reducing power.

Proteolytic ferments have not been found in seminal plasma and hence the presence of proteose cannot be explained on enzymic grounds.

Diastase and thrombokinase have been demonstrated in seminal plasma.

4. Seminal plasma does not appear to contain hormones affecting either the genital tract or carbohydrate metabolism.

CLXV. THE FATTY ACIDS OF PIG LIVER.

III. A GENERAL ANALYSIS.

By EILEEN IRVING and JAMES ANDREW BUCHAN SMITH.

From the Department of Biochemistry, The University of Liverpool.

(*Received April 27th, 1935.*)

In two earlier communications, Channon *et al.* [1934, 1, 2] described their investigations on the nature of the octadecenoic acids of pig liver and discussed in detail the bearing of their results on the question of the desaturation of fatty acids in that organ. In continuation of these experiments the original fatty acids which had been prepared from 100 kg. of pig liver were subjected to further analyses by different methods. They were treated on a scale sufficiently large to give the results something of that completeness which they require, if ever they are to contribute materially to the elucidation of problems concerning fat metabolism in the animal body.

In view of the recognised importance of the liver in fat metabolism, it is surprising to find how little serious work has been carried out so far to establish the precise nature of the fatty acids contained in the mammalian liver. The chief contributors to this subject have been Hartley [1909], who analysed the fatty acids from pig liver, discovering in them the highly unsaturated arachidonic acid, and Klenk and Schoenebeck [1932] who made a thorough examination of those present as glycerides and phosphatides in ox liver. Work in similar fields published from various laboratories in recent years, such as the discovery of a liquid saturated acid in cat's kidney by Turner [1931] and of other liquid saturated acids in tubercle bacilli by Anderson [1929] and Spielman [1934], as well as the evidence put forward by Bosworth and Brown [1933] and by Bosworth and Sisson [1934] for the presence in butter fat of arachidonic and lower unsaturated acids, indicates that a thorough investigation of the lipins from different parts of the animal body has already been too long delayed. There can be little doubt that results accumulating in the course of time from researches of this type will ultimately bring to light the essential details of certain biological processes of which for the present the explanation remains obscure. As a contribution to this end the present work was carried out.

EXPERIMENTAL.

The preparation of the fatty acids and their separation into saturated and unsaturated fractions by the Twitchell process, as modified by Hilditch and Priestman [1931] has already been described by Channon *et al.* [1934, 1]. The main points to be noted for the present communication are these. The original acids had an iodine value of 110 and a mean molecular weight of 299. By the lead soap-alcohol procedure the mixture was shown to contain 34 % of saturated acids (I.V. 2; mol. wt. 277), and 66 % of unsaturated acids (I.V. 153; mol. wt. 321).

Estimation of the saturated acids by the Bertram method.

This consisted of oxidising samples of both the original mixture and the unsaturated fraction with permanganate and precipitating the petroleum-soluble products twice as magnesium soaps [Bertram, 1927].

(*a*) *The original acids.* 5·035 g. gave 1·750 g. saturated acids, or 34·8 %.

(*b*) *The unsaturated acids.* 5·226 g. gave 0·197 g. saturated acids. This is equivalent to 3·8 % of the unsaturated fraction, or to 2·5 % of the original acids.

In summarising these results it can be said that the content of the saturated acids was found to be 34·8 % by the Bertram process alone, and 36·5 % (*i.e.* 34·0+2·5) by the two methods combined. That this higher figure of 36·5 % approximated more nearly to the truth was proved later by distillation methods.

Analysis of the saturated acids.

210 g. of methyl esters were prepared from the saturated acids and fractionally distilled at 2 mm. The fractions were saponified, traces of unsaponifiable matter removed and the melting-points and molecular weights of the acids determined. Assuming that no fraction ever contained more than two adjacent homologues, the amounts of the various fatty acids present were calculated from the results arranged in Table I.

Table I.

					Weight of each fatty acid present			
Fraction	B.P. at 2 mm. (°) up to	Weight of acids g.	M.P. (°)	Mol. weight	Myristic g.	Palmitic g.	Stearic g.	"Arachidic" g.
1	136	1·8	53·5–55·5	249·5	0·4	1·4	—	—
2	141	5·6	57·0–59·0	251	1·0	4·6	—	—
3	141	20·6	58·5–59·5	255·5	0·4	20·2	—	—
4	145	18·4	60·0–61·0	258	—	17·1	1·3	—
5	153	27·7	55·0–56·0	263	—	20·8	6·9	—
6	160	18·6	56·0–57·0	269·5	—	9·6	9·0	—
7	165	75·8	68	285	—	—	73·1	2·7
8	167	13·6	68·5–69·0	286	—	—	12·6	1·0
9	Residue	13·5	62	297	—	—	7·2	6·3
Total		195·6*	—	—	1·8	73·7	110·1	10·0

* This figure indicates a loss of less than 3 % of the total saturated fraction, or 0·9 % of the original mixed acids, and was most probably distributed very evenly over the various fractions.

Although reference is made in the discussion to this method of calculating the composition, two points should be explained at this stage. The acids lower in the series than palmitic have been estimated as myristic because, owing to the solubility of the lead soaps of lower members in alcohol, it is extremely improbable that any acid with less than 14 carbon atoms could ever be found in the saturated fraction from the Twitchell separation. Again, for calculation purposes the acids higher than stearic have been grouped together as "arachidic", although it is fully realised that behenic and lignoceric acids were probably also present in this fraction.

	% of saturated acids	% of original mixed acids
Myristic	0·9	0·3
Palmitic	37·7	12·5
Stearic	56·3	18·6
"Arachidic"	5·1	1·7
Loss	—	0·9
Total	100·0	34·0

Analysis of the unsaturated acids.

Various methods have been applied to the problem of determining the constitution of the unsaturated fraction. These are now described in proper sequence below, the first consisting of fractional distillation, followed by hydrogenation of samples from each fraction as used by Klenk and Schoenebeck [1932].

Distillation followed by hydrogenation. 80·5 g. methyl esters prepared from 77·5 g. unsaturated acids were distilled as usual. After the weights and iodine values of each fraction had been recorded, fractions 1–4 were saponified, traces of unsaponifiable matter removed and the fatty acids isolated. Fraction 1 was not studied further, but the acids from 2, 3 and 4, being semi-solid at room temperature, were subjected to the Twitchell separation and the resulting liquid acids were hydrogenated. 1·0–1·5 g. of the esters from each of the remaining fractions were hydrogenated with palladium black and hydrogen at room temperature and the saturated fatty acids isolated, their molecular weights and melting-points being determined. By assuming once again that only two adjacent homologues were present in any one fraction, the amounts of the different acids could be calculated. The results are summarised in Table II.

Table II.

								Unsaturated acids (total)			—	2·6	50·7	30·3	11·8

For comparison with these results the following theoretical figures are quoted. For the methyl esters of palmitoleic, oleic and linoleic acids the iodine values are 95, 86 and 173; for methyl esters of C_{20} acids, having 1, 2, 3, 4 and 5 double bonds, they are 78, 158, 238, 319 and 402; for methyl esters of C_{22} acids with 2, 3, 4 and 5 double bonds the corresponding figures are 145, 219, 294 and 369. The molecular weights of the fully hydrogenated C_{16}, C_{18}, C_{20} and C_{22} acids are 256, 284, 312 and 340 respectively.

The conclusions which may be drawn from the results set out in Table II are as follows:

1. The result of the Bertram analysis already mentioned has been very well confirmed in that the unsaturated fraction from the Twitchell separation yielded

on fractional distillation 3·8 % of saturated acids (fractions 2*a*, 3*a* and 4*a*). These obviously consisted of palmitic acid, associated with smaller amounts of stearic acid and lower homologues.

2. From a consideration of the melting-points of the hydrogenated fractions, it is clear that no liquid saturated acid could have been present in the original mixture, a fact which cannot be definitely proved at present, except by hydrogenation experiments.

3. The unsaturated acids contained a small amount of lower homologues, which, estimated as palmitoleic acid, amounted to 2·6 % of the total liquid fraction (fraction 2*b* and 3*b*). This finding was confirmed later.

4. Although the assumption that the hydrogenated fractions each contained only two adjacent homologues has yet to be discussed, the principle as used in the present instance indicated that the mixed unsaturated acids were made up of C_{18} compounds to the extent of approximately 50 %, the major part of the remainder consisting of C_{20} and C_{22} acids; while from the iodine values of the higher fractions and the molecular weights of their hydrogenated derivatives, it seemed most probable that the C_{20} and C_{22} acids contained 2, 3 and 4 double bonds.

This last conclusion is of particular interest, for in their work on octadecenoic acids of pig liver, Channon *et al.* [1934, 1] oxidised portions of these liquid acids by methods which were known to give extremely good yields of hydroxy-derivatives, if applied to pure samples of oleic and linoleic acids. Yet their results suggested that the C_{18} acids did not amount to more than about 28 % of the unsaturated fraction, whereas the present experiment suggests the presence of 50 % of such acids. It has already been stated by Lapworth and Mottram [1925] that their method of oxidation gives considerably reduced yields of hydroxy-derivatives if more highly unsaturated acids are present. It was accordingly decided to distil a large amount of methyl esters prepared from the liquid acids and to oxidise samples of the various fractions obtained. By this means it was hoped to segregate the highly unsaturated acids into the higher fractions and so obtain more representative yields of the hydroxy-derivatives from the C_{18} acids in the lower-boiling fractions.

At the same time the opportunity was taken of investigating further the small amounts of saturated and palmitoleic acids already mentioned as being present in the liquid mixture from the Twitchell separation.

Distillation and subsequent oxidation. 208 g. methyl esters were distilled *in vacuo* into eight fractions. The acids from the first four of these were treated by the modified Twitchell process, and then samples of the liquid acids from all the fractions were oxidised by Lapworth and Mottram's method [1925], a second oxidation being carried out in each case on the petroleum-soluble products to ensure that reaction was complete. From each fraction, in addition to the usual di- and tetra-hydroxy-derivatives, there was obtained a certain amount of fatty acid which was soluble in light petroleum, and which, although virtually saturated, was yet only semi-solid at room temperature. Although this substance has not so far been investigated, the yield obtained from each fraction has been recorded, together with its molecular weight, in order to allow calculations to be made should future work explain its occurrence and origin. It is worthy of note that its molecular weight increased with the molecular weight of the acids from which it was derived. The possibility of this substance being unoxidised material is excluded by the fact that it no longer possessed any appreciable iodine value, while the results both of the Bertram oxidation and of the distillation-hydrogenation experiments definitely exclude the possibility that this peculiar product pre-

* These figures have been corrected for small amounts removed after distillation and before Twitchell treatment for determination of iodine values and molecular weights.

existed as such in the liquid acids. That strange by-products are formed by this mild oxidation of these complex mixtures was indicated in every fraction by the fact that a certain amount of unsaponifiable matter was also isolated from the oxidation products, whereas all such matter had been removed from the acids as a whole before their analysis was begun. The results of these distillation-oxidation experiments are set out in Table III.

Several interesting facts should be observed. In the first place only 83 % of the original acids was recovered. The loss of 17 % of the material was due to much decomposition which took place in the undistilled residue, yielding by-products insoluble in light petroleum and not recorded in the table. This fractionation of 208 g. methyl esters was a much longer process than that previously carried out on 80·5 g. (Table II), and this fact, combined with the slightly higher pressure and correspondingly higher boiling-points, accounted for the bulk of the loss. Nevertheless, it may be assumed that the decomposition and consequent loss in iodine value which it necessarily entailed took place entirely in the undistilled residue, in which fraction the most highly unsaturated and therefore the most unstable acids would occur. It may therefore be surmised that as far as oleic, linoleic and palmitoleic acids are concerned, the quantitative results remain unaffected.

With regard to the hydroxy-derivatives, their melting-points are recorded in Table III and are typical for the usual products obtained by this means before purification by fractional crystallisation, while the molecular weights quoted for the dihydroxystearic acid from fractions 5, 6 and 7 approximate closely to the theoretical value of 316. It is of importance to observe that oleic acid was shown by these results to be present in all the fractions except the last, and that linoleic acid was detected in all but numbers 1, 2 and 8. The bearing of this finding on the distillation method of analysis as applied to unsaturated fatty acid mixtures is discussed later.

Palmitoleic acid. The presence of palmitoleic acid in the unsaturated fraction, which was already suggested by the results in Table II, was confirmed in the present instance by the molecular weights and melting-points of the dihydroxy-derivatives from fractions 1, 2 and 3. When the first of these was analysed, the values obtained were C, 67·3; H, 11·0 %; mol. wt., 300. For an equimolecular mixture of dihydroxypalmitic and dihydroxystearic acids, the corresponding figures should be 67·5, 11·35 % and 302. It is therefore probable from both experiments that the content of palmitoleic in the unsaturated acids was 2–3 %.

The saturated acids from the unsaturated fraction. The Bertram oxidation and the results of Tables II and III all suggest that the saturated acids still remaining in the liquid fraction amounted to approximately 3·8 %. In order to analyse these, each of the solid portions obtained in the last experiment was fractionally recrystallised from acetone and its nature investigated.

From fractions 3 and 4 the solid acids (mol. wt. 252 and 254), consisted mainly of palmitic acid. They both gave crops of crystals from acetone, melting between 57·5 and 61·5° and typical C and H figures of C, 74·5; H, 12·5 %. ($C_{16}H_{32}O_2$ requires C, 74·9; H, 12·6 %; mol. wt., 256.)

After recrystallisation, fraction 2, which had mol. wt. 237, melted at 54–56° and therefore most certainly contained palmitic and myristic acids. Fraction 1 (mol. wt. 213·5) gave three crops and a mother-liquor, the details of which are shown in Table IV.

(Required for $C_{10}H_{20}O_2$: C, 69·8; H, 11·6 %; for $C_{12}H_{24}O_2$: C, 72·0; H, 12·0 %; and for $C_{14}H_{28}O_2$: C, 73·7; H, 12·3 %.) It must be concluded from these experiments that this small amount of solid acid, which is not separated in the saturated fraction in the Twitchell method, but is estimated by a Bertram oxidation on the unsaturated fraction, consisted mainly of palmitic with small quantities of myristic, lauric and possibly *n*-decanoic acids. Table II also suggested the presence of stearic acid in small amounts.

Table IV.

Crop	Weight (g.)	M.P. (°)	C %	H %	Probable constitution
1	0·11	55·5–57·5	74·2	12·65	Mainly palmitic acid
2	0·08	45 –46	—	—	Lauric mixed with myristic acid
3	0·18	46	72·4	12·1	
Mother-liquor	0·40	—	69·7	11·5	Possibly *n*-decanoic acid present

The detection of highly unsaturated acids by oxidation. As shown in Table III, 11·97 g. of the undistilled residue were oxidised by the usual method. After extraction with ether, the resulting aqueous solution (12 l.) was evaporated to 700 ml. and the residue allowed to cool. Much inorganic material crystallised out along with small amounts of organic acids and some tar. These were filtered off and the residue extracted three times with boiling absolute alcohol. 0·3 g. of a crude mixture was obtained and was fractionally crystallised from aqueous alcohol and from water after treatment with charcoal. The first crop (0·04 g.) had M.P. 200°, but the major part, even after exhaustive attempts at purification, melted constantly at 186° and gave on analysis C, 55·2; H, 9·35 %. The mineral salts were then extracted three times with boiling 70 % alcohol, and 0·6 g. of a very impure organic acid was isolated. By repeated recrystallisations from both water and aqueous alcohol after charcoal treatment, 0·2 g. of a pure product was prepared, M.P. 195°. (Found: C, 54·5; H, 9·1 %. Required for $C_{20}H_{40}O_{10}$: C, 54·5; H, 9·1 %; and for $C_{22}H_{44}O_{10}$: C, 56·4; H, 9·5 %.) It therefore seems most probable from these figures that the fraction extracted by absolute alcohol was a mixture of octahydroxyarachidic and octahydroxybehenic acids, while that isolated by 70 % alcohol was the former of these alone. Owing to the large amounts of mineral salts and the solubility of these hydroxy-compounds, the extraction cannot be regarded as in any way complete. The experiment does show however that, in addition to the usual arachidonic acid first discovered by Hartley [1909], there is probably also present in liver fat the corresponding C_{22} acid with four double bonds.

Bromination experiments. All the known unsaturated acids form soluble liquid bromo-derivatives, in addition to solid isomerides, and usually the former can neither be identified nor estimated. This explains why bromination has never been regarded as a satisfactory method of analysing fatty acid mixtures. New interest in such a process has recently been stimulated however by the work of Ault and Brown [1934] who have suggested a method, to which reference is made later, for estimating arachidonic acid by this means.

50·3 g. of the unsaturated acids were therefore brominated in ether at 0° in the usual way. The insoluble product was filtered off and washed with ether and then excess bromine removed from the filtrate and washings by sodium thiosulphate solution. On removing the ether and taking up the residue in light petroleum (B.P. 80–100°) and leaving at 0° for one night, a further small amount of insoluble bromo-derivative crystallised out. This was filtered off, the filtrate taken to dryness, dissolved in light petroleum (B.P. 40–60°) and kept at 0° for some days, when crystalline tetrabromostearic acid was deposited. The results are summarised in Table V, where it should be noted that the saturated acids in the unsaturated fraction are taken as being 4 % (the nearest unit) and the true data for the petroleum-soluble bromides appropriately corrected for that amount.

Table V. *Bromination of 50·3 g. unsaturated acids.*

No.	Description	Wt. g.	M.P. (°)	Bromine %	Corresponding wt. of unsaturated acids g.	Original unsaturated acids %	Calculated I.V. of these acids
1	Insoluble in ether	13·2	240 indef.	68·3	4·18	8·3	342
2	Insoluble in high-boiling petroleum	1·75	,,	68·0	0·56	1·1	337
3	Tetrabromostearic acid	2·0	112–113	53·3	0·93	1·8	181
4	Soluble in cold petroleum	77·0	—	45·0	42·4	84·3	130
5	Saturated acids	2·0	—	—	2·0 (sat.)	4·0	—
	Total accounted for				50·0	99·5	

The absence of linolenic acid. Normally when linolenic acid is present in a mixture, it yields a hexabromostearic acid soluble in benzene, insoluble in ether and melting at 180°. To search for this substance, 2·9 g. of the ether-insoluble products of bromination (Table V), were thoroughly extracted with benzene, but the two fractions so obtained melted at the same temperature (240° with decomposition). The absence of linolenic acid was further confirmed by the oxidation experiment already described in which octahydroxyarachidic acid was isolated (p. 1364), for in that case no trace of hexahydroxystearic acid could be found. It is therefore safe to conclude that, if this unsaturated acid were actually present, the amount must have been extremely small.

Apart from this result, the bromination experiment added little to the information already gained. It confirmed the presence of ordinary linoleic acid and of higher unsaturated acids of the C_{20} or C_{22} type, but unfortunately with such a complex mixture nothing of any value could be concluded from the soluble bromide fraction (Table V, No. 4), which constituted such a large proportion of the whole. The minimum amount of highly unsaturated C_{20} and C_{22} acids present can however be stated from fractions 1 and 2 to have been 9·4 % of the total unsaturated fraction.

DISCUSSION.

The general analysis just described has confirmed and extended the preexisting knowledge of the fatty acids contained in mammalian livers and has in several aspects tested the methods by which they may be investigated.

The relative values of the Twitchell and Bertram processes were well illustrated. There is no doubt that the lead soap separation as modified by Hilditch and Priestman [1931] gave an exceedingly good separation of the saturated and unsaturated acids, whilst the small amount of saturated compounds still remaining in the liquid portion was readily estimated by a Bertram oxidation, carried out on the liquid acids rather than on the original mixture. The value so found for these residual acids was confirmed twice by distillation experiments.

The method of calculating the amounts of different acids present by distillation of the esters, followed by estimations made on the assumption that each fraction never contains more than two homologues, has been much used by

Hilditch and his co-workers and has been recently discussed in detail by Hilditch [1934]. Provided that a sufficiently large number of fractions be taken, it is most improbable in the case of the saturated acids alone that any one of the fractions will contain more than relatively small traces of a third homologue. Even in a case, such as the one described in the present communication, where only nine fractions were taken, the final results calculated on this basis probably approximated to within a few units of the true value in the large figures recorded. At the same time it is difficult to assume a greater degree of accuracy than this, for even if it be allowed that the presence of a third homologue be negligible, other small but appreciable errors may arise, as for example in determining the mean molecular weight of each fraction, a figure on which the whole process of deducing the composition depends. Provided these and other small errors at this stage neutralise each other, as they may often do, the conclusions will approximate closely to the true values; but if on the other hand they happen to accumulate, the figures finally arrived at for the main constituents will only approach within a few units of the actual percentages which a more accurate method would yield. Unfortunately a more accurate method for this purpose has not yet been devised.

The liquid acids present a still more difficult problem. In the present case the initial mixture of unsaturated acids was too complex for proper analysis to be made by fractional distillation. The failure of the process for this purpose was shown by the fact that oleic and linoleic acids were proved by oxidation methods to be present in the majority of the fractions, even though the boiling points of these differed in the extreme by as much as 35°. Again distillation followed by hydrogenation made it certain that C_{20} and C_{22} acids, having two, three and four double bonds also existed in the same fractions. Consequently it was impossible to elucidate satisfactorily the composition of the unsaturated liver acids by simple calculation from such fractions, although such a procedure may well be applicable to the less complex fatty acids of the glycerides and phosphatides from plant sources.

Hydrogenation, therefore, as applied by Klenk and Schoenebeck [1932] appears to be the most satisfactory approach so far devised for the analysis of such mixtures, the actual hydrogenation either preceding or following the fractional distillation. Such a method eliminates the danger of overlooking the presence of liquid saturated acids and, taken in conjunction with the other data acquired, it goes far towards yielding a true estimate of the various constituents. For the acids under discussion it has shown better than any other method the relative amounts of C_{16}, C_{18}, C_{20} and C_{22} compounds and has suggested their relative degrees of unsaturation. The figures so obtained for the C_{20} and C_{22} acids, which must have had two or three double bonds, was surprisingly large, but they have confirmed very closely the corresponding values found by Klenk and Schoenebeck in their work on the acids from ox liver. Unfortunately it has been impossible to prepare any derivatives by which these compounds might be characterised. The same method gave the content of C_{18} acids as approximately 50 % of the liquid portion and, from the yields of di- and tetra-hydroxy-derivatives, whether obtained by oxidising the total acids as in Part I of this series [1934, 1] or each of the various fractions resulting on distillation, it may be assumed that the quantity of oleic acid was about five times greater than that of the linoleic acid. The amounts of these acids in the unsaturated fraction should therefore have been of the order of 42 and 8 % respectively.

In at least two ways the presence of a lower unsaturated acid, which was most probably palmitoleic, was proved.

On investigating the saturated acids still remaining in the liquid fraction and obtained from it on distillation, the presence of lauric, myristic and possibly *n*-decanoic acids was shown, in addition to palmitic and traces of stearic acids. According to the theory of β-oxidation of fatty acids, these lower even-numbered members might well be expected to appear in small amounts in the liquid fraction of the liver acids. Any acids having less than 10 carbon atoms would have been previously removed in the preparation of the total acids from the liver, owing to their solubility in water or their capacity to distil readily in steam.

With regard to the true amount of arachidonic acid present, Ault and Brown [1934] have prepared pure arachidonic acid in different ways and brominated the pure product. They found that no matter how the acid was made, 1 g. on the average yielded approximately 0·842 g. of polybromide, instead of the theoretical value of 3·1 g. They then assumed that on brominating a mixture of acids this proportion of ether-insoluble polybromide would remain the same and so they suggested the following formula:

$$\%\text{ of arachidonic acid} = \frac{\text{Weight of ether-insoluble bromide from 100 g. of mixed acids} \times 100}{84{\cdot}2}.$$

When this was applied in the present instance, the content of arachidonic acid became:

$$\frac{13{\cdot}2 \times 100 \times 100}{50{\cdot}3 \times 84{\cdot}2}\,\% = 31{\cdot}2\ \%.$$

Now if it may be assumed for the moment that fraction 4 in Table V consisted entirely of the bromo-derivatives of a C_{20} acid with one double bond, together with the corresponding derivatives of arachidonic acid, the maximum amount of the latter acid which could possibly have been present may be calculated to be 26·5 %. That it must actually have been considerably less than this figure is obvious, for from the distillation-hydrogenation experiment it is certain that the petroleum-soluble fraction (No. 4, Table V) must have contained derivatives of acids all with higher iodine values than that of a C_{20} acid with one double bond, and these would all considerably decrease this estimated maximum for the content of arachidonic acid.

The method of Ault and Brown therefore did not apply in the present case. This might have been due to either of two reasons. In the first place, it is most probable that some highly unsaturated C_{22} acids were present in small amounts in the original mixture, as well as C_{20} compounds other than the ordinary arachidonic acid. These would naturally make it unfair to test the validity of the procedure on such a sample of acids.

In the second place the high value obtained in the present instance by the application of this method might have been due to the fact that in the presence of other unsaturated acids the proportion of arachidonic acid yielding a solid ether-insoluble bromide is greatly enhanced. Such an explanation is possible in the light of the work of Rudy [1932], who found that on brominating acids of this type the relative proportions of the different forms produced varied considerably with such factors as the type of solvent and the speed of bromination. That they may also vary according to the type and proportions of the other acids present in the mixture seems very possible.

The following table shows a summary of the approximate composition of the pig liver fatty acids as far as it may be deduced from these experiments. From the discussion as a whole it is clear that the figures cannot be other than approximate.

	Saturated acids %	Original mixture %
n-Decanoic and lauric acids	1	0·4
Myristic acid	2	0·7
Palmitic acid	39	14·0
Stearic acid	53	18·8
"Arachidic" acid	5	1·7
Total	100	35·6

	Unsaturated acids %	Original mixture %
Palmitoleic acid	2·5	1·5
Oleic acid	44	28
Linoleic acid	8	5
Linolenic acid	Absent	—
C_{20} acid	31	20
C_{22} acid	12	7·5
Total	97·5	62·0

Total loss – 2·4 %.

The C_{20} and C_{22} acids probably existed in the mixture as compounds having from two to four double bonds.

SUMMARY.

The pig liver fatty acids have been analysed by bromination and distillation experiments, the latter being followed both by oxidation and by hydrogenation processes. The results are discussed in full and summarised immediately above.

The authors desire to express their thanks to Prof. H. J. Channon for his continual interest and encouragement during the course of this work.

CLXVI. THE ALGAE.

I. THE LIPOCHROMES OF *FUCUS VESICULOSUS*.

BY ISIDOR MORRIS HEILBRON AND
RICHARD FRANCIS PHIPERS.

From the Chemical Department, University of Manchester.

(*Received April 6th, 1935.*)

THE earliest recorded investigation of the fat-soluble pigments of the brown algae was made by Cohn [cited by Kylin, 1912], who isolated from the Phaeophyceae one brown pigment, phaeophyll, which he presumed was closely related to chlorophyll. Millardet [1869] clarified the position by showing that phaeophyll could be resolved by partition processes between light petroleum and alcohol into chlorophyll, a yellow lipochrome, phycoxanthin, and a brown water-soluble pigment, phycophain. Sorby [1873] came to the conclusion that the Fucaceae, a branch of the Phaeophyceae, contained three different yellow lipochrome pigments, xanthophyll, phycoxanthin (which he renamed fucoxanthin) and lichnoxanthin, the last occurring in very small amounts. Reinke [1876] considered that Sorby's method of distinguishing between the yellow pigments was unreliable and was himself only able to detect fucoxanthin, which was not identical with the xanthophyll of the higher plants. Tswett [1906], employing the chromatographic method, confirmed the presence of carotene first demonstrated by Tammes [1900] and also of fucoxanthin, the presence of which had recently been denied by Gaidukow [1903]. Tswett also distinguished a further lipochrome pigment, fucoxanthophyll, and showed that whereas fucoxanthin develops an intense royal blue colour with hydrochloric acid, fucoxanthophyll gives only a green colour. Kylin [1912] further defined the colour reactions of fucoxanthin and stated that fucoxanthophyll was identical with the xanthophyll of the higher plants (which gives no colour with hydrochloric acid). Willstätter and Page [1914] isolated fucoxanthin as a crystalline compound from various Phaeophyceae and assigned to it the formula $C_{40}H_{54}O_6$ or $C_{40}H_{56}O_6$. By partition processes between aqueous methyl alcohol, ether and light petroleum, they further obtained a pigmented solution which gave no colour with hydrochloric acid and on these grounds concluded that "xanthophyll" was also present. These authors observed that it was apparently impossible to obtain fucoxanthin from brown algae after a period of 10 days had elapsed from the time of gathering; they did not, however, pursue this matter further.

In view of the wide disparity in the results of the earlier investigators we have again carried out an examination of the lipochromes present in *Fucus vesiculosus* and have employed for this purpose both the fresh alga and old dried material. Our results show that whereas fresh *Fucus vesiculosus* contains the characteristic brown algal pigment fucoxanthin together with carotene, the former pigment is wholly absent from the dried material, which contains in its place zeaxanthin. In addition a constitution for fucoxanthin based on its chemical properties, and permitting of such a post-mortal transformation, is discussed later in the paper.

EXPERIMENTAL.

Old dry Fucus vesiculosus. The material, collected during the summer months from the north coast of Scotland, was air-dried over a prolonged period and milled, giving a pale fawn powder which was subjected to a systematic solvent extraction, a typical experiment being outlined below [see also Heilbron *et al.*, 1934]. The powder (36 kg.) was intermittently stirred with 95 % ethyl alcohol (40 l.) for 18–24 hours at room temperature. The deep olive-green solution obtained by filtration through an edge filter was diluted with water (10 l.) and shaken with successive portions of light petroleum (B.P. 40–60°) until the extracts were practically colourless. The latter were combined and concentrated under nitrogen (extract A). The alcoholic phase, after further dilution with an equal volume of water, was completely extracted with ether, the ethereal solution washed with water, dried and concentrated to about 2000 ml. (extract C). The residual meal was extracted with ether (40 l.), the ethereal solution furnishing extract B.

Extract C. This was dried by distillation with an equal volume of benzene (final volume 400 ml.) and the cold benzene solution adsorbed in four portions on columns (50 × 5 cm.) filled with Merck standardised Brockmann alumina (1 part) and ordinary alumina (1 part), the chromatogram being developed with light petroleum (B.P. 40–60°); three distinct bands were thus obtained.

The uppermost band (deep olive-green), which could not be completely eluted with methyl alcohol, was desorbed slowly with a mixture of water, methyl alcohol and pyridine. The pigment, obviously of the chlorophyll type (probably allomerised chlorophyll), was not further examined.

Elution of the second band (deep brick-red, immediately below the green band) was performed with methyl alcohol; the solution was concentrated to small bulk, poured into water and extracted with ether. The washed and dried ethereal solution was concentrated (2 ml.) and diluted with light petroleum. After standing in the ice-chest for 24 hours, the precipitated pigment was repeatedly crystallised from benzene-methyl alcohol, from which it separated in deep red glistening needles, M.P. 211° (uncorr.). It was characterised as zeaxanthin by its absorption maxima in CS_2 (518, 483 and 451 $m\mu$) and by analysis. (Found: C, 83·2; H, 10·1 %. $C_{40}H_{56}O_2$, 0·5 CH_3OH requires C, 83·2; H, 10·2 %) [*cf.* Kuhn and Grundmann, 1934].

The third pigmented section, formed at the base of the column, after elution with methyl alcohol and removal of solvent yielded a pale yellow mobile oil from which no crystalline pigment could be obtained. This zone consisted of terpenoid substances previously reported by Heilbron *et al.* [1934].

Extracts A and B. After removal of solvent the residue in each case was saponified with 10 % methyl alcoholic potash (3 l.) at 40° for 3 hours. The unsaponifiable material obtained by ethereal extraction was freed from fucosterol and hentriacontane by crystallisation from methyl alcohol as described by Heilbron *et al.* [1934], and the deep red methyl alcoholic mother-liquors were steam-distilled in an atmosphere of nitrogen to remove volatile terpenes. The residue was extracted with benzene and the dried concentrated solution (50 ml.) chromatographically resolved as described above. The completed chromatogram showed three distinct red bands, the uppermost of which on elution with methyl alcohol yielded a further quantity of zeaxanthin, M.P. 208–209°. The central band was also eluted with methyl alcohol and the solution concentrated until turbid. The pigment which separated on cooling was recrystallised from benzene-methyl alcohol, giving beautiful metallic flakes, M.P. 178–179° (uncorr.), of β-carotene; absorption maxima in CS_2, 518, 483 and 451 $m\mu$. (Found: C, 89·3, H, 10·8 %. $C_{40}H_{56}$ requires C, 89·5; H, 10·5 %.)

Elution of the brownish red zone at the base of the column provided a further quantity of terpenoid material.

Fresh Fucus vesiculosus. The minced alga (50 kg.) was freed from mucilages by washing twice with aqueous acetone (50 l. of 40 %) as described by Willstätter and Page [1914]. The washed material was covered with methylated spirit (50 l.) and allowed to stand for 24 hours with intermittent agitation. The alcoholic extract was resolved as described above into extracts A, B and C.

Extract C. This was dried with benzene and the solution (3 l.) chromatographically resolved in 15 portions in columns (50 × 5 cm.) filled with partially deactivated alumina (prepared by washing Brockmann activated alumina with methyl alcohol and subsequent drying in air) the chromatograms being developed with benzene-light petroleum (1:1) and finally washed with light petroleum (B.P. 40–60°)[1]. The completed chromatogram formed three definite bands, the uppermost of which, a deep olive-green, appeared to be identical with that obtained from extract C of the old alga. The middle broad crimson band was eluted with methyl alcohol and the deep red solution diluted with an equal volume of water and allowed to stand, atmospheric oxygen being excluded by a thin layer of light petroleum. The pigment which slowly separated as a semi-crystalline precipitate at the interphase was dried *in vacuo* over sodium sulphate. On recrystallisation from ether-light petroleum pure fucoxanthin separated in deep orange-red needle aggregates, M.P. 166–168° (uncorr.); absorption maxima in carbon disulphide, 510, 477 and 445 $m\mu$; in chloroform 487 and 456 $m\mu$. (Found: C, 75·3; H, 9·3 %.) Karrer *et al.* [1931] give the M.P. as 160° (corr.) and maxima in chloroform at 492 and 457 $m\mu$. Willstätter and Page [1914] record a M.P. at 159·5–160·5° (corr.) and 158° (uncorr.). In agreement with these latter authors we have observed that whereas the blue colour produced by the action of acids on fucoxanthin exists in aqueous solution only in the presence of ether, when a light petroleum solution is treated with 25 % hydrochloric acid the blue colour remains entirely in the upper layer.

The third band on elution with methyl alcohol gave an orange-red solution, which in contrast to that obtained above, yielded its contained pigment to light petroleum on dilution. When a test portion of this was treated with 25 % hydrochloric acid a magenta colour was observed in the acid layer in addition to the royal blue colour in the light petroleum. The solution, obviously complex, was ultimately resolved by adsorption on fuller's earth, two distinct pigments being obtained. That occurring in the larger proportion on recrystallisation from ether-light petroleum yielded fucoxanthin, whilst the other (*circa* 2 mg.), which was extremely resinous, has not as yet been obtained in a crystalline state. Its ethereal solution gives with 25 % hydrochloric acid a colourless upper and a magenta lower layer and in carbon disulphide shows general absorption with a marked inflection at 500 $m\mu$. The pigment is presumably the "fucoxanthin-β" referred to but not isolated by Kylin [1927], who stated that there was a small amount of another pigment giving a more violet colour with hydrochloric acid.

We are inclined to believe that it is partially oxidised fucoxanthin, a view supported by catalytically hastening the autoxidation [*cf.* Palmer and Thrun, 1916] of the pure pigment. A solution of fucoxanthin (25 mg.) in glacial acetic acid (10 ml.) was heated on a steam-bath for 1 hour with ferric chloride (10 mg.) and the cooled solution rendered alkaline with dilute sodium hydroxide solution.

---

[1] If fully activated alumina is used the pigments are so strongly adsorbed that separation of the zones is impossible.

The pigment was removed with ether and the washed and dried ethereal solution evaporated. The residue was dissolved in benzene (25 ml.) and chromatographically examined on a column of activated alumina, when only one strongly adsorbed red band was obtained. Elution with methyl alcohol yielded a red solution from which no crystallisable material could be obtained. The pigment contained in this eluate was, however, identical with "fucoxanthin-β" in that treatment of an ethereal solution with 25 % hydrochloric acid gave a magenta-coloured acid layer and in CS_2 it showed a pronounced inflection at $502 m\mu$.

Extract A. This was examined in detail in order to ascertain whether any "xanthophyll" other than fucoxanthin was present. The concentrated light petroleum solution (3000 ml.) was directly resolved by adsorption in 12 portions on partially deactivated alumina, giving a complex chromatogram showing five distinct bands (Fig. 1).

Fig. 1.

Band B. This band was eluted with methyl alcohol and the eluate diluted to 75 % with water and extracted twice with light petroleum. The lower phase, after separation and further dilution, yielded precipitated fucoxanthin, M.P. 161–163°. The washed light petroleum phase was dried and a test portion evaporated, dissolved in ether and treated with 25 % hydrochloric acid; a green lower layer (finally changing to blue) was thus obtained (agreement with Tswett's [1906] fucoxanthophyll). This solution should, however, according to Willstätter and Page [1914] contain "xanthophyll". The total light petroleum solution was consequently evaporated and the residue treated with cold methyl alcohol; a quantity of brown pectinoid material (*circa* 2 g.) was precipitated[1]. The mother-liquors were evaporated, the residue was dissolved in the smallest volume of ether and a large excess of light petroleum added. After standing for 24 hours, the practically colourless light petroleum solution (which was found to contain fucosterol, M.P. 124°) was decanted from the deep red crust, which, on recrystallisation from ether-light petroleum, yielded pure fucoxanthin, M.P. 166–167° (uncorr.). It is thus evident that the green "acid" colour is not due to any specific pigment such as fucoxanthophyll but must be mainly fucoxanthin contaminated with the above materials.

---

[1] When using alga gathered in the winter months we have found that the amount of this substance is so large as to render the isolation of any pigment exceptionally difficult.

Band C. The bright red band on elution and resolution by the methods just described furnished fucoxanthin and fucosterol.

Using the methods described the amounts of fucoxanthin and zeaxanthin were 1–1·5 g. and 2 g. respectively.

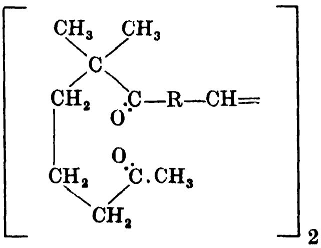
Fucoxanthin.

Although the analytical values clearly reveal the presence of six oxygen atoms, Zerewitinow determinations on the pure pigment indicate that only four of these exist as hydroxy-groups. The following determinations were kindly performed for us by Drs Roth and Möller of Heidelberg:

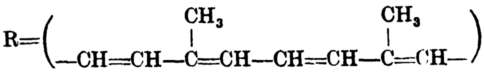
6·74 mg. fucoxanthin 0·93 ml. CH_4 (N.T.P.) : 3·9 active H.
6·478 mg. „ 0·92 ml. „ 4·0 „

Karrer *et al.* [1931] have stated that fucoxanthin was optically active ($[\alpha]_{Cd}+73\cdot5°$ in chloroform) but a re-investigation of our higher-melting pigments shows that it is inactive ($\alpha^{20}_{Cd} \pm 0\cdot02°$ in benzene) ($c=0\cdot062$; $l=1$). This finding presents a striking parallel with the results obtained by Kuhn and Grundmann [1934], who by purification processes raised the melting-point of zeaxanthin from 207° to 215° and likewise found that the reported optical activity ($[\alpha]_{Cd}-70°$) of this pigment was non-existent.

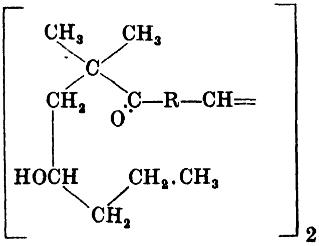
Repeated attempts have been made, without avail, to demonstrate the presence of carbonyl groups in the pigment, and thus, if such exist, they cannot



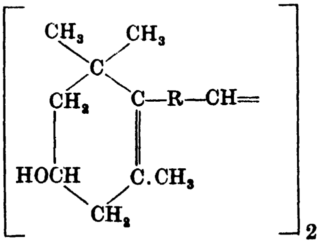
I



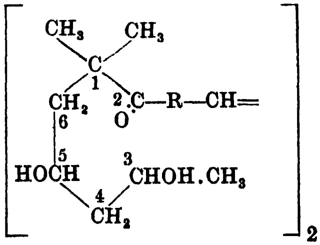
$$R=\left(-CH=CH-\overset{CH_3}{\overset{|}{C}}=CH-CH=CH-\overset{CH_3}{\overset{|}{C}}=CH-\right)$$



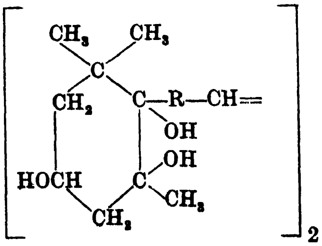
II



III



IV



V

occupy positions analogous to those in astacene [Karrer and Loewe, 1934] or rhodoxanthin [Kuhn and Brockmann, 1933]. This does not, however, preclude the possibilities of such groups actually being present, for β-carotenone (I) [Kuhn and Brockmann, 1932] only yields a dioxime, and capsorubin (II) which according to Zechmeister and v. Cholnoky [1935] is a dihydroxyketone fails altogether to form any ketonic derivatives.

The parallel with the inert oxygen atoms in fucoxanthin leads us tentatively to suggest the possibility that this pigment has the structure (IV) (being in effect a dihydroxy-capsorubin[1]). Such a constitution necessitates a formula $C_{40}H_{60}O_6$ in place of the hitherto assumed $C_{40}H_{56}O_6$, and that such an alteration is justified is seen from the following analyses.

	Carbon %	Hydrogen %
$C_{40}H_{56}O_6$	75·9	8·9
$C_{40}H_{60}O_6$	75·4	9·4
Found	75·3	9·3
Found [Karrer *et al.*, 1931]	75·5	9·1

Further, as has already been shown, the structure for fucoxanthin must be such as to accommodate a facile *post mortem* transformation into zeaxanthin (III). Whereas our suggested formula would permit of such a transformation it would be extremely difficult to account for this if fucoxanthin had hydroxy-groups in either positions $C_4 : C_4'$ or $C_6 : C_6'$.

Additional support of (IV) has been unexpectedly obtained by drastic perhydrogenation with an excess of platinum catalyst. The hydrogenation was carried out in acetic acid under an average pressure of 30 lbs./sq. in. The fully hydrogenated product (tetranitromethane test) crystallised from methyl alcohol-ethyl acetate in small plates, M.P. 63–64°, and was proved by analysis to have an oxygen content lower than that of the anticipated perhydrofucoxanthin. (Found: C, 82·3; H, 13·9 %. $C_{40}H_{78}O_2$ requires C,.81·4; H, 13·2 %.) Unfortunately, owing to lack of material we have so far been unable to confirm the above result, but our experiments will be continued as soon as suitable fresh *Fucus vesiculosus* becomes available.

Against formula (IV) Karrer *et al.* [1931] found that only 10 molecules of hydrogen were required to saturate fucoxanthin whereas 13 molecules would be required for a complete conversion into perhydrozeaxanthin. Further, as a product of energetic oxidation these authors only detected αα′-dimethylmalonic acid whereas αα′-dimethylsuccinic acid is also to be anticipated. We intend to reinvestigate these results on our chromatographically purified pigment in due course.

The fact that alcoholic alkali reacts with fucoxanthin to produce a substance much more susceptible to the action of acids was first observed by Kylin [1912] and confirmed by Willstätter and Page [1914]. We have now examined this effect in detail. Fucoxanthin (100 mg.) was allowed to stand for 24 hours with 5 % methyl alcoholic potash (25 ml.) in an atmosphere of nitrogen. The alkaline solution, after dilution, was extracted with ether. The washed and dried solution was evaporated to dryness under nitrogen and the residue dissolved in methyl alcohol. The resultant solution is extraordinarily sensitive to acids, rapidly developing a deep blue colour when exposed to the atmosphere, and this extreme lability has so far precluded attempts at recrystallisation. That the products formed (which for convenience we propose to name generically the *iso*fucoxanthins) are multiple is evidenced by chromatographic resolution from a benzene solution on alumina, when three distinct crimson bands are formed. It is possible to obtain a partial distinction between these components by the effect of $N/10$ acetic acid (acid of this strength being without action on fucoxanthin itself).

---

[1] In this connection the recent isolation by Lederer [1934] of capsorubin from the ascidian *Botryllus Schlosseri Pallas* is highly significant.

Band	Action of $N/10$ acetic acid	Absorption maxima in CS_2 $m\mu$	Estimated amount %
A	Slight browning	474, 448, 422	25
B	Intense royal blue	474, 448, 422	60
C	Blue colour slowly develops	475, 449, 420	15

The shift in absorption maxima implies that the number of conjugated double bonds has decreased, and bearing in mind the nature of the reaction it seems possible to us that fucoxanthin (IV) undergoes an aldol condensation, giving rise to (V).

SUMMARY.

Fucus vesiculosus has been exhaustively examined with regard to its lipochromes, and it has been found that whereas the dead material contains β-carotene and zeaxanthin the living plant contains β-carotene and fucoxanthin. These results explain the apparently contradictory statements of the earlier investigators.

No trace of the xanthophylls usually associated with the higher plants could be detected in the fresh alga, and thus zeaxanthin must be a *post mortem* product of fucoxanthin.

A chemical investigation of fucoxanthin shows that the formula of this pigment is probably $C_{40}H_{60}O_6$. The melting point has been raised to 166–168° (uncorr.); the pure pigment, contrary to earlier statements, is optically inactive.

We wish to thank Mr A. E. Gillam of this Department for carrying out spectroscopic determinations and Mr A. Lumley and Dr J. A. Lovern of the Torry Research Station, Aberdeen, for the algal materials. Our thanks are also due to the Department of Scientific and Industrial Research for a grant to one of us (R. F. P.).

CLXVII. THE ALGAE.

II. THE RELATIONSHIP BETWEEN CERTAIN ALGAL CONSTITUENTS.

BY ISIDOR MORRIS HEILBRON, EDRYD GWYLFA PARRY
AND RICHARD FRANCIS PHIPERS.

From the Chemical Department, University of Manchester.

(*Received April 6th, 1935.*)

IN a former publication [Heilbron *et al.*, 1934] covering a preliminary examination of the Phaeophyceae a description was given of the isolation of a new sterol, fucosterol, $C_{29}H_{48}O$. We have now extended our investigations to members of the Chlorophyceae and Rhodophyceae in order to ascertain whether this sterol is common to all species of algae and also to determine the character of the lipoid pigments. No mention of the presence of sterols in these plants is to be found in the literature and little is known of the carotenoid pigments. Willstätter and Page [1914] showed that the marine green alga *Ulva lactuca* contained only carotene and xanthophyll, and Kylin [1927] using qualitative capillary analytical methods for detection, but without actually isolating any pigments, stated that the lipochromes existent in the stated species were as shown in the following table:

	Carotene	Phyllorhodin	Xanthophyll	Phylloxanthin	Fucoxanthin
Higher plants	+	+	+	+	–
Chlorophyceae	+	+	+	+	–
Rhodophyceae	+	+	+	–	–
Phaeophyceae	+	–	+	+	+

The presumed pigments, phyllorhodin, phylloxanthin and even xanthophyll require re-identification in the light of our present knowledge of the plant lipochromes.

In our present study we have examined three freshwater Chlorophyceae, *viz.*: *Cladophora sauteri*, *Oedogonium* and *Nitella opaca*, and have taken *Rhodymenia palmata* as a typical member of the Rhodophyceae.

EXPERIMENTAL.

General procedure.

Cladophora sauteri (150 kg. wet weight) collected from Hickling Broad, Norfolk, was covered with methylated spirit (300 litres) and allowed to stand for 24 hours with intermittent agitation. The deep olive-green extract after concentration to one-third its volume was saponified at room temperature for 24 hours by the addition of 20 % aqueous KOH (2 litres). The whole was diluted with water, exhaustively extracted with ether, the ethereal solution washed with water and dried over sodium sulphate. In the case of *Rhodymenia palmata* (50 kg. wet weight) (collected from the north coast of Scotland), the plant was washed free from mucilages with 40 % acetone [see Heilbron and Phipers, 1935] and extracted with methylated spirit (50 litres), the alcoholic extract being saponified and the unsaponifiable material transferred to ether as described above.

The sterols were obtained from the non-saponifiable fractions by removing the solvent, dissolving the residues in the minimum quantity of boiling methyl alcohol and cooling to −75°.

The unsaponifiable fractions of *Nitella opaca* and *Oedogonium* were both obtained from the Torry Research Station, Aberdeen, the sterols being isolated by us by crystallisation from methyl alcohol as above.

STEROLS AND HENTRIACONTANE.

(*a*) Cladophora sauteri.

The pale yellow semi-crystalline mass was repeatedly crystallised from methyl alcohol giving (i) a small amount of a sparingly soluble waxy material which after several recrystallisations from ethyl acetate melted at 67–68° and was shown to be the paraffin hydrocarbon, hentriacontane, previously recognised as a constituent of the Phaeophyceae by Heilbron *et al.* [1934] and (ii) a more soluble portion, obviously sterolic, M.P. 80–120°. This latter was acetylated in the usual manner and a portion of the acetylated product (3 g.) in ether (30 ml.) treated with a 5 % solution of bromine in glacial acetic acid (40 ml.). After standing in the ice-chest for 24 hours the precipitated white powder, M.P. 130°, was directly debrominated by the method of Windaus and Hauth [1906], yielding after recrystallisation an acetate, M.P. 118–119°, which gave no depression in melting-point on admixture with an authentic sample of fucosteryl acetate. Hydrolysis of the acetate furnished fucosterol, M.P. 124°. After the removal of the fucosteryl acetate tetrabromide the mother-liquors were precipitated with methyl alcohol and the ether removed in a current of air. Crystallisation of the deposited material from methyl alcohol yielded a bromide, M.P. 120° (sitosteryl acetate dibromide melts at 120° [Anderson *et al.*, 1926]), debromination of which gave an acetate, M.P. 135°, $[\alpha]_D^{20°}$ −45·12° ($c=8$ in chloroform), which on hydrolysis furnished the free sterol, M.P. 136°. (Found: C, 84·1; H, 11·8 %. $C_{29}H_{50}O$ requires C, 84·05; H, 11·9 %.) The benzoate, prepared in pyridine with benzoyl chloride, melted at 143°.

The confused state of the sitosterol literature [compare Anderson *et al.*, 1926; Bonstedt, 1928] makes it difficult to assign a specific name to our sitosterol but from the appended table it would appear that it is a mixture of the *β*- and *γ*-forms.

	Sterol M.P.	Acetate M.P.	Benzoate M.P.	Rotation of acetate
α-Sitosterol	135–136°	127–128°	145°	−17·2°
β-Sitosterol	139–140	127–128	145	−39·0
γ-Sitosterol	142	143	—	−46·1
Algal sitosterol	136	135	143	−45·1

(*b*) Nitella opaca.

The crude mass was taken up in hot light petroleum, leaving a small amount (5 mg.) of an insoluble material, M.P. 280°, which was purified by crystallisation from aqueous pyridine, giving a micro-crystalline powder, M.P. 283–285°. (Found: C, 72·4; H, 10·3 %. $C_{35}H_{66}O_6$ requires C, 72·7; H, 10·5 %.) This compound responds to both the Liebermann-Burchard and the Salkowski tests, and this fact, taken in conjunction with the analytical data, indicates that it is a phytosterolin, a class of compound originally discovered by Power and Salway [1913] and more recently examined by Heyl and Larsen [1934].

The light petroleum solution was evaporated and the residue crystallised from methyl alcohol, giving a small amount of a sparingly soluble low-melting residue which on recrystallisation from ethyl acetate yielded hentriacontane,

M.P. 67–68°. The crude sterols obtained on concentration of the methyl alcoholic mother-liquors were separated by bromination, and fucosteryl acetate tetrabromide, M.P. 131–133°, and sitosteryl acetate dibromide, M.P. 120°, were thus obtained.

(c) Oedogonium.

Similar treatment of the crude material yielded a small amount (2 mg.) of the same phytosterolin, M.P. 283–285°, as obtained above; the sterol fraction on crystallisation from methyl alcohol yielded sitosterol, M.P. 135°; no trace of fucosterol could be found but hentriacontane was again detected.

(d) Rhodymenia palmata.

The crude sterols, M.P. 114–115°, on repeated crystallisation from methyl alcohol, furnished hentriacontane and fucosterol, M.P. 122–123°. Bromination of a portion of the crude sterol acetate gave only fucosteryl acetate tetrabromide, M.P. 130–132°.

CAROTENOID PIGMENTS.

The deep crimson methyl alcoholic solutions obtained after removal of the sterols in the manner described were subjected to the Kraus partition with 90 % methyl alcohol and light petroleum.

Cladophora sauteri.

(a) *The light petroleum phase.* Adsorption on activated alumina and development of the chromatogram with light petroleum gave three distinct orange-red bands. The uppermost band, on elution with methyl alcohol and subsequent crystallisation from the same solvent yielded a deep red solid, M.P. 175–177° (uncorr.), having absorption maxima in carbon disulphide at 505 and 473 $m\mu$ (see later).

Attempts to crystallise the concentrated methyl alcoholic eluate of the second zone were abortive owing to the presence of terpenes and sterols. We have now found that lipochromes can be completely freed from terpenes by adsorption on fuller's earth. Whereas the pigments are strongly adsorbed, prolonged washing of the developed chromatogram with benzene effectively removes all terpene. The eluted pigment solution, now only contaminated with sterol, was further purified by adsorption on calcium carbonate; in this case the pigment passed down the column, the sterol being retained in the upper section. The pigment obtained by concentration of the final methyl alcoholic eluate yielded, on crystallisation from the same solvent, lutein as a fine red powder, M.P. 187° (uncorr.), having absorption maxima in carbon disulphide at 512 and 479 $m\mu$.

The third band passed rapidly through the column and was collected in the filtrate. Removal of solvent gave a deep red odoriferous oil from which terpenes were removed by the process described above. Elution of the pigment and repeated crystallisation from methyl alcohol-benzene furnished β-carotene in small glistening coppery plates, M.P. 178–179° (uncorr.), having absorption maxima in carbon disulphide at 518, 483 and 450 $m\mu$.

(b) *The methyl alcoholic phase.* The solvent was removed and the residue dissolved in a mixture of benzene-light petroleum (1:3) and adsorbed on activated alumina, giving a very complex chromatogram consisting of four orange-red zones. Since the eluates of the zones were spectroscopically identical (maxima in carbon disulphide at 505, 474 and 446 $m\mu$) the complexity of the chromatogram is definitely due to sterol and terpene contaminants. Concentration of the eluates yielded red solids, M.P. 175–178° (uncorr.), which were combined with the pigment showing similar absorption maxima from the light petroleum chromatogram. Kuhn and Lederer [1932] have obtained a pigment showing the same absorption maxima from *Leontodon autumnalis*; by repeated chromatographic treatment on calcium carbonate these authors finally resolved it into taraxanthin and lutein. Adopting a similar procedure the above pigment, M.P. 175–178°, was resolved from benzene-light petroleum (1:3) by adsorption first on calcium carbonate and finally on activated alumina, taraxanthin and a further quantity of lutein being thus obtained. Crystallisation of the taraxanthin from methyl alcohol containing a trace of ether yielded glistening deep orange-red needles, M.P. 178–179° (uncorr.), having absorption maxima in carbon disulphide at 502, 472 and 442 mμ. Analytical values for the mixed pigment (C, 83·1; H, 9·8 %) indicate that the ratio of lutein to taraxanthin is approximately 7:3.

Nitella opaca.

(*a*) *Light petroleum phase.* The solution, after adsorption and development on calcium carbonate, showed two distinct red zones, the lower and more intense of which on elution and crystallisation from benzene-methyl alcohol furnished β-carotene, whilst the upper and smaller band was found to be spectroscopically identical with lutein.

(*b*) *Methyl alcoholic phase.* The deep red residue obtained on removal of solvent was dissolved in a mixture of light petroleum-benzene (2:1) and adsorbed on activated alumina. Development of the chromatogram gave two broad orange-red bands, the lower of which on elution and crystallisation from benzene-methyl alcohol furnished lutein in glistening deep red plates, M.P. 189–190° (uncorr.) having absorption maxima in carbon disulphide at 511, 479 and 445 mμ). The upper zone contained only a small amount of pigment, M.P. 175–176°, spectroscopically identical with taraxanthin.

Oedogonium.

(*a*) *Light petroleum phase.* The solution after adsorption on calcium carbonate gave a chromatogram showing three distinct bands, the upper of which, as shown by Kraus partition, consisted of traces of xanthophylls which had escaped partition. The second and main band furnished β-carotene, while the third, which was of a bright yellow colour, was spectroscopically characterised as α-carotene (absorption maxima in carbon disulphide at 510 and 478 mμ).

(*b*) *Methyl alcoholic phase.* The pigments were adsorbed on activated alumina as previously described, when two distinct bands were obtained, the upper of which yielded taraxanthin; the lower band contained a pigment, M.P. 175–177°, which after re-adsorption on calcium carbonate was resolved into lutein and taraxanthin.

Rhodymenia palmata.

(*a*) *Light petroleum phase.* The lipochromes, which were resolved in the usual manner, consisted of β-carotene and a trace of lutein.

(*b*) *Methyl alcoholic phase.* Chromatographic analysis yielded results identical with those obtained from the corresponding phase derived from *Cladophora sauteri*, the pigments thus being taraxanthin and lutein.

DISCUSSION.

A review of the relationship between algal species and their lipoid contents reveals many striking features as shown in Table I. It will be observed that each group of algae possesses characteristic lipochromes, the Chlorophyceae and

Table I.

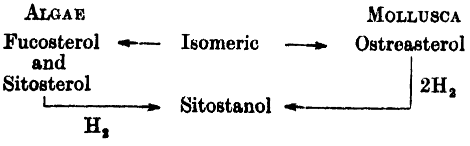
* Unpublished investigations.

Rhodophyceae containing taraxanthin and lutein in contrast to the Phaeophyceae which are distinguished by the presence of fucoxanthin [Heilbron and Phipers, 1935]. A gradual transition from the constituents of the normal land plants is observed through the species, the Phaeophyceae bearing little resemblance to the former.

According to Fritsch [1935] the botanical properties indicate that the Oedogoniales "are a sharply circumscribed group, showing but few points of affinity with the other Chlorophyceae". Our investigations provide strong proof of this statement, and indeed as far as the chemical composition of the lipoids is concerned, these plants can be considered as land plants. The normal Chlorophyceae contain both the phytosterol, sitosterol and the algal sterol, fucosterol. From the Rhodophyceae, sitosterol is absent, only fucosterol being observed; although this group does not contain the land plants' sterol, it still retains the typical phytoxanthophylls, *viz.* taraxanthin and lutein. In the Phaeophyceae even this last relationship with the land plants is severed, the characteristic pigment fucoxanthin being substituted.

Turning now to the results reported by Kylin [1927] and comparing them with our findings (see Table I) the identity of phyllorhodin with taraxanthin and of xanthophyll with lutein is evident. We are extremely doubtful as to the existence of a lipochrome, phylloxanthin, which Kylin states gives a green colour with 25 % hydrochloric acid, for we have repeatedly observed such a phenomenon with crude algal pigment solutions. Careful resolution, however, invariably yielded pigments giving no such colour on treatment with acid (see also preceding paper).

Reference has also been made [Heilbron *et al.*, 1934] to the interesting relationship existing between fucosterol and the isomeric sterol of the molluscs, ostreasterol (a dehydrositosterol) [Bergmann, 1934]. The evidence now brought to light that many species of algae also contain sitosterol further emphasises the very close biological relationship between these three sterols:



SUMMARY.

The unsaponifiable material from *Cladophora sauteri*, *Nitella opaca*, *Oedogonium* and *Rhodymenia palmata* has been examined. A clear-cut change in the character of the lipoids is observed when passing from one species to another.

(1) Whereas *Oedogonium* resembles the land plants in containing only sitosterol, *Cladophora sauteri* and *Nitella opaca* produce both the former sterol and fucosterol, the latter alone being present in the marine algae *Rhodymenia palmata* and *Fucus vesiculosus*.

(2) All algae contain small amounts of the paraffin hydrocarbon hentriacontane.

(3) A new phytosterolin, M.P. 283–285°, has been isolated from *Nitella opaca* and *Oedogonium*.

(4) The lipochrome pigments lutein, taraxanthin and β-carotene were isolated from all species and α-carotene was observed in *Oedogonium*. This presents a marked contrast to the Phaeophyceae (see preceding paper).

The evidence adduced shows that the Oedogoniales show a closer chemical relationship to the land plants than to the typical algae.

Our thanks are due to Mr A. Lumley and Dr J. A. Lovern, of the Torry Research Station, Aberdeen, for the supply of the algae, and to Mr A. E. Gillam, of this Department, for spectroscopic data. We also gratefully acknowledge a grant in aid of this work from the Department of Scientific and Industrial Research.

CLXVIII. THE ALGAE.

III. THE ISOLATION OF LACTOFLAVIN.

By ISIDOR MORRIS HEILBRON, EDRYD GWYLFA PARRY
and RICHARD FRANCIS PHIPERS.

From the Chemical Department, University of Manchester.

(*Received April 6th, 1935.*)

Whilst lactoflavin is widely distributed in both the animal [Kuhn *et al.*, 1934] and vegetable kingdoms [György *et al.*, 1934], it is still uncertain whether this flavin is the sole member of the group or whether there are several such compounds, *i.e.* hepatoflavin from horse liver [Stern, 1933], hepaflavin from malt [Karrer *et al.*, 1934], uroflavin from urine [Koschara, 1934] and renoflavin from ox kidney [Guha and Biswas, 1934].

In order to investigate the possible presence of lyochromes in the algae and to ascertain whether the flavin, if present, is identical with lactoflavin, we have examined the marine brown alga *Fucus vesiculosus* and the fresh water green alga *Cladophora sauteri* in detail.

During our investigations a communication appeared by Euler and Adler [1934] in which they claim to have detected the presence of flavins in several marine Phaeophyceae. As, however, these authors relied solely upon spectroscopic evidence, the question as to the identity still remained open.

EXPERIMENTAL.

Fucus vesiculosus.

The pale brown aqueous acetone washings from the fresh alga (50 kg. wet weight) [see Heilbron and Phipers, 1935] were very glutinous owing to large amounts of mucilage, thus rendering the usual procedure for the isolation of flavins by adsorption on fuller's earth impracticable. To overcome this difficulty we employed the methods described by Warburg and Christian [1933] whereby the photo-derivative lumilactoflavin is obtained. A portion of the extract (10 l.) was freed from acetone and made $N/2$ with respect to alkali by the addition of aqueous sodium hydroxide (380 ml. of $13N$). After irradiation, the lumiflavin was extracted from the acidified aqueous solution with chloroform. The bright yellow pigment, after purification by conversion into the sodium salt and finally by crystallisation from water, melted at 310° decomp. (uncorr.) and exhibited an absorption maximum in chloroform at $447 m\mu$. Warburg and Christian give for lumilactoflavin M.P. 320° (corr.) and an absorption maximum in chloroform at 445–$455 m\mu$. Kuhn, Rudy and Wagner-Jauregg [1933] give M.P. 328° (corr.) and report an absorption maximum in chloroform at $445 m\mu$.

Cladophora sauteri.

The methods described by Kuhn and Kaltschmitt [1935] for extraction of lactoflavin from hay were employed. The alga (50 kg. wet weight) was covered with hot dilute hydrochloric acid (50 l. at p_H 1·2) and allowed to stand with intermittent agitation for 12 hours. The flavin was removed from this aqueous extract by adsorption on fuller's earth and further purified by adsorption on lead sulphide and frankonite KL. The pigment was acetylated and chromatographically separated from impurities on a column of alumina. After elution, crystallisation of the pigment from aqueous methyl alcohol yielded red-brown crystals decomposing at 230° (uncorr.) with slight sintering at 180° (absorption maxima in water at 445 and $360 m\mu$). Kuhn and Wagner-Jauregg [1933] give for tetra-acetyl-lactoflavin M.P. 235° decomp. (corr.) and absorption maxima in water at 445 and $374–376 m\mu$.

SUMMARY.

Marine and fresh water algae as typified by *Fucus vesiculosus* and *Cladophora sauteri* both contain flavins. Lactoflavin has been obtained from the latter alga by direct adsorption from the aqueous extract, a process inapplicable to the former from which the photo-derivative lumilactoflavin was isolated.

We wish to thank Mr A. E. Gillam of this Department for the spectroscopic data, and the Department of Scientific and Industrial Research for a grant to further this research.

CLXIX. THE LIPOCHROMES OF SEA ANEMONES.

I. CAROTENOID PIGMENTS OF *ACTINIA EQUINA*, *ANEMONIA SULCATA*, *ACTINOLOBA DIANTHUS* AND *TEALIA FELINA*.

By ISIDOR MORRIS HEILBRON, HAROLD JACKSON
and RICHARD NORMAN JONES.

From the Department of Chemistry, University of Manchester.

(*Received April 6th, 1935.*)

Although during the past few years the structure of the plant lipochromes has been more or less completely elucidated, comparatively little is as yet known concerning the polyene pigments of marine animals. Indeed, up to the present, only one such pigment, astacene, which appears to be widely distributed in marine fauna, has been isolated and its structure determined [Kuhn and Lederer, 1933; Kuhn, Lederer and Deutsch, 1933; Karrer and Benz, 1934; Karrer and Loewe, 1934; Karrer *et al.*, 1935].

Euler *et al.* [1933] have described the occurrence of a pigment, salmenic acid, in the salmon whilst Euler and Hellström [1934] have isolated a further pigment, asterinic acid, from the starfish (*Asterias rubens*). Lönnberg [1931, 1, 2; 1932; 1933] has recorded spectroscopic data for the pigment extracts of numerous species of marine invertebrates. Various other pigments have been isolated by Lederer [1933; 1934, 1, 2] from different species of ascidia, mollusca and crustacea, the more important being pectenoxanthin, m.p. 182°, from the mollusc, *Pectin maximus*; glycymérine, m.p. 148–153°, from the scollop, *Pectunculus glycymeris*, and cynthiaxanthin, m.p. 188–190°, from the ascidian, *Halocynthia papillosa*. None of the above pigments has been examined in any great detail owing to the extreme difficulty of obtaining them in adequate quantity.

In the case of the pigments of various species of sea anemone, only one member has previously received attention. From *Actinia equina* Fabre and Lederer [1934] isolated a pigment, actinioerythrin, m.p. 85°, which they showed was a carotenoid ester. Prior to the appearance of these authors' paper we were ourselves engaged upon an examination of this pigment and, working on a larger scale, have obtained from it a hydrolysis product, m.p. 191–192°, which is, so far as we know, unique among carotenoids both as regards colour and absorption spectrum. Whereas actinioerythrin has absorption maxima in carbon disulphide at 574, 538 and 497$m\mu$ the new pigment, for which we propose the name "*violerythrin*", shows maxima in the same solvent at 625, 576 and 540$m\mu$.

In addition to the above, three other species, *Actinoloba dianthus*, *Tealia felina* and *Anemonia sulcata*, have so far been examined. Like *Actinia equina*, both *Actinoloba dianthus* and *Tealia felina* contain, apart from carotene, only esterified carotenoids. The red pigment of *Actinoloba dianthus* is readily hydrolysed, yielding an acid, m.p. 195–196°, both acid and ester showing a single absorption maximum in carbon disulphide near 495$m\mu$. From *Tealia felina* two pigments have been isolated; of these one is possibly identical with actinioerythrin whilst the second on hydrolysis yields an acid, m.p. 205–208°, with a single absorption maximum near 500 mμ in carbon disulphide. *Anemonia sulcata* differs from the other three species in containing no esterified pigments. The main lipochrome, *sulcatoxanthin*, for which the formula $C_{40}H_{52}O_8$ is suggested by analytical data, is characterised by three absorption maxima in carbon disulphide at 516, 482 and 450 mμ.

The present communication deals with the method of isolation of the pigments and certain preliminary observations as to their nature.

EXPERIMENTAL.

1. Actinia equina.

Isolation of actinioerythrin. The anemones were minced and repeatedly extracted with a mixture of ether and acetone (1:1) at room temperature. The combined extracts were concentrated to small bulk and diluted with water and the pigment was transferred to light petroleum. Phosphatides and sterols were removed by precipitation from the concentrated light petroleum solution with acetone, followed by further concentration and freezing to − 10°. The pigment was again transferred to light petroleum and adsorbed on alumina (Merck standardised Brockmann diluted with an equal volume of inactive alumina); the chromatogram was developed with benzene; the actinioerythrin formed an intense violet-black zone on the upper half of the column, whilst a yellow pigment, spectroscopically identified as carotene, washed rapidly through. The ester was eluted with light petroleum-methyl alcohol and readsorbed from light petroleum on calcium carbonate, whereby remaining traces of sterol, terpene material and a further yellow pigment (absorption maxima at 502, 472 and 442 mμ in carbon disulphide and probably a taraxanthin ester) were removed. After elution and removal of solvent, the crude actinioerythrin was crystallised from absolute alcohol giving microscopic red-black needles, M.P. 83° (uncorr.) (Fabre and Lederer [1934] give M.P. 85°). In agreement with these authors we find that whereas in carbon disulphide the pigment is characterised by three absorption maxima at 574, 538 and 497 mμ, in alcohol only one band with head at 511 mμ is present. On partition between light petroleum and 90 % methyl alcohol actinioerythrin is wholly epiphasic (the yield of crystalline pigment from 500 anemones is approximately 30 mg.).

Isolation of violerythrin. Fabre and Lederer [1934], working with a minute quantity of the ester, noted its ready hydrolysis but state that the resultant "acid" decomposed on liberation. We have found, however, that under carefully controlled conditions of saponification a crystalline product can be isolated. As a result of numerous experiments the following method has been found the most satisfactory. A solution of actinioerythrin (5 mg.) in light petroleum was saponified by shaking at room temperature with methyl alcoholic sodium hydroxide (20 ml. of 2·5 %) until the pigment was completely transferred to the alcohol phase (approximately 1 hour). The latter was diluted with water and rendered faintly acid with 5 % acetic acid, the end-point being readily observed by a colour change from cherry-red to orange. The pigment was extracted with ether and the washed solution dried over anhydrous sodium sulphate. After removal of solvent the crude solid was recrystallised from aqueous pyridine, when violerythrin (1 mg.) separated in deep violet microcrystals, M.P. 191–192° (absorption maxima at 625, 576 and 540 mμ in carbon disulphide). The pigment exhibits a remarkable range of colours in various solvents; in benzene it is deep blue, in pyridine and acetone bright blue, in ether and alcohol violet-red and in carbon disulphide purple.

From the above it would be anticipated that violerythrin is itself acidic in nature but this does not appear to be the case since dilute alkali is without action upon it. Probably the initially formed "acid" rearranges from an enolic to a stable ketonic form; more detailed study of the hydrolytic process is being carried out.

2. Anemonia sulcata.

500 animals were finely minced and extracted with ether-acetone (1:1). Whereas the initial extracts were of a deep reddish yellow colour, the later ones were typically chlorophyll-like in character. The combined extracts were concentrated, diluted with water and extracted with light petroleum and the resulting solution was partitioned with 65 % methyl alcohol. The residual petroleum phase was found to contain, in addition to carotene and chlorophyll, a small quantity of a xanthophyll pigment (absorption maxima at 478 and 450$m\mu$ in carbon disulphide) which passed readily into 90 % methyl alcohol.

The sulcatoxanthin contained in the 65 % methyl alcohol was transferred to benzene and adsorbed on activated alumina. The chromatogram was developed by washing with benzene-ether (4:1), the pigment being held as a bright red zone near the head of the column. After elution and removal of solvent, the residue was dissolved in carbon disulphide and readsorbed on calcium carbonate. On addition of light petroleum to the concentrated ether eluate the sulcatoxanthin separated as a flocculent deep scarlet precipitate (50 mg.).

Properties of sulcatoxanthin. The pigment is insoluble in light petroleum, sparingly soluble in carbon disulphide and readily soluble in benzene and alcohol. It possesses no sharp melting-point but suddenly shrinks at 110°, softens at 125° and is completely melted at 130°. In carbon disulphide it shows three absorption bands with maxima at about 516, 482 and (450)$m\mu$. It is strongly adsorbed on sugar from carbon disulphide as a uniform rose-coloured zone (further evidence of its homogeneity) and this, together with its ready partition into 65 % methyl alcohol, is clearly indicative of a high state of oxidation. Treatment with alkali, even under mild conditions, causes complete destruction of the pigment, whilst with concentrated sulphuric acid a blue colour is produced. (Found: C, 72·4, 72·4; H, 8·1, 7·9 %. $C_{40}H_{52}O_8$ requires C, 72·7; H, 7·9 %.)

Chlorophyll-a from Anemonia sulcata. The presence of a chlorophyll-like substance in this species was first observed by MacMunn [1885] and confirmed by Elmhirst and Sharpe [1920], who attributed its occurrence to the presence of symbiotic algae in the tentacles. We have identified this pigment as chlorophyll-a in the following manner. The tentacles were removed from a dozen freshly killed animals and the total pigments transferred to light petroleum (B.P. 60–80°). The sulcatoxanthin was removed with 90 % methyl alcohol and the residual emerald-green solution examined spectroscopically and found to be identical with pure chlorophyll-a examined in the same solvent (absorption maxima at 657, 612, 571, 532, 504, 494, general abs. from 465$m\mu$).

3. Actinoloba dianthus.

The pigment from 50 anemones was obtained in light petroleum solution in the usual manner. Partition with 90 % methyl alcohol indicated the presence of epiphasic carotenoids only. By adsorption of the light petroleum solution on calcium hydroxide one pigment was retained as a reddish brown band whilst a second passed through the column (absorption maxima at 501 and 471$m\mu$ in carbon disulphide). The adsorbed pigment was transferred to light petroleum and shaken with calcium carbonate by which it was readily held. From this a deep red, low-melting solid was obtained which could not be crystallised. On saponification with alcoholic sodium hydroxide (10 ml. of 5 %) at room temperature the ester was rapidly hydrolysed, giving on dilution an insoluble red sodium salt. The free acid crystallises from aqueous pyridine in deep violet-red prisms, M.P. 195–196° (2 mg.), showing a single absorption maximum in carbon disulphide at 495$m\mu$.

4. Tealia felina.

The degree of pigmentation of this species of anemone varies considerably but on the whole is small. Two varieties were examined, a small shore form and a larger deep water animal. The pigments were obtained in light petroleum and a partition experiment with 90 % methyl alcohol showed the absence of hypophasic carotenoids. The chromatogram, developed with benzene on activated alumina, exhibited a violet-red zone, whilst a yellow pigment (carotene) washed through the column. Re-adsorption on calcium carbonate furnished three zones, coloured violet, red and yellow respectively, the last being present in only minute amount. The violet zone yielded, after crystallisation from absolute alcohol, a violet-black wax, M.P. 65–73°, with absorption maxima in carbon disulphide at 569, 530 and 497$m\mu$. This pigment shows a close resemblance to actinioerythrin, but definite identification can only be established when larger quantities are available.

From the red zone an orange-red low-melting ester was obtained (absorption maximum at 500$m\mu$ in carbon disulphide), hydrolysing to give on dilution an insoluble red sodium salt. The free pigment, obtained in the usual manner, separated from aqueous pyridine in black feathery needles, M.P. 205–208° (1 mg.), having the same absorption spectrum as the parent ester.

SUMMARY.

1. A preliminary investigation into the carotenoid pigments of four species of sea anemone has been made.

2. Actinioerythrin (M.P. 85°), the principal pigment of *Actinia equina*, has been isolated and hydrolysed to a non-acidic pigment, *violerythrin*, M.P. 191–192°.

3. The pigment of *Anemonia sulcata* consists mainly of a new lipochrome, *sulcatoxanthin*, probably $C_{40}H_{52}O_8$. The presence of chlorophyll-a in the tentacles has been demonstrated.

4. From the species *Actinoloba dianthus* a red acidic pigment, M.P. 195–197°, has been isolated.

5. Two lipochrome esters, one possibly identical with actinioerythrin, have been isolated from *Tealia felina*.

6. Spectroscopic data concerning the above and other polyenes present in these species have been obtained.

We desire to express our thanks to both the Department of Scientific and Industrial Research and to Messrs Tootal Broadhurst Lee Co., Ltd., for maintenance grants to two of us (H. J. and R. N. J. respectively), to Mr A. E. Gillam, who carried out the spectrographic determinations and to Dr J. A. Lovern of the Torry Research Station, Aberdeen, for supplies of material.

CLXX. THE ASSIMILATION OF INORGANIC NITROGENOUS SALTS, INCLUDING SODIUM NITRITE, BY THE GRASS PLANT.

BY WILLIAM GEORGE ELFORD EGGLETON.

From the Imperial Chemical Industries, Agricultural Research Station, Jealotts Hill, Berks.

(*Received April 16th, 1935.*)

THE primary object of this investigation was to obtain information regarding the effect of applying sodium nitrite to grassland and to determine whether the nitrite accumulated in sufficient quantity in the herbage to cause metabolic disturbance. For comparative purposes, however, three other treatments were included: ammonium sulphate, sodium nitrate and potassium sulphate. By sampling and analysing the herbage at intervals after the application of the salts to the soil, it was hoped to follow to some extent the course of the elaboration of protein-N from the various forms of inorganic nitrogen assimilated by the plant. For this purpose the amide-N, pepsin-HCl-soluble N, true protein-N and total-N were determined as well as ammonia-N, nitrate-N and nitrite-N. It had been hoped to obtain a measure of the total amount of dry matter at each sampling, so that the nitrogen partition could be considered in terms of absolute weight per unit area, but unfortunately other considerations prevented this being done on a sufficiently accurate basis. Consequently the amounts of nitrogen present in various forms in the herbage are of necessity expressed as parts per 100 of dry matter, and this must be borne in mind when making comparisons. The course of the nitrogen transformations in the soil was followed to some extent by analyses of samples of soil taken from the various plots at time of grass sampling, the ammonia-N, nitrate-N and nitrite-N being determined in the soil extract.

EXPERIMENTAL.

The experimental plot, a five by five latin square, was situated in Drownboy Field, at this Station. The various salts were applied in solution from a small watering can fitted with a fine rose, in amounts corresponding to an application of ammonium sulphate at the rate of 3 cwt. per acre; the potash was applied at the rate of 2 cwt. per acre. The foliage was well watered afterwards to ensure that no salts adhered to the grass, the control plots receiving the same total quantity of water, 0·25 in., as the treated plots.

The soil was sampled to a depth of 3 inches with a soil sampling tube of 1 inch diameter, and the grass by plucking the required quantity from random positions over the five replicates.

So far as the analyses of the soil nitrogen are concerned, the methods used were substantially the same as those already described by the author [1934].

The "true protein"-N in the dried and finely ground grass was determined by Stützer's method, which involves precipitation of the proteins by a suspension of cupric hydroxide in glycerol and water and subsequent determination of the nitrogen content of the washed precipitate.

The amide-N was determined by the difference in ammonia-N content of a known weight of dried and ground grass before and after boiling with HCl (5 %) to convert amides into ammonium chloride.

The pepsin-HCl-soluble N, which may be taken as a good comparative measure of the digestibility of the herbage, was determined by comparing the total nitrogen content of the original dried and ground grass with that of the residue left after digestion with pepsin-HCl. Since the figure obtained includes inorganic nitrogen if present, the necessary corrections were subsequently applied.

The ammonia-N content of the dried and ground grass was determined by distillation with magnesia.

Estimation of nitrite-N in grass. Immediately after sampling, 10 g. of the wet grass, the dry matter content of which was subsequently determined, were macerated in a stone mortar with 50 g. of sand previously extracted with HCl and ignited. The grass was effectively disintegrated only when the very minimum of water was added. After maceration, the remainder of 100 ml. water was added, and the whole filtered on a Büchner funnel. An aliquot (50 ml.) of this filtrate was immediately clarified by the addition, in order, of 2 ml. of *N* $CuSO_4$, 0·5 g. $MgCO_3$ and 0·5–1·0 g. $Ca(OH)_2$. After filtration, the nitrite was determined colorimetrically on an aliquot by the Griess-Ilosva method, the whole operation not taking more than half an hour.

Estimation of nitrate-N in grass (*due to Mr F. L. Ashton*[1]). The method consisted of boiling the finely ground grass with water and determining the nitrate content of an aliquot part of the clarified extract by the phenoldisulphonic acid method. Since the accuracy of the method depends entirely on the efficiency of the clarification, both as regards removal of organic material and the non-removal of nitrate, a brief description of the method used to clarify the water extract is necessary. The bulk of the organic matter present was precipitated by the addition of a solution of basic lead acetate, and, after filtering and washing, the cold filtrate was shaken with a small quantity of "norite". The excess lead and any chlorides present were then precipitated by the addition of $(NH_4)_2SO_4$ and Ag_2SO_4 and the combined precipitates, including the norite, filtered off. The nitrate determination was then conducted colorimetrically on an aliquot of the filtrate after taking to dryness. In control experiments satisfactory recoveries of known amounts of added nitrate were obtained.

Nitrogen partition in the soil.

In Table I are set out the amounts of ammonia-N, nitrate-N and nitrite-N found in the soil on the various sampling dates.

The nitrogen was added at the rate of 69·5 lb. per acre which, since the weight of 1 acre of dry soil from Drownboy Field to a depth of 3 in. is $0 \cdot 9 \times 10^6$ lb., corresponds to 77 p.p.m. of dry soil. It will be seen that the figures for ammonium sulphate, sodium nitrate and sodium nitrite, given in Table I, fall short of this amount by 42, 49 and 54 p.p.m. respectively. Whilst, as is shown by Table III, some of this deficiency is undoubtedly due to assimilation by the grass during the interval between applying the salts and sampling the soil, by far the greater part must have arisen from inefficient separation of soil and root by the sieving process, particularly as regards the surface layer, where the added salts were mainly located. It is consistent with this that the amounts recovered were materially higher on the following day after a night's rain, when presumably the salts were washed down into layers where the smaller amount of organic débris

---

[1] A detailed account of this method, including several modifications subsequently introduced, is now in the press.

permitted a more efficient separation of the soil. The deficiencies on this occasion were less; 34, 40 and 50 p.p.m. respectively. It is apparent from this that if the assimilation of nitrogenous salts were to be followed in any detail from the soil side, adequate provision would have to be made to ensure a much more effective separation of soil from root than that provided by the sieving method now employed. It might even be advisable to consider soil and root together by drying the soil sample *in vacuo*, sieving and re-incorporating the organic matter thus separated after grinding in a suitable mill.

However, in spite of the complication mentioned above, several points are abundantly clear. Firstly, only a very small fraction of the nitrogen originally added remained in the soil in the form of ammonia, nitrate or nitrite 8 days after addition. So far as can be judged from the above figures, ammonium sulphate has disappeared least quickly and sodium nitrite most quickly, with sodium nitrate intermediate. So much is in accord with accepted opinion. The disappearance of the nitrite, however, does not appear to have been accompanied by an increase in nitrate-N in the soil. Moreover, there was no corresponding accumulation of nitrite-N or nitrate-N in the herbage. For example, on the 24th day there were still 580 p.p.m. of nitrate-N in the grass which had been treated with sodium nitrate, but the grass which had been treated with sodium nitrite had by this time no more nitrate-N than it had at the beginning of the experiment, *viz.* 10 p.p.m. This rather gives the impression that the nitrite has been dealt with either in the soil or in the plant much more quickly than the nitrate and, moreover, in a way which presumably has not entailed its conversion into nitrate, in which case it should have been detected in this form either in the grass or in the soil. This might be explained by assuming an enhanced rate of synthesis of protein, but the fact that the amount of pepsin-HCl-soluble N, which fraction includes amino-acids, was lowered in the nitrite-treated grass (see Tables V and VII), lends colour to the view that a proportion of the nitrite had reacted with amino-compounds present in the grass with the resulting formation of free nitrogen.

Another feature of Table I is that the amount of ammonia-N in the soil was increased following the application not only of ammonium sulphate (which is, of course, expected), but also of sodium nitrate and, to a greater extent, of sodium nitrite. This increase in ammonia-N, which has been observed in the case of sodium nitrate on other occasions, indicates that some of the added nitrate and nitrite had undergone a process of reduction.

Finally, it may be noted that a slight increase in nitrite-N took place immediately following the application of sodium nitrate, although the added sodium nitrate was free from nitrite.

Nitrogen partition in the herbage.

All the nitrogenous salts had the effect of increasing the proportion of total nitrogen in the dry matter of the herbage, the greatest increase occurring with

sodium nitrate and the least with sodium nitrite. Potassium sulphate also increased the total nitrogen content. The results are shown in Table II as increases relative to the control.

Ammonium sulphate, sodium nitrate, potassium sulphate and sodium nitrite all increased the proportion of ammonia-N in the dry matter, in order of descending magnitude, the maximum increase occurring shortly after application to the soil (see Table III). The increase in ammonia-N content of the herbage following application of potassium sulphate may be explained in terms of base exchange, the potash liberating ammonia from the soil colloid complex.

The proportion of nitrate-N was very markedly increased soon after addition of the sodium nitrate. Ammonium sulphate and sodium nitrite in the order mentioned also increased the nitrate content, but the increases were not immediately apparent. No change in nitrate content followed the application of the potassium sulphate.

The proportion of nitrite-N showed immediate increases in all cases where a nitrogenous salt was added, the increase being greatest for sodium nitrite and least for ammonium sulphate. Potash was without effect. Only faint traces of nitrite-N were detected in any treatment 24 hours after application, and none was detected subsequently. So far as the eye could judge, the grass suffered no harm from the application of sodium nitrite at the rate of 3 cwt. per acre.

(Mean value for control on 1st day = 0·109 % ± 0·013.)

The proportion of amide-N was increased after an initial drop, due to the application of other forms of nitrogen and reached a maximum about 8 days after application. At the end of the experiment the proportion of amide-N on all the treated plots was substantially lower than on the control.

Table V. *Increases in % pepsin-HCl-soluble N (less inorganic N) in the dry matter of spring grass, following treatment with various fertilisers.*

(Mean value for control on 1st day = 2·81 % ± 0·08.)

The proportion of pepsin-HCl-soluble N was also increased, sodium nitrate showing the greatest and most permanent increase, followed in order by ammonium sulphate and potassium sulphate. The pepsin-HCl-soluble N was only slightly increased by the sodium nitrite treatment and was actually slightly less than that of the control at the end of the experiment.

A rise in the proportion of "true protein"-N occurred in all cases on the day after application; this increase was maintained with ammonium sulphate and sodium nitrate until the end of the experiment, but with sodium nitrite the proportion was substantially the same as in the control by the 9th day and was

(Mean value for control on 1st day = 3·23 % ±0·08.)

markedly lower on the 24th day. Potassium sulphate increased the proportion of "true protein"-N on the day after application, but the increase did not persist.

It is of interest to consider the sum of the following forms of nitrogen, which according to the methods of analysis employed are mutually exclusive, in relation to the total amount of nitrogen found to be present by separate Kjeldahl determination.

Table VII. *Amount of nitrogen in spring grass in the form of "true protein", amide, NH_3, NO_3 and NO_2, expressed as °/₀ of the total N present.*

K_2SO_4	92·9	88·4	91·1	88·6	104·7

At the commencement of the experiment all four samples agree in showing that between 7 and 12 % of the nitrogen known to be present remains undetermined. On the 24th day of the experiment this undetermined fraction, which, from the nature of the analysis, consists of fairly simple amino-acids, peptides, and other simple soluble organic nitrogen compounds other than amides, not precipitable with Stützer's reagent, has decreased to negligible proportions in all cases; indeed, on the control grass this state of affairs has been reached by the 9th day. It would appear, therefore, that by the beginning of May the rate of protein synthesis is such that the margin of partially elaborated nitrogen compounds is extremely small, and that this condition may not be reached until some weeks later when inorganic nitrogenous salts are added to the soil.

The presence of nitrite-N in the expressed juice of spring grass.

Schimper [1888] showed that nitrites are always present in the living leaf when the plant is in the dark, and that they disappear when the leaf is exposed to light. With regard to its occurrence in the plant under illuminated conditions, Rimington and Quin [1933] have found traces in the fresh juice of certain members of the genus *Tribulus*. It has also been detected in the stem of grape vines, in the leaves of carrot and in the leaves of soya bean in the early stages of growth, but so far as can be ascertained, its occurrence normally in spring grass has not been recorded. The amounts found by the author were always small (< 1 p.p.m. of dry matter).

In the experiment described above, the amount of nitrite in the expressed juice was increased within 2 hours of application to the soil, not only on the plots treated with sodium nitrite and sodium nitrate, but also on those treated with ammonium sulphate, a fact which seems to indicate that some at least of the ammonium sulphate was oxidised in the leaf. (There was no increase of nitrate in the leaf until a few days later.) Attention has been already drawn to the rapid assimilation of nitrogenous salts by Eckerson [1924], who observed nitrate in the leaves of tomato 24 hours after applying calcium nitrate to the roots—she also observed nitrite 36 hours after treatment.

Mevius and Dikussar [1930] showed that in neutral or alkaline solution *Zea Mays* could utilise nitrites without metabolic disturbances. They found that the optimum nitrite concentration was about 50 p.p.m. in a neutral solution, and that at greater concentrations protein synthesis was retarded with simultaneous accumulation of amides and ammonia but not nitrite. In the experiment recorded here no evidence was obtained of accumulation of the forms of nitrogen mentioned. During the first 9 days after application the nitrite materially increased the percentage of true protein-N and pepsin-HCl-soluble N, as did the other fertilisers tested but to a smaller extent, but by the 24th day after application, the percentages of total-N and pepsin-HCl-soluble N, true protein-N, amide-N and ammonia-N were found to be depressed below the corresponding values in the untreated grass, although the applied nitrite had already disappeared from the soil and the herbage by the 9th day. The highest concentration of soil nitrite-N recorded in this experiment was 27 p.p.m., corresponding to 190 p.p.m. of soil solution, and the p_H of the soil was 6·8.

The temporary accumulation of nitrite in unmanured grass is undoubtedly conditioned by rapid assimilation of nutrients and by low intensity of solar radiation, a state of affairs which may be presumed likely to occur only in early spring or late autumn (or in summer under heavy shade). It appears likely, therefore, that it is a contributory factor in the so-called "grass tetany" of cattle which is sometimes observed at these times and is usually associated with high inorganic nitrogen content of the herbage.

In this connection it is of interest to record an observation made at Jealotts Hill. On May 9th, 1933 it was noticed that stock had broken out of a field (A) which had been treated with nitrochalk a few days previously. They were found grazing contentedly in the adjoining field (B) which had not been so treated. To the eye, no difference in the herbage of the two fields was apparent, but in view of the possibility that the stock had detected some disagreeable quality in the herbage, samples were taken from both fields and examined for nitrite by the above method, with the following results.

Table VIII.

	Nitrite-N		Potassium nitrite
	p.p.m. wet grass	p.p.m. dry matter	g./cow/day*
Field A	1·2	7·0	0·6
Field B	0·4	2·0	0·19

* Assuming a daily consumption of 30 lb. dry matter per cow per day.

Thus it will be seen that there was at least three times as much nitrite present in the grass which the stock found unpleasant as in the grass which they found palatable.

Unfortunately nitrite was the only nitrogenous constituent looked for on this occasion, so that there still remains the probability that nitrate was also present in the treated grass, although this is known to be considerably less toxic than nitrite. Nevertheless, apart from the certain amount of circumstantial evidence concerning the part played by nitrite in "grass tetany", the figures demonstrate that nitrite occurs naturally in grass in the spring, and that the amount may increase after treatment with a nitrogenous manure.

The significance of nitrite-N in protein synthesis.

Berthelot and Gaudechon [1911] demonstrated nearly twenty-five years ago that nitrite was formed when solutions of ammonium salts were exposed to ultraviolet radiation, and more recently Dhar *et al.* [1933] and Corbet [1934] have confirmed that nitrite formation can be effected by ultraviolet light in the absence of micro-organisms. It would appear likely that the same reaction occurs in the grass leaves under the action of sunlight. The appearance of nitrite after the application of sulphate of ammonia certainly supports this view and raises the question whether the ammonia taken up as such all goes through the nitrite stage or whether part is directly synthesised into amino-compounds and only a fraction is converted into nitrite. In any case, the simultaneous occurrence of amino-compounds and nitrites may constitute a fruitful source of loss of nitrogen in the elementary form, the reaction forming what is probably a natural safeguard against undue accumulation of nitrite.

It might be mentioned in passing that the much vexed question whether ammonia-N or nitrate-N is more readily utilised by the grass plant has still to be answered, and although there is a mass of circumstantial evidence based on the observed ready uptake of applied ammonia by the plant under certain conditions, no conclusive evidence has yet been brought forward to show that nitrogen is freely taken up by grass in the ammoniacal form *in natura.* It is true that plants grown *in vitro* and supplied with ammonium salts as a sole source of nitrogen definitely do assimilate ammonium salts as such, but the conditions are far from natural. Even the entirely practical conditions of manuring in the field with ammonium sulphate, when again ammonia can be shown to be taken up, as in the above experiment, can hardly be described as normal to the plant Nevertheless, the point to be stressed is that even when the plant is faced with the necessity of dealing with its nitrogen in the ammoniacal form, a mechanism certainly exists whereby a part, if not all, can be oxidised to nitrite, thereafter to be dealt with possibly as suggested by Baly *et al.* [1922].

Work has been in progress in this laboratory on the photosynthesis of amino-acids from solutions of nitrite and sugars, and definite evidence of a reaction has been obtained, and recently also Dhar and Mukherjee [1934] have been successful in synthesising amino-acids by exposing solutions of glycol or glucose and nitrates to sunlight in the presence of titania as a catalyst. The reaction obviously proceeds through the nitrite stage. There would thus appear to be substantial grounds for believing that the photochemical formation of nitrite from nitrate and ammonia is of primary and fundamental importance in the synthesis of protein in plant tissue.

SUMMARY.

An attempt has been made to follow the transformation of various forms of inorganic nitrogen applied to the soil into elaborated organic nitrogen in the grass plant.

Under the conditions of the experiment, applied inorganic nitrogen was detected in substantial amounts in the herbage only 2 hours after application to the soil.

In early spring, synthetic processes in the leaf are slow enough to permit the accumulation of simple inorganic and organic compounds. This margin of partially elaborated nitrogen rapidly disappears, but at a diminished rate, when inorganic nitrogenous salts are applied to the soil.

Nitrite occurs naturally in spring grass, and the amount is increased when the grass is treated with ammonium sulphate or sodium nitrate at this time. It

is suggested that nitrites play a significant part in the so-called "grass tetany" of cattle, which is usually associated with herbage of high inorganic nitrogen content.

Grass treated with sodium nitrite at the rate of 3 cwt. per acre showed no visible signs of distress, although chemical analysis of the herbage gave evidence of metabolic disturbance.

The possible significance of nitrite in the synthesis of protein is briefly discussed.

Thanks are due to Mr H. J. Page for helpful criticism and to Messrs Imperial Chemical Industries, Ltd., for permission to publish this paper.

CLXXI. THE DETERMINATION OF FRUCTOSE IN BLOOD.

By JOCELYN PATTERSON.

From the Department of Biochemistry, Charing Cross Hospital, Institute of Pathology.

(*Received April 27th, 1935.*)

In direct determinations of blood fructose by colorimetric means, use has generally been made either of the original Selivanoff reaction [Folin and Berglund, 1922; Roe, 1934], or of the van Creveld [1927] reaction [Kronenberger and Radt, 1927; Radt, 1928; Corley, 1929] which employs diphenylamine. The present communication is concerned with the latter reaction only, which was investigated with the main object of comparing the results obtained with those resulting from the application of a new principle worked out in this laboratory [Scott, 1935].

Preliminary trials of the method described by Radt [1928] as suitable for the estimation of blood fructose furnished evidence which seemed to make it desirable to modify it in certain directions. The first unsatisfactory feature is that much more amyl alcohol is required to extract the coloured product in the treated blood filtrate than is required to carry out the corresponding operation upon the standard solution, and this has the effect of upsetting the volume relationships which it is desirable to maintain between unknown and standard. It was found that the extraction was greatly facilitated by the introduction of a little solid ammonium sulphate, which process enabled the final colour in both standard and unknown to be contained in the same volume.

The second important drawback to the method lies in the choice of blood filtrate. When using whole blood the filtrate from protein, precipitated with HCl and mercuric chloride, contains substances which interfere with the colour reaction between fructose and diphenylamine and have the effect of causing the development of colour in the unknown to proceed faster than in the standard and eventually to reach an intensity beyond that which could be attributed to the fructose present. This difficulty was readily overcome by a suitable choice of filtrate, for recent work on blood sugar has provided a number of filtrates established as satisfactory for true sugar determination, and though these are much more dilute than is advisable for the estimation of the very minute amounts of fructose that appear in blood after the ingestion of such quantities of the sugar as are commonly used in tolerance tests, the subsequent concentration was an operation easily accomplished without danger of vitiating the estimation.

On general grounds a zinc filtrate appeared to be eminently suitable for the purpose, and in that the form of precipitation used by Scott gave the opportunity of making this work strictly comparable with his, and further provided a greater volume of filtrate than that available from the standard Somogyi method, exactly the same procedure was adopted as that forming the preliminary stage to the bile salt colorimetric method. The quantities used were identical with those described as being applicable to a determination upon 2 ml. whole blood.

The subsequent stages of the estimation were carried out as follows. After the acidification with acetic acid the 10 ml. filtrate (equivalent to 1 ml. blood) were evaporated down (using a small Bunsen flame for direct heating) in a test-tube graduated at 4 ml. until the volume fell to just below the mark. It was then made up exactly to 4 ml. volume. This concentrated filtrate was then treated with 4 ml. HCl (5 parts concentrated acid + 3 parts distilled water), and 0·4 ml. 20 % alcoholic diphenylamine, the mixture shaken thoroughly, and then heated in a boiling water-bath for 15 minutes. On cooling to room temperature, 10 ml. butyl alcohol were added, followed by 2 g. solid ammonium sulphate. The tube was then stoppered and shaken up vigorously to permit extraction of the blue colour by the organic solvent. A solution of fructose (that containing 0·1 mg. fructose in the 4 ml. volume was the most suitable standard for use in tolerance tests) was similarly treated, and the butyl alcoholic layers were pipetted off for comparison in the colorimeter. Blank determinations on normal fasting bloods showed only the slightest trace of colour, which might for practical purposes be regarded as negligible. Actually it would appear to be equivalent to about 1 mg. fructose per 100 ml. blood, from the values recorded in Table I, which shows a comparison between the results ascertained by the process just outlined, and those obtained by the bile salt method.

Table I.

Sample	Estimated fructose mg./100 ml. Present method	Estimated fructose mg./100 ml. Scott's method	Type of case
1. With added fructose	11	10	Normal
2. With added fructose	16	15	Normal
3. 1 hour after fructose	13	12	Cirrhosis of liver
4. 2 hours after fructose	9	8	Cirrhosis of liver
5. 1 hour after fructose	19	18	N.A.B. Jaundice

The satisfactory agreement between the two sets of values establishes confidence in both methods as a means of determining blood fructose.

CLXXII. QUANTITATIVE STUDIES ON THE RESPONSE OF THE CAPON'S COMB TO ANDROSTERONE.

By ALAN WILLIAM GREENWOOD, JANET SCOTT SALMON BLYTH AND ROBERT KENNETH CALLOW.

From the Institute of Animal Genetics, University of Edinburgh, and the National Institute for Medical Research, London, N.W. 3.

(*Received April 30th, 1935.*)

I. *Introduction.*

SINCE it was first reported by Pézard in 1911 that injection of extracts of testicular substance restored the characteristic sexual phase of growth in the comb of the castrated bird, this response has been used extensively to determine the efficacy of preparations containing the male hormone. A review of the literature to 1931 on the assay of male hormone will be found in the article by Koch [1932].

The earlier work of Gallagher and Koch and their co-workers, 1928–1930, [*cf.* Koch, 1932] showed that the marked individual variations in the responses of the capons to the hormone were not determined by such factors as age, weight of birds and initial size and shape of comb. This lack of influence of body weight and initial comb size on the extent of the reaction was confirmed by Blyth *et al.* [1931] but not by Freud *et al.* [1932]. It was found however that the effect of these individual variations could be minimised by previously selecting the birds and by using a number for each test.

Gallagher and his co-workers defined a bird unit as the amount of hormone which, when injected daily for 5 days, yields an average of 5 mm. increase in length *plus* height of the combs of at least 5 Brown Leghorn capons. In the studies recorded here the American procedure has been followed mainly for the reason that considerable familiarity with this method over a long period of time has led, in our opinion, to results which are as free from obvious irregularities as can be expected of any biological measurement.

Another method of estimating the amount of comb growth induced is that in use in the Laqueur laboratory where the increase in total area of the comb is determined by means of planimetric measurements of the photographic shadow. On this basis the unit of male hormone has been defined as one fourth of the smallest amount which, administered in 8 doses of 0·5 ml. in 4 successive days (morning and evening) subcutaneously or intramuscularly in oil solution, produces on the fifth day, in at least 2 of a group of 3 animals, a comb increase of at least 15 %, or if more than 3 birds are used, in the majority of the animals. Reference may also be made to the methods described by Schoeller and Gehrke [1931], Butenandt and Tscherning [1934], and Ruzicka and Tschopp [Ruzicka *et al.*, 1934].

The standardisation of preparations of male hormone by the comb growth method, like other biological assays, is unsatisfactory in that experiments carried out in different laboratories with the same technical procedure and the same hormone preparation do not necessarily give the same response. (Results of an international experiment carried out in 1933 under the direction of Koch in the laboratories of Laqueur, Koch, Butenandt and Greenwood (unpublished).) The discovery of a method for the artificial preparation of the male hormone, androsterone, by Ruzicka *et al.* [1934; 1935] and its production in larger quantity has suggested an extensive examination of the variables involved in the reaction between the hormone and the comb.

II. *Material and methods.*

Androsterone. This material was prepared in London by the method described by Ruzicka *et al.* [1934] with certain minor modifications [*cf.* Callow and Deanesly, 1935]. Material recrystallised from ethyl acetate and having a melting-point not below 182° was used. Solutions in arachis oil for injection were prepared by warming on the water-bath.

The stability of the oil solution was tested by heating a sealed ampoule containing the solution in an oil-bath, the temperature of which was thermostatically controlled at 149–151°, for 24 hours.

Care of capons. The birds on which these observations have been made were bred and kept at the Institute of Animal Genetics. They are housed under uniform conditions in a roof-lit, brick poultry house divided into pens each capable of holding 16–20 birds; the fowls are given access daily to floored sun porches but never come in contact with the ground.

Husbandry has been standardised as far as possible; the composition of the food remains the same throughout the year and consists of grain and mash in the summer months, while in the winter-time a hot mash is added. Cod-liver oil, green stuff, minerals and grit are also provided to supply the necessary special food requirements which cannot be picked up as on free range.

From October to March lighting is switched on in the evening until 6 o'clock and in the summer the birds are confined to the building from this time until 9 a.m. No artificial heating is provided.

Routine observations of the size of comb and body weight are made regularly. For the present series of experiments altogether 63 Brown Leghorn capons have been used, varying in age from 4 months to 6 years. The age at which the birds were castrated varied considerably as shown in Table I.

In preparation for the experiments measurements of the birds' combs and body weights were made (18. ii. 35) and 40 of the large group of 2-year-old castrates divided up into lots of 5 so that the average comb size and body weight of each was similar (see Tables II and III).

Table I. *Age at castration in different age groups.*

Prefix to no. of bird	Hatched	No. of birds	Average age at castration days	Range in days
A	1929	4	25	8–54
B	1930	4	26	18–33
D	1932	5	47	29–51
E	1933	45	39	21–51
G	1935	5	42	Nil

Comb measurement. All the birds were measured at the time of first injection and the differences in the average comb size (length *plus* height) of the groups from the preliminary measurement varied from $-0{\cdot}2$ to $+0{\cdot}8$ mm.

Since it appears that the technique of comb measurement employed by various operators does not yield strictly comparable results, a fairly detailed description of the procedure used in Edinburgh will be given. The measurements of greatest length and greatest height of the comb were made by means of a small pliable celluloid scale graduated in mm., and all data recorded were obtained from the measurements made by a single observer. The determination of the height of the comb usually presents no great obstacles, though very occasionally it is difficult to obtain a definite base line between the comb and the head. The length however is a different matter: as an anterior point from which to measure, the junction of the comb with the beak is not satisfactory since it fairly frequently happens that the bird damages this region with the result that the fleshy tissue retracts, and, if this occurs during an experiment a source of error is introduced into the results. While in a few of the capons the front of the comb runs down in an unbroken line to meet the beak, in most there is a slight transverse groove towards the front, and this wherever possible has been used as the anterior limit. In the normal cock the comb ends in a large blade extending posteriorly, but in the capon this part of the undeveloped comb frequently curves upwards so that its upper edge lies parallel with the last point of the comb; when growth is initiated it begins to move through an arc towards the position it would occupy in the normal cock, so that the line of greatest length from a fixed anterior point would not fall consistently on the same posterior point. In order to minimise the error in these cases, the initial measurement is made with the posterior blade of the comb pulled down to the position it would subsequently occupy. Apart from this manipulation the comb is not abnormally stretched in measuring; an attempt is merely made to get it lying as flat as possible between the points to be measured.

The injections were made at approximately the same time each day, and all groups of birds, with one exception, received the hormone preparation deep into the pectoral muscles, alternate injections being given in the left and right sides. The exceptional group received subcutaneous injections.

In all cases where small doses were given daily (0·2 ml.) the substance was administered by means of a 1 ml. tuberculin syringe graduated in 0·01 ml.

During the course of the experiments the combs were measured normally 3 and 5 days after the initial injection was given but, exceptionally, daily measurements were made to which special reference will be made later. The rate of comb regression following the cessation of injections has been determined for some groups by measurements up to 30 days from the initial injection.

III. *Examination of variables.*

Relation between dose and response. The first experiment, on the relation between the amount of hormone injected and the magnitude of the comb response, was performed on a series of 25 capons divided into groups of 5, each bird receiving daily injections of 0·2 ml. of arachis oil solution for 5 days. The amount of hormone given was doubled in each successive group, and the total dose per bird ranged from 0·5 to 8 mg. of androsterone.

The data are recorded in Table II and plotted in Fig. 1. The individual points on the graph show that the variability of the response to the different doses is very similar. Thus, for the mean responses in the five groups receiving 0·5, 1, 2, 4 and 8 mg. total dose, σ is respectively 3·0, 1·9, 2·3, 2·5 and 1·8. This means that the relative variability (coefficient of variation, or σ/mean × 100) is much less for the larger responses than for the smaller ones, which suggests that for comparative work it is desirable to aim at a substantial response. In

(Daily dose: 0·2 ml.)

view of the constant magnitude of the variability of the response with different doses it is legitimate to consider the whole of the 25 observations together and to calculate a combined σ. The figure obtained is 2·1, which may be taken as the standard deviation of the comb response under the conditions and range of dosage used. The standard error of the response may therefore be taken as ± 1·0

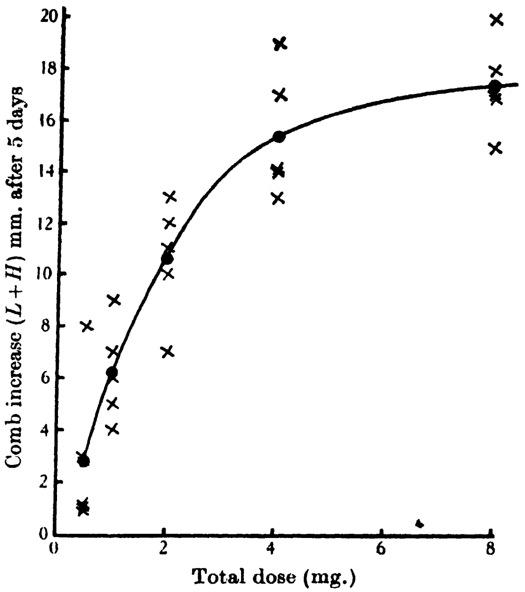

Fig. 1. Relation of increase of size of comb to the total dose of androsterone given over 5 days. Series A. × Individual birds; • mean values for groups of 5.

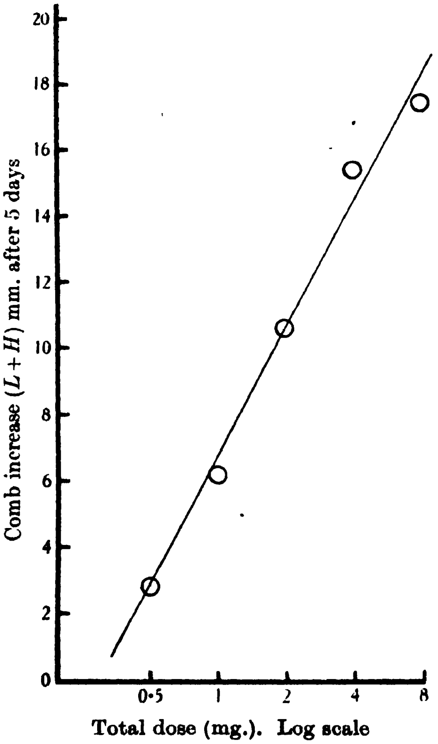

Fig. 2. Relation of increase of size of comb to log (total dose).

for a group of 5 capons, or ±0·7 for a group of 10 capons. In comparing the responses in two groups of 5 therefore a difference of not less than 3·0 mm. is required in order to be statistically significant.

The curve drawn through the means in Fig. 1 obviously gives the elements of a standardisation curve; its shape suggests that the relation between dose and response is logarithmic, and when, as in Fig. 2, the response is plotted against the logarithm of the dose, it is seen that the points lie approximately along a straight line. The observations embodied in this (log dose)/(response) line were all made during the same week, and it is well known that such lines vary from time to time in both position and slope—an important factor in assay work. They can, however, always be reorientated by giving two different doses of a standard preparation at the same time as an assay is made.

From the line in Fig. 2 we obtain graphically $\frac{du}{dx}=\frac{12\cdot 8}{1}$, where u = comb response in mm. and x = logarithm of the dose in mg. The standard error of ±1·0 in the mean response of a group of 5 capons will thus represent an error of about ±0·08 in the determination of the logarithm of the dose. This is equivalent to an error of about ±18 % in the determination of the dose. With groups of 10 capons the error would be reduced to about ±12 %.

Nature and volume of medium. Two tests were designed to examine the possible influence of changes in the medium in which the hormone is dissolved. In series B (Table III and Fig. 3) the actual amount of hormone injected daily was the same as in group 3 of the first experiment, namely 0·4 mg., but the volume of oil in which it was administered was increased from 0·2 to 1·0 ml. In series D (Table III and Fig. 3) the amount of hormone was again kept the same but the medium altered, both in nature and quantity, being a solution in 10 % aqueous alcohol, given in a daily dose of 4 ml. Five birds were used for each test, their average comb size and body weight being approximately the same as those for the groups in series A. An examination of the responses obtained in these two experiments, compared with that obtained from a similar amount of hormone injected into group 3 of the first experiment shows that the increase in comb size of 12·4 mm. resulting from the administration of the aqueous-alcoholic solution (series D) is nearly twice that obtained in series B (7·4 mm.) with the increased volume of oil, while that in series A (which will be shown later to approximate closely to the average of all increases obtained from this dosage) is intermediate between them.

It is clear then that in any procedure for the standardisation of the hormone it is necessary to consider not only the nature of the solvent employed but also the volume.

Site of injection. In the next experiment (series C, Table III and Fig. 3) the same dosage was adopted as in A 3, but the injections were given subcutaneously instead of intramuscularly. It will be seen from Fig. 3 that the reactions obtained in the two experiments follow similar courses, the response elicited by subcutaneous injection being slightly but not significantly less than by intramuscular injection.

Heat stability of androsterone. Data concerning the effect of subjecting the hormone to heating at 150° for 24 hours are to be found in Table IV. Control and heated solutions of androsterone were administered in the same concentration and dosage as in A 3. The birds in this experiment had been used previously (series C and D respectively) and, 17 days after the final injection, the comb size in both groups had regressed to approximately the same extent.

Fig. 4. Effect of age of bird and of incomplete castration (upper curve) on comb growth. (Dose 2 mg. in 5 days.) Series G.

Age of bird. The possible effect of age of the capon on the amount of comb-response induced was considered in the next experiment. Age groups of 2, 3, 5 and 6-year-old capons as well as one of 4 months were subjected to the same treatment as group A 3 (0·2 ml. daily for 5 days of a solution containing 2 mg. of androsterone per ml.). The small number of older birds available from which to select subjects for these tests made it necessary to include only 4 birds in each of the two oldest groups instead of five as in other experiments. The 2-year-old birds, group G 4, included in this test had been previously discarded, because, although the combs in point of view of size fell well within the range of the completely castrated birds their appearance and colour suggested that castration had not been satisfactorily complete. This suspicion was confirmed when the results of the test became available and it was seen that, whilst the responses obtained from the other age groups fell relatively closely to one another, that from the 2-year-old group was significantly larger (Table V and Fig. 4).

If, however, series A 3, which is more strictly representative of the 2-year-old birds, is used for comparison, it is found that the increase obtained after 5 days is just above that of the 3-year-old group (10·6 mm. to 10·4 mm. respectively) which in turn exceeds somewhat the increase elicited in the remaining three groups; these small differences are not significant.

(Total dose: 2 mg. of androsterone, 2 mg./ml.)

Weight of birds. If the possible effect of initial body weight on the magnitude of the comb response is examined it might be considered on *a priori* grounds that the concentration of the hormone in the body fluids is a factor in determining the amount of response and that therefore an inverse relationship would exist between the comb increase obtained and the body weight of the bird. However, no such relationship can be discovered in our experiments. Moreover, in the age series (Table V) the 4-months-old group, which has an average body weight of 1560 g. compared with an average body weight of from 2630 to 3040 g. in the older groups (2 years to 6 years old), produced a comb increase which was not above the average for the dosage and indeed was slightly lower.

Initial size of comb. An analysis of the responses obtained from the relatively large number of 2-year-old capons with a view to determining whether any relation exists between the initial comb size and the magnitude of the comb reaction, in previously untreated birds, leads, if we exclude the age group G 4 for reasons explained above, to the conclusion that no consistent relation exists between them.

Previous treatment. In order to determine the effect of previous treatment on the magnitude of subsequent responses, 26 days after the cessation of the first experiment all the birds in series A were subjected to a further series of androsterone injections. The dosage was the same in all groups, being a daily injection of 0·2 ml. of a solution containing 2 mg. of the hormone per ml. On the previous occasion only one group (A 3) received this dosage, two of the others (A 1 and A 2) having had lower doses and two higher (A 4 and A 5).

When these results (Table VI and Fig. 5) are examined for evidence of any "priming" effect, it is found that 25 capons receiving 2 mg. gave an average increase in comb size of 11·3 mm., compared with 10·6 mm. given by a group of 5 birds a month before; the difference is not significant. The maximum differences between the groups are barely significant, and any correlation with the degree of previous priming is disposed of by the low response in group 5, unless it can be speculatively suggested that the responses in groups 3 and 4, which show a difference on the verge of statistical significance, indicate an optimum priming effect.

Rate of comb growth. The rate of growth of the combs in the first experiment (Table II and Fig. 6) where different amounts of androsterone were used, presented no exceptional features. When comb measurements were made 3 days after the initial injection it was found that the increase in comb size was roughly related to the amount of hormone injected. The measurements at 5 days indicated that increased responses were obtained with increasing dosage in the growth period between 3 and 5 days except in the case of the maximum dosage where the response to the two highest doses was similar. The lack of a directly proportional response of the comb to the amount of hormone injected is suggested by the amount of growth in the various groups at 3 days but is well marked in the amount of growth occurring in the succeeding period.

In this series, where the comb measurements were recorded after 3 and 5 days from the initial injection, a point of note is that those groups receiving the lower doses showed a distinct lag in response during the first period, suggesting that a definite latent period exists before the influence of the hormone can be expressed in the comb, or that a threshold of stimulus had to be attained before the hormone could prove effective. (The stimulation provided by the higher doses was apparently sufficient rapidly to overcome this inhibition or to mask it.) In this respect the data for the daily measurements at the second test of this series (Table VI) are of interest. As was expected with the moderate dosage used the increase obtained 24 hours after the initial injection was small and between 24 and 48 hours comparatively large. On the 4th and 5th days the daily increment in the size of the comb approached that obtained at 48 hours, but on the 3rd day the figure recorded was distinctly low. Since there appears no obvious reason why such a lag in the amount of the response should occur at this time the question arises whether it can be explained by errors in measure-

ment, but this seems unlikely since for this reading the amount of increase recorded is consistently low for all the groups. (It is true that in group 3 it approaches a higher level but equally true that it is lower than the daily observations made immediately preceding and following it.) Whatever its meaning, the observations made force us to the conclusion that it is a real phenomenon.

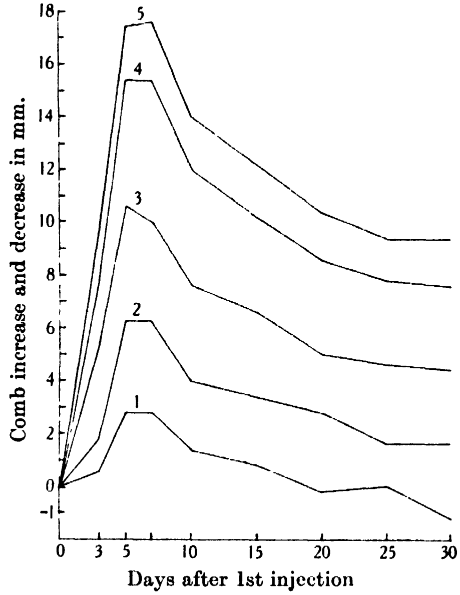

Fig. 6.

Fig. 5. Effect of previous treatment on growth of comb of groups of 5 birds receiving 2 mg. of androsterone over 5 days. Series F.

Fig. 6. Growth and regression of combs in groups of 5 birds receiving different doses. Series A. Group 1, 0·5 mg.; group 2, 1 mg.; group 3, 2 mg.; group 4, 4 mg.; group 5, 8 mg.

Rate of comb atrophy. The behaviour of the capon's comb after treatment has ceased may also be studied briefly in the same two tests. In series A measurements were made on the 7th and 10th days from the commencement of the experiment and thereafter at 5-day intervals for a further 20 days (Table II and Fig. 6). In series F the daily measurements were continued until the 7th day. For the former group the section of the curve under consideration may be conveniently divided into two parts, that between the 5th and 7th days, which shows comparatively little change, and the remainder of the curve, characterised by an initial phase of rapid regression which however is not maintained. The individual curves, though exhibiting some variability, suggest that the rate of regression decreases as the comb size becomes progressively smaller. The decline also appears to be greater in groups receiving the higher doses and this is particularly evident in the first sharp fall in the size of the comb (between the 7th and the 10th days). Nevertheless the inter-group divergence in regression rate is slight and it is clear that, whilst the combs of the first group have returned to their original state by the 20th day, a considerable time must elapse before those of the birds receiving the higher doses do so. In fact by the 30th day the average comb size in the birds of group A 5 had only regressed to the level attained by A 3 at its maximum.

With regard to that part of the curves between the 5th and 7th days, whereas A 3 exhibited a slight decrease the other groups remained stable at their maximum level. It is interesting to compare these results with those for series F. Here, daily measurements were recorded, and while group 1 showed a definite increase in the size of the comb on the 6th day, the others were more or less stable at the maximum size. By the 7th day however all had regressed to a size below that obtaining on the 5th day, the fall in the majority of the groups being greater than that in A 3.

SUMMARY.

1. A quantitative study has been made of the response of the comb of the Brown Leghorn capon to crystalline androsterone, and the effect of certain variables has been investigated.

2. In order to minimise the effect of individual variation, groups of five birds of similar initial comb size and body weight were used. These have been kept under constant conditions, and the technique of comb measurement has been carefully standardised.

3. Daily injections were made for 5 days, and the response was measured in terms of the increase in maximum length *plus* height of the comb.

4. The relation between the amount of hormone injected and the response of the comb measured on the day after the 5th injection is not linear when doses greater than 2 mg. of androsterone over 5 days are administered, corresponding to an increase of about 10 mm. in length *plus* height, but the response is directly proportional to the logarithm of the dose between the limits 0·5 and 8 mg. over 5 days.

5. The results are considered in relation to the formulation of a satisfactory technique for the assay of the male hormone. Careful measurement on selected groups of 5 birds yields results which imply a standard error of about ± 18 % in the determination of the dose.

6. The amount and nature of the solvent influence the response.

7. The responses to subcutaneous and to intramuscular injection are similar.

8. The differences in response with groups of widely differing ages (4 months to 6 years) are negligible.

9. It has been shown that in certain cases, probably as the result of the presence of a fragment of testis, unusually large responses are obtained. It is suggested that, as a precaution, birds should be used not earlier than 12 months after castration.

10. No relation between body weight and comb response could be demonstrated, nor could any consistent relation between initial comb size and amount of growth be found.

11. It is important to fix the period of the assay, since the amount of comb growth on successive days is not regular.

12. Only when a relatively small amount of comb growth is induced can regression of the comb to its pre-injection level be expected within a month, but after this period the responses to a new series of doses, whilst slightly irregular, do not show any significant effect of "priming".

13. The activity of androsterone is unaffected by heating the solution in arachis oil at 150° for 24 hours.

We are indebted to Dr A. S. Parkes for much useful advice and criticism in the course of this work.

CLXXIII. GROWTH AND MAINTENANCE OF THE FOWL'S COMB BY ADMINISTRATION OF ANDROSTERONE.

By ROBERT KENNETH CALLOW and ALAN STERLING PARKES.
From the National Institute for Medical Research, London, N.W. 3.

(*Received April 30th, 1935.*)

I. *Introduction.*

GREENWOOD *et al.* [1935] have discussed certain quantitative aspects of the capon comb response to androsterone. In view of the need for economy in both time and material a comparatively small degree of response is most suitable for assay work. Thus the criteria commonly used, a 20 % increase in area or an increase of 5 mm. in length + height, take the capon comb only a fraction of the way towards the size of the normal cock's comb. Owing to lack of material and preoccupation with assay work, comparatively little effort has hitherto been made to produce and maintain full-sized combs in capons.

Early in the work on the preparation of male hormone from testis, McGee *et al.* [1928] obtained comb growth in a Leghorn capon to a size ($L \times H$) of 48 cm.^{2} in 5 weeks, about half the area (thus calculated) for a really good Brown Leghorn cock comb. Schoeller and Gehrke [1931] obtained an increase to 40·3 cm.^{2} in 6 weeks with urine concentrates.

Ruzicka *et al.* [1934] obtained a surface area of 20 cm.^{2} (from 6·5 cm.^{2}) in 20 days during early work with their "synthetic" androsterone and Ruzicka and Tschopp [1935] record an increase from 4 to 27 cm.^{2} in 16 days. The record comb of the literature, however, appears to have been produced by Freud *et al.* [1932]. As a result of nearly 4 months' injection of male hormone concentrate from bull testis, ultimately in a dose corresponding to 6 kg. of testis daily, they obtained a comb of 83 cm.^{2} (planimeter reading), which may be considered as being full size. This problem is of importance because there is some reason to suppose that androsterone may not represent the full endocrine activity of the mammalian testis, and an examination of the requirements for the complete replacement of testicular activity in birds should be instructive.

We have also taken the opportunity of recording some observations on the effect of androsterone on the atrophic vas deferens.

II. *Methods and material.*

Birds. Two Brown Leghorn capons (EC 5 and 8) were obtained from the stock maintained by Dr A. W. Greenwood, having been operated on as chicks. One Brown Leghorn (EC 1) and two Plymouth Rocks (EC 2 and 3) were successfully caponised as adults and used for maintenance experiments. One Plymouth Rock (EC 7) and the Sebright Bantam were operated on as adults, and kept for more than a year before use, by which time the combs were indistinguishable from those of birds caponised as chicks. The difficulties of caponising adult cocks are considerable, and several birds were lost in obtaining reasonably clean operations. Two normal hens, one Rhode Island Red and one Brown Leghorn were also used.

Accommodation. The groups of capons discussed in Section VII were kept in an outside run open only to the north-east. The other birds were kept loose in an inside room, well lighted by two large windows, but receiving no direct sunlight.

Comb measurements. In the long period experiments combs were measured twice a week or, during periods of rapid growth, every day. In the comparative experiments described in Sections V and VIII the method of testing described by Greenwood *et al.* [1935] was used.

In order to give an adequate impression of the changes in comb size it is necessary to obtain either the surface area or the volume of the comb or an index of one of these. Length + height ($L+H$), whilst a convenient basis for assay work, does not indicate the actual changes in the appearance of the comb. We have therefore taken $L \times H$ as an index of comb size. The measurements (length × breadth in the case of the rose comb of the Sebright Bantam) were made as described by Hill and Parkes [1934].

Source of androsterone. The androsterone used in these experiments was part of the stock referred to by Callow and Deanesly [1935]. Whilst lower concentrations were used at the beginning, the bulk of the work was carried out with solutions of 10 mg./ml. arachis oil. A solution of this strength can readily be made by heating the oil, and the material afterwards remains in solution at room temperature. Stronger solutions in arachis oil can be made but they tend to crystallise out on cooling. A concentration of 10 mg./ml. represents about 100 capon units/ml. and makes it possible to keep the amount of oil injected down to a comparatively small quantity.

III. *Induction of full comb growth.*

Sebright Bantam capon. A Sebright Bantam cock was castrated in December 1933, when about 6 months old. The comb, 5·7 × 2·6 cm. at operation, atrophied rapidly, and 2 months later was 4·0 × 1·5 cm.; 3 months later it was 3·1 × 0·8 cm., at which it remained constant for 8 months. During this time the henny plumage was superseded by typically cocky plumage and spurs developed. 13 months after castration, injections of androsterone were begun, starting at

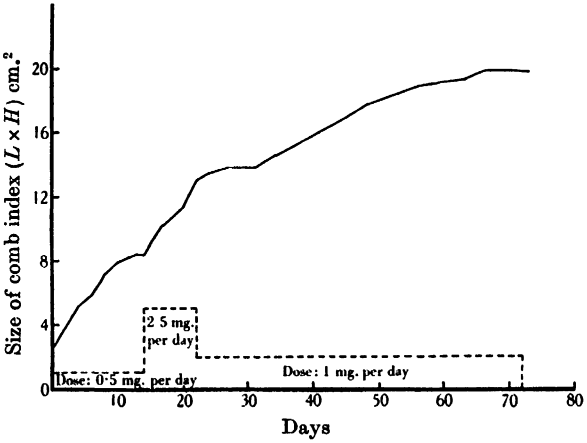

Fig. 1. Growth of comb in a Sebright Bantam capon.

0·5 mg., rising to 2·5 mg. and dropping again to 1·0 mg. daily. At the end of treatment, the comb was larger than at the time of castration and was in fact far larger than that of the normal cock. The treatment had no effect on the capon plumage [see Callow and Parkes, 1935]. The details of the experiment are shown in Fig. 1. It may be concluded that 0·5 mg. will cause appreciable growth of the comb of the Sebright capon, but will not take it to full size. 1·0 mg. daily, on the other hand, will grow the comb to abnormal size and will maintain it there. It may thus be supposed that the testes of the normal Sebright cock have a comb growth-promoting activity equivalent to that of rather more than 0·5 mg. androsterone administered as above.

Brown Leghorn capon. This bird was from Dr Greenwood's stock. The comb was flaccid and though rather large (5·7 × 2·7 cm.) when stretched, was brown and shrivelled and evidently that of a complete capon (Plate IV, fig. 7). It was thus ideal for the experiment in view, *viz.* the production of a full-sized comb in the minimum time. 5 mg. androsterone daily were given. Really remarkable growth was produced (Fig. 2), and after 22 days' treatment the comb measured 11·8 × 7·2 cm. and would readily have passed as that of a normal cock, except possibly that the papillae were not very marked (Plate IV, fig. 8). Wattles and

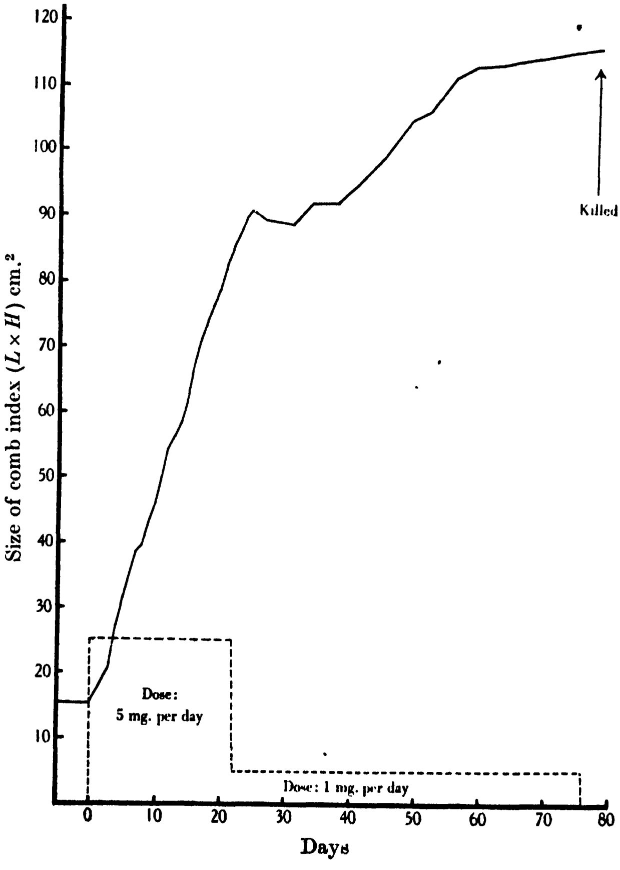

Fig. 2. Growth of comb in a Brown Leghorn capon.

ear lobes were also prominent. The dose was then dropped to 1 mg. daily, which was thought to be about the probable maintenance requirement. After a set-back, due probably to the sudden drop in dosage, growth was resumed, though at a much slower rate. This second growth phase gradually died away and in the end the comb was being comfortably maintained by administration of 1 mg. daily at a size which was above rather than below the usual standard for the breed. 10 days after the first injection this bird was observed to be making vigorous efforts to "tread" a hen, and a few days later it began to crow sporadically, a condition which was maintained till it was killed. This induction of "treading" and crowing is of interest as an effect of the administration of a pure crystalline substance. According to Appel [1929] the syrinx is morphologically similar in hens, capons and cocks, so that the power to crow presumably depends merely on the "instinct" to do so.

Comparison of Brown Leghorn and Plymouth Rock capons. The combs of Brown Leghorn cocks are usually 12–14 × 7–8 cm. Abnormally large ones run up to 16 × 9 cm., or even more. The cocks of heavy breeds of fowl in general have smaller combs. The combs of Plymouth Rock cocks maintained at the Institute's Field Laboratories, for instance, are usually only 9–10 × 4–5 cm., and they never attain such an appearance of luxuriant growth as those of Leghorns. It seemed of interest therefore to determine whether this difference is due to a difference in the amount of male hormone produced by the testes in the Plymouth Rocks, or to a greater sensitivity of the combs of the Leghorns. For this purpose, Leghorn and Plymouth Rock capons with combs similar

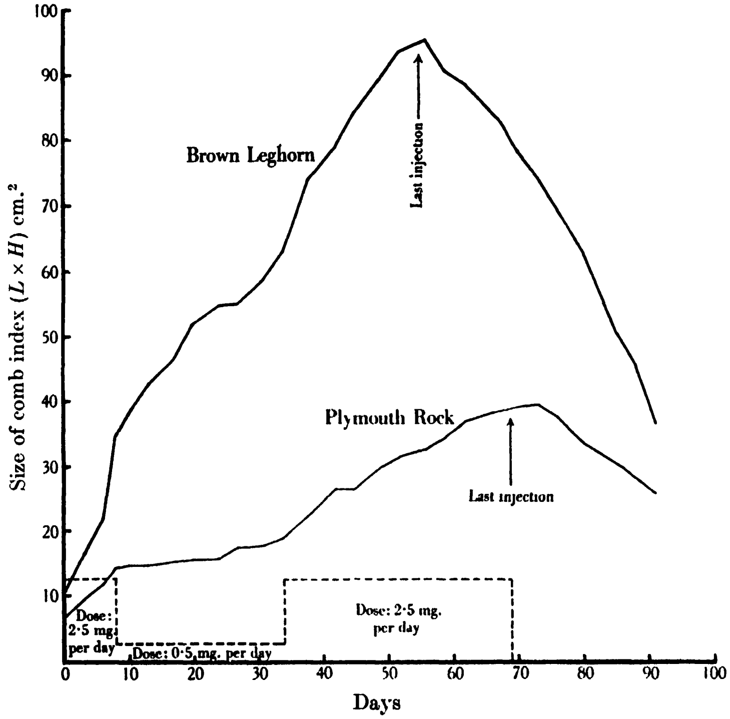

Fig. 3. Comparison of comb growth in a Brown Leghorn and a Plymouth Rock capon.

in size and shape were chosen. The Leghorn, again one of Dr Greenwood's stock, had a comb 4·7 × 2·2 cm. The Plymouth Rock, which had been castrated 14 months previously as an adult, had a comb which had been fairly constant at about 4·7 × 1·4 cm. for many months. These birds were each given 2·5 mg. daily for 8 days, then 0·5 mg. daily for 25 days and finally 2·5 mg. again (see Fig. 3). During the first 8 days the comb of the Leghorn more than tripled in $L \times H$; that of the Plymouth Rock just doubled. During the administration of 0·5 mg. daily, the Leghorn comb nearly doubled, that of the Plymouth Rock hardly grew at all. During the second period of administration of 2·5 mg. daily the Leghorn comb increased in $L \times H$ by 50 % in 21 days. The comb of the Plymouth Rock rather more than doubled in 35 days, but the actual increment was much less than in the case of the Leghorn. When injections were stopped the comb of the Plymouth Rock was rather larger than at the time of castration 16 months previously. As shown in Fig. 3 the differential rate of growth in these two birds was paralleled by the differential rate of atrophy after the last injection. This experiment suggests strongly that the difference in comb size in Leghorns and Plymouth Rocks is due to genetic difference in the sensitivity of the combs to the comb-growth-promoting hormone. A similar conclusion is arrived at from the maintenance experiments described below.

One rather curious point of difference in behaviour between the Leghorn and Plymouth Rock combs may be mentioned here. When the latter was almost stationary at quite a small size on 0·5 mg. androsterone daily, it was very noticeable that the papillae became well developed, more so than those of the fast-growing Leghorn comb. Further, the papillae of the comb of the Leghorn described on p. 1416 underwent comparatively little development during the phase of very rapid comb growth, but grew later to the normal size. This difference during induced growth is obviously correlated with the difference shown during atrophy. The comb of the Leghorn after adult castration very soon loses its papillae, and at 10 days after operation it is usually quite smooth, as well as being very blanched. The comb of the Plymouth Rock, on the other hand, retains papillae and a red colour for much longer after adult castration.

IV. *Maintenance of full comb size.*

Brown Leghorn. An adult Brown Leghorn cock, comb 12·9 × 7·8 cm., was castrated. 10 days later, when the comb was showing easily appreciable shrinkage and loss of colour, the injection of 1 mg. of androsterone daily was started and was continued for 12 days. This treatment caused the comb to regain colour, and the papillae began to reappear. The effect on the course of regression is shown in Fig. 4. After the first 3 days the size of the comb increased steadily, and had the injections been continued the comb would presumably have been maintained at a greater size than when injections were begun, even if not at the size observed at the time of operation. This experiment therefore confirms the supposition that the full-sized Leghorn comb can be maintained by about 1 mg. androsterone daily.

Plymouth Rock. Two Plymouth Rocks were castrated when adult. 11 days later, when both combs had shrunk considerably but were about equal in size, injection of 1 mg. androsterone daily into one bird was started, whilst the other was kept as a control. Subsequently the dosage to the first bird was raised to 2·5 mg. daily. Details of the size changes in the combs are shown in Fig. 5. The dose of 1 mg. daily restored the comb to just about its previous size and would, no doubt, have maintained it at this level. Raising the dose at this point increased the size of comb slightly, but at the time of killing there were signs that the comb size was becoming stabilised at a point not far above the normal.

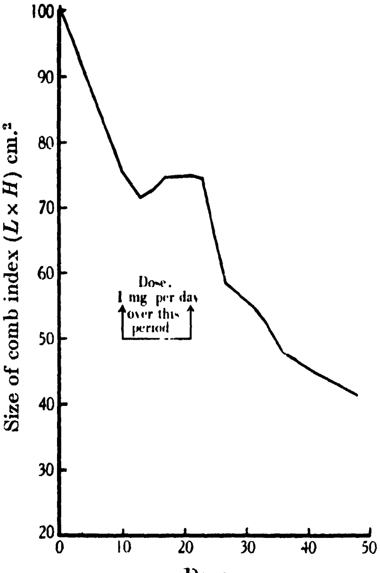

Fig. 4.

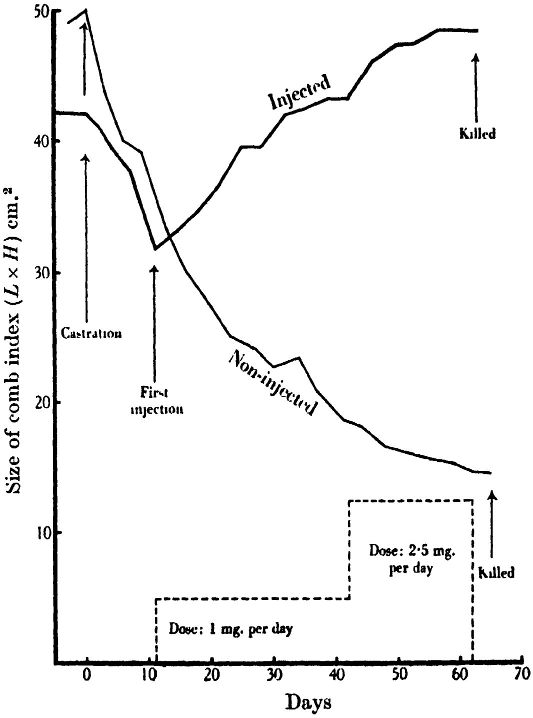

Fig. 5.

Fig. 4. Maintenance of comb size after adult castration of Brown Leghorn cock.

Fig. 5. Maintenance of comb size after adult castration of Plymouth Rock cock.

V. *Comparative sensitivity of combs of Leghorn and Plymouth Rock capons.*

The experiments recorded above show that the testes of the Plymouth Rock cock produce as much comb-growth factor as those of the Leghorn or even more, and that the lesser size of the Plymouth Rock comb is due to its lesser sensitivity. This conclusion has a bearing on a matter of practical importance, *viz.* choice of breed for capon comb assay work. White and Brown Leghorns have been used almost exclusively up to date, but Plymouth Rocks have the advantage that they can be easily caponised at a much later stage than can Leghorns. As a further check therefore on the difference in sensitivity, a group of 5 Leghorn capons and one of 5 Plymouth Rock capons were tested. The Leghorns were given 1 mg., and the Plymouth Rocks 5 mg. over 5 days, the final comb measurements being made 1 day after the last injection (Table I). This dosage was arranged in the hope of getting a good measurable response in both groups.

Greenwood *et al.* [1935] have shown that in Leghorns over this range of growth the size increase has an almost linear relation with the dosage, and it is

Table I.

	Average $L+H$ at start mm.	Average $L+H$ increase mm.
5 Leghorn capons each receiving 1 mg. over 5 days	45 + 20	11
5 Plymouth Rock capons each receiving 5 mg. over 5 days	42 + 16	10·7

unlikely that the Plymouth Rock combs exceeded the range over which the relation is linear. One must therefore conclude that to obtain a similar response in the Plymouth Rock capon demands about 5 times the dose required for the Leghorn capon. Breed thus appears to be an important variable in assay by the comb-growth method.

VI. *Histological observations on the vas deferens.*

The paper by Callow and Deanesly [1935] shows that pure androsterone is relatively inefficient in causing growth of the accessory organs of castrated mammals. It is thus important to know whether the internal accessory organs of capons show a response comparable with that of the comb or whether, like the mammalian accessory organs, they only respond to relatively high doses. In practice one is reduced to examination of the effect on the rudimentary or atrophic vas deferens of the capon. In the present series the vasa deferentia of the Leghorn recorded on p. 1416 and in Fig. 2, of the 2 Plymouth Rocks (p. 1418 and Fig. 5) and of an uninjected Leghorn capon are available for histological examination. The vas deferens of the uninjected capon, as might be expected, was greatly atrophied; in places the lumen, lined by low cuboidal cells, was scarcely patent (Plate IV, fig. 9). That of the uninjected Plymouth Rock, 65 days after adult castration, was less atrophic, but had obviously undergone extensive involution (Plate IV, fig. 11). In the injected Plymouth Rock the vas deferens was fully maintained as regards the appearance of the epithelium, and the general size, though subnormal, was much greater than in the uninjected control (Plate IV, fig. 12). A similar condition (Plate IV, fig. 10) was shown by the vas deferens of the Leghorn (EC 5). In view of the fact that the large size of the normal vas deferens must be partly due to distention with testicular products, it is likely that the vasa deferentia of these two capons were almost completely maintained and developed respectively by the administration of androsterone. In comparing these results with those on rodents, it should be remembered that very large amounts of androsterone were given over prolonged periods.

VII. *Effect of androsterone on the comb of the hen.*

It seems to be established that oestrin has only the smallest effect, if any, on the comb of the hen. The question thus arises as to what induces comb growth in the hen and in particular why does the comb increase in size and colour when the bird is in lay? The obvious reply is to suggest that in the same way as the fowl testis produces oestrin in addition to male hormone, so the ovary produces male hormone in addition to oestrin. We are not however aware of any experiments on the effect of male hormone on the comb of the hen.

Two hens were injected with androsterone. The first was a Rhode Island Red with a small, erect comb, and the second was a Brown Leghorn with a large, drooping comb. 2·5 mg. daily were given: the results are shown in Fig. 6. The enlargement produced was of quite a different order from that in the capon comb. In 3 weeks the comb of the Rhode Island Red barely doubled in $L \times H$, while the similar comb of the very refractory Plymouth Rock capon (p. 1418, and fig. 3) more than doubled in $L \times H$ in 8 days on the same dosage. The Leghorn hen's comb increased in $L \times H$ from 22·0 cm.^{2} to 45·1 cm.^{2} in 33 days. This may be contrasted with the Leghorn capon EC 8 which, on a dose of only 0·5 mg. daily, increased in $L \times H$ from 34 cm.^{2} to 63 cm.^{2} in 26 days.

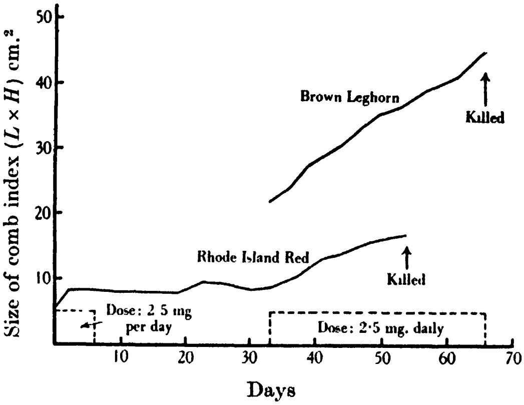

Fig. 6. Effect of androsterone on hens' combs.

VIII. *Discussion.*

It is clear from the results described above that the administration of large amounts of androsterone to capons will induce comb growth at a rate well above normal, and that crowing and "treading" occur. Further, this normal condition can be maintained by moderate daily doses. Increased efficiency is known to result from more frequent dosing [*cf.* Freud *et al.*, 1932], and moreover the comb-growth-promoting substance is probably liberated from the testis in a more effective manner than can be simulated by injection in oil. The experimental results show that daily injection of about 1 mg. of androsterone is equivalent to the comb-growth-promoting activity of the normal testis, and there is little difficulty in supposing that the testes could produce sufficient androsterone to account for the total endocrine activity as far as comb size and behaviour are concerned. It must be remembered however that there is no evidence that the testes actually do produce the particular chemical compound androsterone, which may be merely the excreted form of the testicular hormone.

The few results on the behaviour of the vasa deferentia do not allow of such definite conclusions as to the sufficiency of androsterone, and it must remain an open question whether, as in the case of rodents [Callow and Deanesly, 1935], some other substance may be involved. It should be mentioned that Callow and Parkes [1935] have shown that the plumage peculiarities of breeds such as the Sebright Bantam can only be accounted for by the assumption that the avian testis produces oestrogenic material.

A large difference was observed in the response of two different breeds of fowl to doses of androsterone. Doses of the same order are required for restoration of the comb to normal size in either Brown Leghorns or Plymouth Rocks, and the same applies to the doses necessary for maintenance. The relative sizes of the normal combs of the two breeds are however so different that the absolute increase of size of comb is several times as much for a given dose in the Leghorn as it is in the Plymouth Rock. Stated rather differently, the Leghorn comb is several times as sensitive as the Plymouth Rock comb.

It is of interest to compare the rates of comb growth obtained with these large doses given once daily with the rates obtained on similar birds under the conditions of assay employed by Greenwood *et al.* [1935]. Although a linear relation between response and dose is observed for small doses over a limited range, for larger doses (up to 8 mg. given over 5 days) the response is closely proportional to the logarithm of the dose. In the case of the Leghorn capon plotted in Fig. 2 an increase in length + height of 31 mm. occurred in 5 days with a total dose of 25 mg., and this response is of the order which would be expected on the basis of the assay results. It should be emphasised that prolonged administration of a smaller dose of androsterone will produce a comb of normal size with less total material than a brief period of heavy dosing.

As regards changes in the rate of increase on a constant dosage, Gallagher and Koch [1930] showed that with a moderate daily dosage the rate of increase was fairly constant for about a week and then fell off rapidly until the comb was approaching stability. The work recorded here shows that this kind of thing happens over a wide range of dosage, the steepness of the initial rise and the time taken for the growth curve to flatten off depend on the magnitude of the dose given, and, of course, on the breed of bird. The first Leghorn (EC 5) showed an unbroken straight line for comb growth during the period when it was getting 5 mg. daily. Such a rate of growth could obviously not have been maintained much longer, but it is probable that a very large comb would have been produced if material had been available to continue the heavy dosage indefinitely.

The relatively much lower growth rate found in hens after injection of androsterone raises an interesting problem. The strain of egg-laying might have some effect in inhibiting comb development, but actually during the period of the experiment the Rhode Island Red hen laid 1 egg only, and the Leghorn hen 2 eggs only, though the ovary was fully functional at autopsy. Three other explanations suggest themselves: (*a*) that the hen's comb is inherently less responsive to male hormone than the cock's, (*b*) that some substance in the hen, possibly oestrin, inhibits the action of androsterone on the comb, and (*c*) that androsterone is transformed in some way by the ovary. The first suggestion is difficult to reconcile with the known effects of testicular grafts on ovariectomised hens. As regards the second suggestion, the simultaneous injection of oestrin and male hormone concentrate according to Schoeller and Gehrke [1933] may actually increase the effect of male hormone on the comb. In an experiment carried out on capons we found that 1 mg. of androsterone *plus* 1 mg. of oestrone administered over 5 days gave a slightly lower response than the administration of 1 mg. of androsterone alone. This isolated result is not in accordance with the results of Schoeller and Gehrke, nor, on the other hand, was the difference sufficient to explain the results with intact hens. The third suggestion is at the moment speculative, and further investigation of the phenomenon is obviously necessary.

SUMMARY.

1. Very rapid growth of the combs of capons, with complete restoration to normal size in the course of a few weeks, may be induced by injection of crystalline androsterone in doses of the order of 2·5–5 mg. daily.

2. The comb can be maintained at the normal level by daily doses of the order of 1 mg. of androsterone. This requirement is not inconsistent with the view that secretion of androsterone accounts for the whole androkinetic activity of the testis of the cock. Observations on the restoration of the vas deferens have also been made.

CLXXIV. EFFECT OF ANDROSTERONE AND OF MALE HORMONE CONCENTRATES ON THE ACCESSORY REPRODUCTIVE ORGANS OF CASTRATED RATS, MICE AND GUINEA-PIGS.

By ROBERT KENNETH CALLOW and RUTH DEANESLY.

From the National Institute for Medical Research, London, N.W. 3.

(*Received April 30th, 1935.*)

I. Introduction.

The accessory reproductive glands of castrated rodents have long been recognised as suitable objects for testing the activity of male hormone preparations. A full bibliography will be found in Koch [1932] and the other literature cited below. Moore and Gallagher [1930, 2], enumerating mammalian indicators for male hormone, state that, after the spermatozoon motility test (one not in general use), the restoration of normal prostatic structure is the most sensitive test, the next being cytological restoration of the seminal vesicles. Many tests of this kind have been made, but although histological changes in the glandular epithelium have been brought about by a few days' treatment, yet the stimulation or maintenance of glands of normal adult size in groups of animals castrated for as long as 10 or 14 days has not been quantitatively demonstrated, until recently by Dingemanse *et al.* [1935]. These workers give the average seminal vesicle weights in 5 immature castrated rats injected for 24 days with a testis extract as 538 mg., approximately equivalent to the glands in a normal 175 g. rat (Fig. 3) and about two-thirds of the full size. Now that androsterone, the male hormone first extracted from urine, can be obtained artificially in larger quantities, by the method of Ruzicka *et al.* [1934, 2; Ruzicka, 1935], it has been possible to make an extended quantitative investigation of the responses in weight of the prostate and seminal vesicles. For comparative purposes, a number of experiments have also been made with several urine concentrates.

The two types of experiment which have been carried out are: (1) maintenance of normal size glands in rats and mice castrated as adults, and (2) production of growth in the glands of prepubertally castrated rats, mice and guinea-pigs.

An experiment of the first type was reported by Moore and collaborators [1930], who state that they maintained in normal condition the accessory glands of two adult castrated rats for 20 days by injections of crude male hormone begun on the day following castration; unfortunately no figures are given for either the weight of the rats or the weight of the glands. Hansen [1933] also carried out maintenance experiments on rats for 10-day periods but the accessory glands were not weighed, only examined histologically. Martins [1930] carried out similar partial maintenance experiments on mice of about 18 g. weight, using a length-breadth index of seminal vesicle size.

Many experiments of the second type have been reported on rats [Moore and collaborators, 1930; Freud *et al.*, 1930; 1932; Korenchevsky and collaborators, 1932–1935] and others have been carried out on mice [Voss and Loewe, 1931].

The actual increases in prostate and seminal vesicle weights (particularly the latter) caused in these prepubertally castrated rats and mice have in most cases been so small as to be almost negligible (a point emphasised by Voss and Loewe) and consequently the majority of these workers have relied on histological changes as an index of the activity of their extracts. Korenchevsky and his co-workers alone have attempted to base a quantitative method of assay on the increase in weight of the atrophied glands.

Freud and his collaborators have tried to obtain improved results in this type of experiment by combinations of oestrin with male hormone urine concentrates. They have also tested various oestrin derivatives [David *et al.*, 1934]. For assaying purposes these workers rely on the capon comb test, but Freud [1933] notes that in the purification of extracts male hormone activity could be lost as regards rats while being retained as regards capons [*cf.* also Laqueur, de Fremery *et al.*, 1931].

The present experiments were designed not only to test the biological activity of pure androsterone on rodents but also to compare it with the activity of crude urine extracts, since a significant difference between the two might imply the natural occurrence of more than one active substance.

II. MATERIAL.

Note on nomenclature. The term androsterone is applied to the crystalline compound first isolated by Butenandt from urine and prepared artificially from cholesterol by Ruzicka and his co-workers. The term "male hormone" is applied generally to this substance and to concentrates from natural sources without implying that they are necessarily identical. It seems desirable to avoid such terms as "testicular hormone from urinary sources" in the present state of knowledge.

Crystalline androsterone. The method described by Ruzicka *et al.* [1934, 2] for the preparation of androsterone from cholesterol was followed closely except in the preparation of *epi*cholestanol and in the isolation of androsterone in the final stage. The reduction of cholestanone was carried out in quantities of 100 g. dissolved in 3 litres of amyl ether. To this were added 100 ml. of concentrated hydrochloric acid and platinum black prepared by Vavon's method [1914] from 35 g. of platinum chloride. Absorption of hydrogen was complete in 4 hours with fresh catalyst. After filtering the hot solution from the catalyst, the *epi*cholestanol was allowed to crystallise out and the mother-liquors were used for a second reduction. The addition of fresh catalyst was necessary after four reductions. A yield of 397 g. of recrystallised *epi*cholestanol, M.P. 180–183°, was obtained from 786 g. of cholestanone in one series of reductions.

Some attempt was made to modify the conditions of the oxidation of *epi*cholestanyl acetate, the most wasteful stage in the preparation. Oxidation at a higher temperature (102–105°) for a shorter time yielded however a ketonic fraction containing much oily material. The isolation of the ketonic fraction was carried out with the help of the new reagent trimethylaminoacetohydrazide chloride, $Cl.Me_3N.CH_2.CO.NHNH_2$ [Girard and Sandulesco, 1934]. The neutral fraction of the oxidation product from one batch (80 g.) of *epi*cholestanyl acetate, freed from the bulk of unchanged material and methylheptanone, was evaporated to dryness and dissolved in 25 ml. of glacial acetic acid. To this solution was added a solution of 10 g. of Girard's reagent in 25 ml. of acetic acid and the mixture was warmed gently for a short time. The mixture was then poured into water and oily material extracted with ether. The aqueous layer, containing the ketonic fraction as a water-soluble hydrazone, was then warmed on the water-bath with a slight excess of dilute sulphuric acid; the material which separated was extracted with ether, and the extract evaporated. The crude acetate thus obtained was hydrolysed with alcoholic sodium hydroxide and yielded 1·4 g. of crude ketone, M.P. about 120°, which was recrystallised from ethyl acetate. Crude androsterone (0·4 g., M.P. 168–176°) separated, mixed with flocculent material. Recrystallisation from ethyl acetate, a good, though rather wasteful, solvent for the purpose, yielded pure androsterone, M.P. 184–185°, $[\alpha]_D^{20^\circ}+93·6^\circ$, $[\alpha]_{5461}^{20^\circ}+115·8^\circ$ in absolute alcohol. About 3 g. of androsterone were obtained from 3 kg. of cholesterol by this method. Under good conditions the over-all yield was about 0·2 % of the theoretical.

Fractional crystallisation of the product from the mother-liquors and the flocculent material accompanying the crude androsterone yielded a *ketone*, M.P. 166–167°, from aqueous alcohol, $[\alpha]_D^{20^\circ}+20^\circ$, $[\alpha]_{5461}^{20^\circ}+22^\circ$ in absolute alcohol. It showed no selective absorption in the ultra-violet in 0·1 % solution. This material did not induce measurable comb growth in capons in a total dose of 10 mg. over 5 days. Its composition has not yet been further investigated, but it seems likely that it is a product of incomplete removal of the sterol side-chain, possibly *epiallo*pregnanolone.

We are indebted to Mr A. L. Bacharach of Glaxo Laboratories for the supply on special terms of the cholesterol used in this preparation.

In addition to the material prepared in the laboratory, about 1·4 g. of androsterone were placed at our disposal by Messrs Ciba of Basle, to whom our very best thanks are due for this most generous assistance. A supply of androsterone from natural sources (50 mg. of crystalline "Proviron") was very kindly made available by Prof. Schoeller, Schering Kahlbaum A.G., Berlin.

Solutions of androsterone in arachis oil for injection were prepared by mixing at 100–150°. Greenwood *et al.* [1935] have shown that androsterone is stable under these conditions.

Male hormone concentrates.

(*a*) 2300 capon units of "Proviron" urine concentrate were given by Prof. Schoeller.

(*b*) 1000 capon units of "Enarmon" urine concentrate were given to us by Dr Itoh, Teikokusha Institute, Kawasaki, whom we also take this opportunity of thanking.

(*c*) A small supply (240 capon units) of "Hombreol" Organon was purchased, but only two experiments were possible with this material because of its high price.

iso*Androsterone*. 3-Hydroxy-17-keto-aetio*allo*cholane, isomeric with androsterone, referred to as *iso*androsterone for convenience, was prepared from cholestanyl acetate as described by Ruzicka *et al.* [1934, 1], but was isolated with the help of Girard's reagent.

Oestrin was administered in the form of oestrone (ketohydroxyoestrin) or, in earlier work, oestriol (trihydroxyoestrin) for which we are indebted to the British Drug Houses, Ltd.

Comb growth promoting activity of the materials. As a basis for comparison of the results obtained on rodents, the various preparations were first tested on Brown Leghorn capons belonging to Dr Greenwood's stock, but kept in London. The assay of pure androsterone differs slightly from that carried out in Edinburgh by Dr Greenwood [Greenwood *et al.*, 1935], probably because of differences in environmental factors, but the assays in London were all carried out under identical conditions, and should thus be comparable with each other, the only essential point. The results of these assays are given in Table I.

Table I. *Assays of male hormone preparations on capon combs.*

Material	Daily dose for 5 days	Av. comb increase $L+H$ mm.	Wt. or volume of capon unit (approx.)	Capon units per mg. or per ml.
Androsterone (Ciba)	0·2 mg.	10·9	100γ	10 per mg.
Androsterone (present paper)	0·2 mg.	9·3		
*iso*Androsterone	1·4 mg.	12·0	600γ	1·6 per mg.
"Enarmon"	0·2 ml.	10·2	0·1 ml.	10 per ml.
"Proviron"	0·1 ml.	9·7	0·05 ml.	20 per ml.
"Hombreol"	0·1 ml.	11·1	0·045 ml.	22 per ml.

Each assay was carried out on a group of 5 capons, and the capon unit is defined as that amount of preparation which, injected daily for 5 days, produces an average increase in $L+H$ of 5 mm. one day after the last injection. For purposes of calculation, it is assumed that the dose/response relation is linear up to a $L+H$ increase of 12 mm., a quite warrantable assumption [Greenwood *et al.*, 1935]. The dosage in each case was an amount expected to give about 10 mm. increase in $L+H$ in the 5 days, *i.e.* a good accurately measurable response.

The weight of the capon unit of crystalline androsterone agrees closely with that obtained by Ruzicka *et al.* [1934, 2], using a slightly different method of assay, involving however a very similar amount of growth. In the case of *iso*androsterone, close agreement is also seen with Ruzicka's assays, in which it was found that the isomeride had about one-seventh the activity of the hormone; the above assays make the ratio 1 : 6. For comparative purposes the activity of crystalline androsterone is taken as 10 capon units per mg. Only two samples of androsterone were assayed in London, but a series of assays carried out by Dr Greenwood failed to show any significant difference in activity between androsterone "Ciba", androsterone prepared in this laboratory and androsterone "Proviron" from urine.

The "Enarmon" preparation, a urine concentrate in oil, was labelled as 10 capon units per ml., no information being available as to the method of testing. The above assay entirely agrees with this definition of its strength. "Enarmon" was also slightly oestrogenic. 1 ml. of "Enarmon" oil produced cornification in an ovariectomised rat, and 0·1 ml. oil injected into each of three ovariectomised mice gave a positive response in two.

The batch of "Proviron" urine concentrate used in this test had been in the laboratory for nearly 2 years and was labelled as 25 capon units per ml. (for method of assay, see Schoeller and Gehrke [1931]). Actually, it assayed at almost exactly 20 units per ml. by our method. The difference, if significant, may be due to difference in assay method or deterioration of the preparation.

The "Hombreol" urine concentrate was labelled as 20 units per ml. (for method of assay, see Freud *et al.* [1932]). Our assay, recorded above, agrees substantially with this description; the difference is doubtfully significant.

The remarkable thing about these assays is the close agreement between the standardisations of the four different preparations carried out in as many different countries. It is doubtful if any of the differences between the observed and labelled activities are significant: there appears to be greater unanimity as to what constitutes a capon unit than might have been expected. In view of these findings it is rather surprising that the androsterone tests carried out in Edinburgh [Greenwood *et al.*, 1935] should have given uniformly lower values, especially since the birds were from the same stock as those used in London.

III. Description of prostate and seminal vesicles; methods of dissection.

(*a*) *The rat.* The rat prostate has been frequently described; references will be found in Walker [1910]. It is illustrated in Figs. 1 *a* and 1 *b*, which show the terminology adopted in this work. The gland consists essentially of three pairs of lobes:

(1) Cranial lobes or coagulating glands attached to the length of the seminal vesicles. These are termed the anterior lobes by Moore, Price and Gallagher [1930], as were similar lobes in the mouse prostate by Deanesly and Parkes [1933]; but since Walker [1910] uses the term in another sense it seems better to discard it.

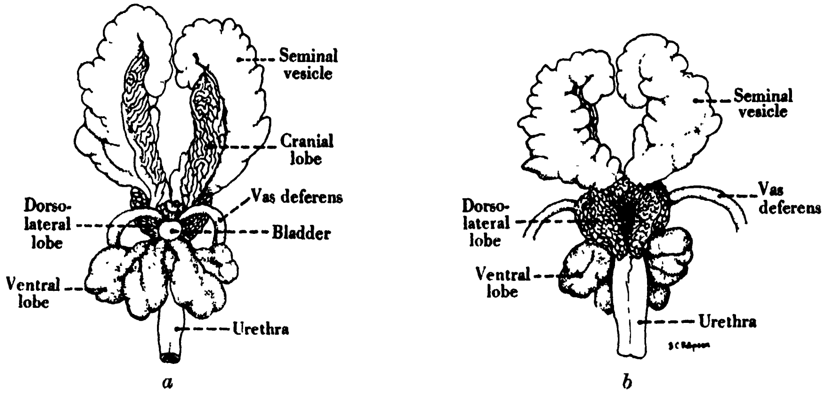

Fig. 1. Prostate and seminal vesicles of the rat. *a*, ventral view; *b*, dorsal view. The ventral lobes have been drawn back to expose the rest of the glands.

(2) Dorso-lateral lobes lying round the base of the seminal vesicles and almost encircling the urethra. Moore, Price and Gallagher [1930] call these the middle lobes, whereas Walker calls them the posterior lobes.

(3) Ventral lobes attached to the caudal end of the prostate only by their ducts. These are the posterior lobes of Moore, Price and Gallagher [1930] and the anterior lobes of Walker [1910].

In addition to these lobes there is a pair of small ventral ampullary glands at the point of entry of the vasa deferentia, which for weighing purposes may be included with (2).

The bulk of the rat prostate is made up of the dorso-lateral and ventral lobes, which are much better developed than the corresponding structures in the mouse. Since these react more readily to male hormone than the cranial lobes or the seminal vesicles, the rat is a more satisfactory test animal for small doses than the mouse.

The rat seminal vesicles are shown in Figs. 1 *a* and 1 *b* and require no description here.

The dissection and weighing of the accessory glands were carried out as follows: the entire reproductive tract was dissected free of fat, fixed in Bouin's fluid and then transferred to 70 % alcohol. At this stage the cranial prostate lobes were dissected off the seminal vesicles and the latter freed from the dorso-lateral lobes and removed for separate weighing. Next, the ventral and dorso-lateral lobes were freed from the urethral musculature by dissection from the caudal region and the vasa deferentia were cut off at their points of entry. After removal of the bladder and of any remaining connective tissue, the dissected prostate consisted almost entirely of glandular substance. In the larger prostates the three pairs of lobes were weighed separately but this was not done for the smaller glands. Dissection was carried out as rigorously as possible, but naturally prostates of 15–40 mg. were more difficult to dissect cleanly and accurately than the larger glands. All glands were thoroughly drained before weighing. No glandular tissue from inside the urethral muscle was included with the prostate, since it was desirable to simplify and standardise the dissection as far as possible.

(*b*) *The mouse.* The mouse seminal vesicles and prostate have already been described [Deanesly and Parkes, 1933]. The method of dissection used in this work was the same as before; the seminal vesicles, with the cranial (anterior) lobes of the prostate attached to them, were cut off after fixation at the level of the entry of the vasa deferentia and weighed together. The mouse prostate, particularly when atrophied, is unsuitable for clean dissection and weighing.

(*c*) *The guinea-pig.* The guinea-pig prostate has been described by Walker [1910] and Engle [1926]. Although consisting of the same three pairs of lobes it is less compact and well-developed than that of the rat and accordingly less suitable for quantitative work with male hormone, since its sensitivity is much the same as that of the rat.

The seminal vesicles of the guinea-pig are elongated tubular structures which regress after castration more slowly than those of the rat or mouse. They were dissected out from the prostate after fixation and weighed separately.

IV. GROWTH OF THE PROSTATE AND SEMINAL VESICLES OF THE RAT.

The growth and post-castration atrophy of the accessory reproductive glands of the normal mouse have already been dealt with [Deanesly and Parkes, 1933], and the growth of the seminal vesicles of the guinea-pig will be described elsewhere [Deanesly and Rowlands]. As a control on the experiments in Sections V and VI however it was necessary to make an extensive study of the growth of both the prostate and seminal vesicles of the rat. All animals used were albino and belonged to the Institute's stocks.

Growth of the prostate and seminal vesicles. The weights of the prostate and seminal vesicles were obtained in 79 normal rats, ranging in body weight from 42 g. to 250 g. The gland weight, plotted against body weight, is shown in Figs. 2 and 3, and the curves drawn through the same points are shown in Figs. 4 and 5 as a standard against which the experimental results described in Section V can be compared. In order to facilitate comparison, the growth curve for the seminal vesicles has been superimposed as an interrupted line on the prostate diagram and *vice versa.*

Although the figures show considerable variations in gland size in relation to body weight, especially in the smaller rats, the main trend of growth is quite clear. In both prostate and seminal vesicles little appreciable enlargement occurs before the body weight is 100 g. In this slight early growth the seminal vesicles, which start very much below the prostate, lag behind still farther, so that at 90 g. body weight the prostate averages about 80 mg. while the seminal vesicles are only about 20 mg. Above 100 g. body weight both the glands enlarge very rapidly and tend to approximate in size. At 150 g. body weight the prostate is rather above and the seminal vesicles rather below 300 mg. At 180 g. body weight both are about the same at 500 mg., while soon after 200 g. body weight the glands attain what appears to be their full weight of 700–800 mg. each. Above a body weight of 250 or 275 g. the prostate and seminal vesicles of the rat do not seem to show any regular increase in size although both may occasionally reach a weight of 1 g. in large rats. In some large animals however, presumably old ones, both seminal vesicles and prostate have obviously regressed. The initial lag in the growth of the seminal vesicles suggests that they have a threshold requirement different in kind or degree from that of the prostate.

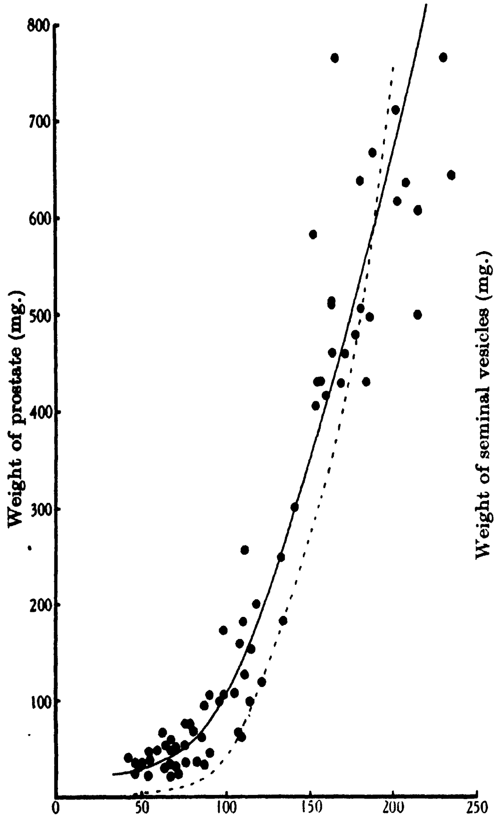

Fig. 2.

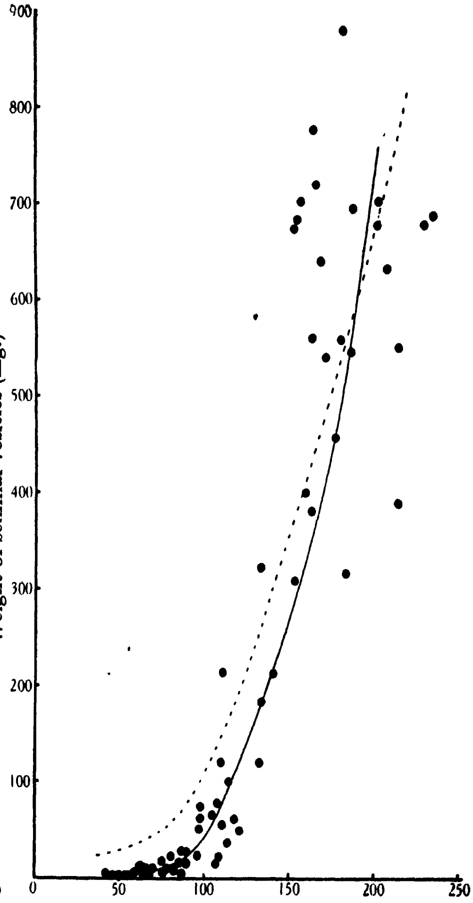

Fig. 3.

Fig. 2. —— Growth of prostate in the normal rat; ---- growth of seminal vesicles for comparison.

Fig. 3. —— Growth of seminal vesicles in the normal rat; ---- growth of prostate for comparison.

V. Maintenance of the prostate and seminal vesicles of the rat after postpubertal castration.

Previous workers have shown that in the adult rat, as in the mouse, considerable atrophy of the accessory glands takes place in the first fortnight after castration. Certain "maintenance" experiments have been carried out in which attempts have been made to replace testicular activity in sexually mature rats by injections begun immediately after castration. Since some body growth takes place in the 14 days' course of the experiments, complete maintenance of the accessory glands in their normal relation to body size implies not merely maintaining the size of the glands at the time of castration but actually inducing normal growth.

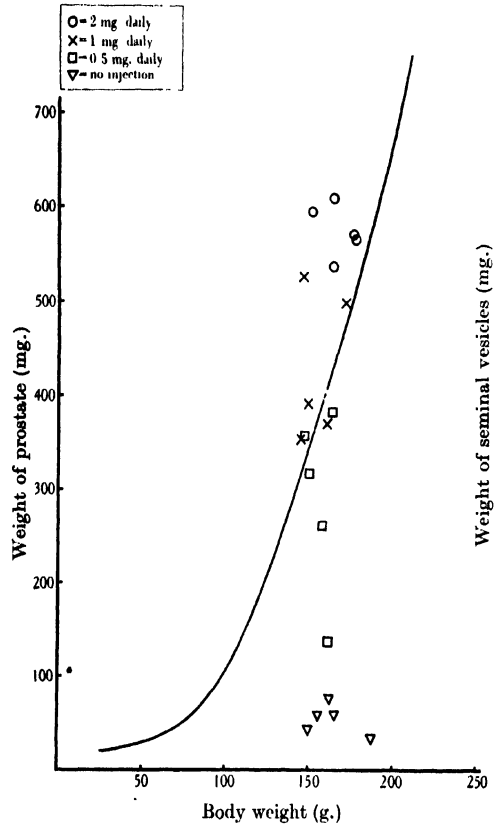

Fig. 4.

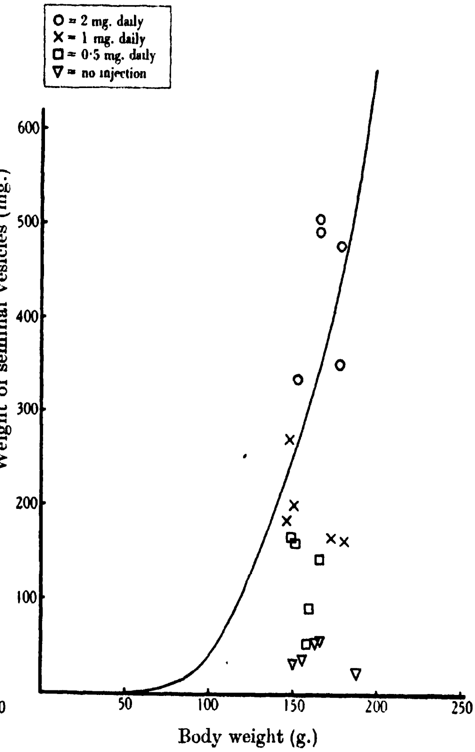

Fig. 5.

Fig. 4. Maintenance of prostate in postpubertally castrated rats by injection of androsterone.

Fig. 5. Maintenance of seminal vesicles in postpubertally castrated rats by injection of androsterone.

Three groups of five rats each of 130–155 g. body weight were castrated and injected with androsterone in arachis oil for 14 consecutive days and then killed 24 hours after the last injection. Rats of the first group were given 0·5 mg. daily, those of the second 1 mg. daily and those of the third 2 mg. daily. The weights of the prostate and seminal vesicles at autopsy are shown in Figs. 4 and 5 and Table II in relation to the normal growth curve and to their weights in uninjected normal and castrated groups.

It will be seen that:

(*a*) The prostates of all the rats receiving 1 or 2 mg. daily and of 4 of those receiving 0·5 mg. are substantially normal in size. Considered as groups, those receiving 2 mg. are rather above normal size, those receiving 1 mg. (slightly smaller animals) are almost normal, whilst those receiving 0·5 mg. are below normal (Table II).

Table II. *Growth and maintenance of rat accessory glands after postpubertal castration.*

No. of rats	Condition	Daily injection of androsterone mg.	Av. body wt. at castration g.	Av. body wt. at autopsy g.	Av. prostate wt. mg.	Av. seminal vesicles wt. mg.
5	Normal	—	—	139	283	230
5	Normal	—	—	162	511	474
5	Normal	—	—	198	624	650
5	Castrated	3	199	212	867	665
1	Castrated	—	220	205	128	168
5	Castrated	2	138	167	577	431
5	Castrated	1	138	155	429	204
5	Castrated	0·5	141	157	291	122
5	Castrated	—	138	165	55	51

(*b*) The seminal vesicles have been less well maintained. All rats receiving 2 mg., 3 of those receiving 1 mg., and 2 of those receiving 0·5 mg. have seminal vesicles approximately normal in size, but the average seminal vesicle weight in all groups is below that of the controls, although the difference is probably not significant for the group receiving 2 mg. daily.

It is apparent that while 1 mg. of androsterone daily will maintain the prostate in rats of this size after removal of the testes, about twice as much is required to maintain the seminal vesicles. This obvious difference in threshold requirement (noted in earlier qualitative experiments by Moore and Gallagher, [1930, 2; Hansen, 1933]) can be associated with the difference in size in the early stages of growth.

Hansen [1933] estimates the maintenance requirements of seminal vesicles of adult rats at six or seven of Gallagher and Koch's capon units of testicular extract [Koch, 1932], whereas two such capon units are ample for the prostate.

In order to ascertain whether the larger glands of larger rats required a correspondingly increased amount of hormone for maintenance, a group of 5 rats 185–230 g. in weight were castrated and given 3 mg. daily for 14 days and then killed. The seminal vesicles averaged 665 mg., and, allowing for normal variation, were apparently fully maintained (Table II). The prostates averaged 867 mg. and were, if anything, exceptionally large. Only one uninjected castrated control was used for this group, since the previous experiments had shown that the glands of rats receiving injections should be compared with normal ones rather than with those of castrates.

VI. STIMULATION OF THE PROSTATE AND SEMINAL VESICLES OF THE RAT AFTER PREPUBERTAL CASTRATION.

(*a*) *Body weight at castration; size of prostate and seminal vesicles.* In the experiments recorded below an attempt was made to stimulate rudimentary accessory glands with male hormone preparations. Rats were castrated at 35–70 g. weight, the majority at 40–50 g., before prostate or seminal vesicles had grown appreciably. In ten normal rats, 51–67 g. in weight, the average prostate size was 34 mg. and that of the seminal vesicles 4 mg. A control series of 16 uninjected rats, castrated at 35–70 g. and killed 16–68 days afterwards (with the same body weight range as the experimental animals), had prostates averaging

16 mg. (9–25 mg.) and seminal vesicles of 4 mg., the latter unaffected in weight by castration. These rats obviously provide a very low starting point for growth experiments. The figures given by Freud [1933] and David *et al.* [1934] for rats of this size and smaller are of the same order, but are rather lower for the prostate and higher for the seminal vesicles. Apparently in their method the whole prostate is not weighed together; the seminal vesicles are weighed (fresh) with a connecting bridge of prostatic tissue, and of the rest of the prostate only the weight of the "anterior" lobes is given. The peri-urethral tissue is weighed separately. Exact comparisons with the present experiments cannot therefore be made. To the differences in presenting the data must be added the fact that the Amsterdam workers in earlier experiments inject the young rats only 3 days after castration. More recently, Dingemanse *et al.* [1935] give the average weight of the prostate and seminal vesicles in 5 prepubertally castrated rats as 8 mg. and 6 mg. respectively.

The figures (50–70 mg.) given by Korenchevsky *et al.* [1932, 1934, 1, 2], although relating to Bouin-fixed prostate and seminal vesicles from prepubertally castrated rats, are so much higher than our own that they imply a difference of technique.

(*b*) *Method of testing.* Rats were injected, generally in groups of 5, beginning 20–90 days after castration. No attempt was made to standardise either the time after castration or the body weight of the animals at the time of injection, since the series of control rats showed that these factors did not influence appreciably the size of the rudiment. Most of the rats were injected at 100–220 g. weight [*cf.* Dingemanse *et al.*, 1935]. The dose is generally expressed as the total dose per rat.

Different preparations and amounts of male hormone were injected into groups of 5 prepubertally castrated rats, for a period of 10 days unless otherwise stated, after which the animals were killed and the growth and anatomical changes in the accessory glands were noted.

(*c*) *Administration of androsterone.* Ten groups of rats were given androsterone alone; the details are set out in Table III.

Table III. *Effect of androsterone on the immature castrated rat.*

No. of exp.	Days injected	Total dose per rat mg.	Medium and amount daily (ml.)	Average weight of Prostate mg.	 Seminal vesicles mg.
34	5	3·5	2·5 10% alcohol	37	9
33	10	3·5	1·0 "	67	11
44	10	4·0	2·0 "	57	8
42	10	20·0	0·1 70% "	170	56
38	10	3·5	0·1 arachis oil	44	9
56	10	6·0	0·1 "	64	14
45	10	10·0	0·1 "	112	32
57	10	15·0	0·1 "	129	17
46	10	20·0	0·2 "	129	26
63	28	28·0	0·1 "	394	46

The average weights of prostate and seminal vesicles in control rats are 16 and 4 mg. respectively. There are 5 rats in each experiment except No. 56 where there were 6.

It is immediately obvious that androsterone does not produce such striking growth in the accessory glands of the castrated rat as can be produced by oestrin in the uterus of the ovariectomised female. In the case of the seminal vesicles particularly, the growth is trifling compared with that of the normal gland. The following observations may be made with reference to these experiments.

(i) From experiments 33 and 34, it is clear that a small dose is more effective when spread over 10 days than over 5 days. From experiments 46 and 63, it also seems that the efficiency of large doses on the prostate can be greatly increased by extending the time over which administration is spread.

(ii) A comparison of the five groups receiving graduated amounts of androsterone in arachis oil over 10 days (Exps. 38, 56, 45, 57, 46, Fig. 6) suggests that the maximum growth in that period will produce a prostate of only about 130 mg. Certainly, very little is gained by increasing the total dose from 10 mg. to 20 mg. It is clear however that a prostate can actually grow to a greater weight than 130 mg. in 10 days. Thus in experiments with immature 40–50 g. normal rats, prostates averaging nearly 200 mg. were produced as the result of testicular stimulation for 10 days with prolan injections. In other experiments with androsterone (*e.g.* Exp. 42), prostates of more than 130 mg. were produced. The response of the seminal vesicles was poor in all the five groups referred to above, a total dose of 10 mg. androsterone actually giving the greatest effect.

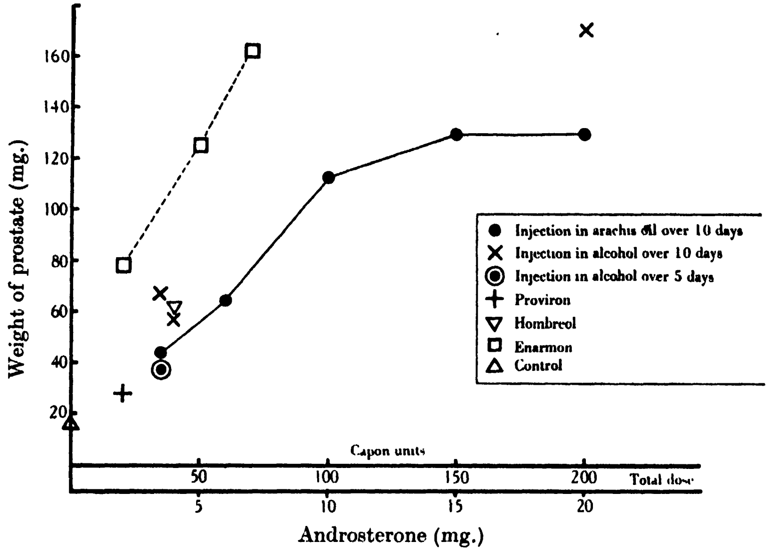

Fig. 6. Growth of prostate in prepubertally castrated rats by injection of male hormone.

(iii) It is possible that the relative ineffectiveness of the large doses may have been due, at least in part, to inefficient absorption of the material from oil. The old observation that oil is a bad medium for subcutaneous injection of rodents is amply confirmed by these experiments. Thus 3·5 mg. given as a colloidal solution in aqueous alcohol caused apparently twice as much growth in the prostate as the same amount of androsterone given in 0·1 ml. of oil daily. Similarly a total dose of 20 mg. in 70 % alcohol produced a much better effect than a total of 20 mg. in 0·2 ml. of oil daily. The increased growth of the seminal vesicles was particularly noticeable in Exp. 42. Both prostate and seminal vesicles in this group of rats show a greater approach to their maximum 10-day growth. It is difficult to ascribe these differences to any factor other than better absorption from the aqueous-alcoholic solutions. Unfortunately, only very dilute colloidal solutions in 10 % alcohol can be made, and the stronger alcoholic solutions caused bad local reactions. It should be noted that even where intramuscular injection of the oil is possible, as in the capon, aqueous media appear to be more efficient.

(iv) Exp. 63, in which the rats were injected with 1 mg. androsterone daily for 28 consecutive days, gave a very interesting result. The prostate size was nearly 400 mg., more than three times as large as that produced by a daily dose of 1·5 mg. for 10 days, but the seminal vesicles, as in all the experiments recorded in Table III, were small, weighing 46 mg., and consequently the relationship between the size of the two glands was quite abnormal for that stage of prostate development [*cf*. Korenchevsky, 1935]. In a normal rat with a 400 mg. prostate the seminal vesicles would be very similar to it in size.

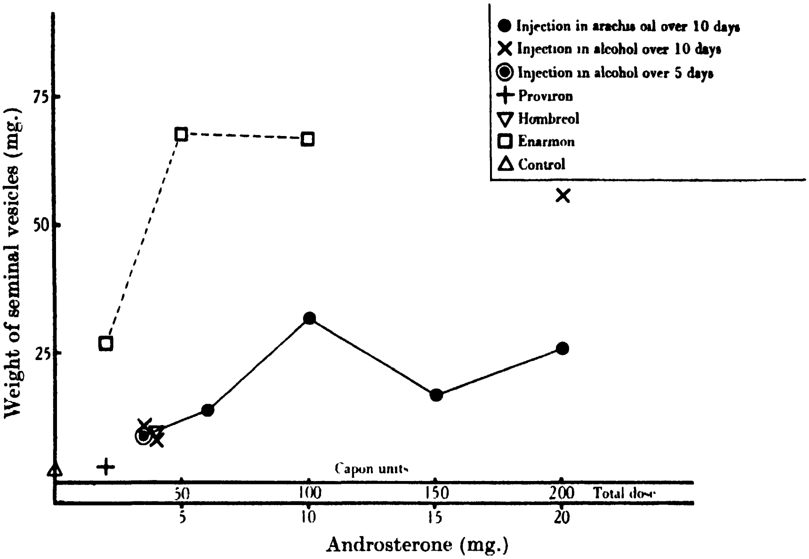

Fig. 7. Growth of seminal vesicles in prepubertally castrated rats by injection of male hormone.

This suggests that although androsterone in sufficient doses will maintain the seminal vesicles in a normal condition after castration and will also grow them from a rudimentary size up to a stage containing secretion, yet it is not as active on these glands as male hormone preparations from testis [Dingemanse *et al.*, 1935] or urine (Table IV). It is noteworthy however that Moore, Hughes and Gallagher [1930], who injected immature castrated rats for as much as 20 or 40 days with testis extract, never produced seminal vesicles of anything approaching normal adult size. This of course may have been due to absorption difficulties.

(*d*) *Administration of male hormone urine concentrates*. Five experiments were carried out, one each with "Hombreol" and "Proviron", and three with "Enarmon". The details are given in Table IV and Figs. 6 and 7. The results relating to both prostate and seminal vesicles are quite clear. Assuming 10 capon units per mg. of androsterone, Fig. 6 shows that a capon unit of either "Proviron" or "Hombreol" has about the same effect on the prostate as a capon unit of crystalline androsterone. The same conclusion may be drawn from Fig. 7 for the seminal vesicles. There is thus presumptive evidence that the only active principle of the two concentrates is androsterone. The activity of "Enarmon"

Table IV. *Effect of male hormone oil concentrates on the immature castrated rat.*

						Average weight	
No. of exp.	No. of rats	Male hormone	Capon units per ml.	Total dose per rat in C.U.	Days injected	Prostate mg.	Seminal vesicles mg.
52	5	"Proviron" (1933)	20	20	10	28	3
51	5	"Hombreol"	22	40	9	62	10
37	3	"Enarmon"	10	20	10	78	27
47	5	"Enarmon"	10	50	10	125	68
55	4	"Enarmon"	10	70	10	162	67

per capon unit however is more than twice as great as that of crystalline androsterone, "Hombreol" or "Proviron". The effect on the size of the seminal vesicles is more than 4 times as great. This clearly indicates that the comb growth promoting principle in "Enarmon" is not ordinary androsterone, or else that one or more supplementary substances with little or no effect on comb growth, but active on the accessory glands of rats, are present in addition to androsterone. In view of the work of Freud [1933] and David *et al.* [1934] confirmed by Korenchevsky and Dennison [1934, 1, 2], an obvious suggestion seemed to be that it was the small amount of oestrogenic substance present in "Enarmon" which was causing the difference in response. On the other hand, the fact that the prostate, which is much less affected by oestrone over short periods than the seminal vesicles, also showed the increased response, made this doubtful. The possibility was investigated by experiments on the effects of oestrone alone and of androsterone *plus* oestrone.

(*e*) *Administration of oestrone alone.* Two experiments were carried out with oestrone. The first group of rats was given 0·1 mg. oestrone each over 10 days, and the second 1·0 mg. The results in the two groups are identical and may be considered as representing the maximum development of rudimentary male accessory glands on oestrone alone in 10 days. The prostates showed some enlargement, possibly up to 50 %, while the seminal vesicles showed an increase to about 3 times the control weight (Table V). Allowing for the differences in the control weights and the duration of injection, these results are entirely similar to those obtained by David *et al.* [1934] and Korenchevsky and Dennison [1934, 1] except that the former obtained a rather greater effect on the prostate.

Table V. *Effect of oestrone alone and of androsterone* plus *oestrone on groups of immature castrated rats.*

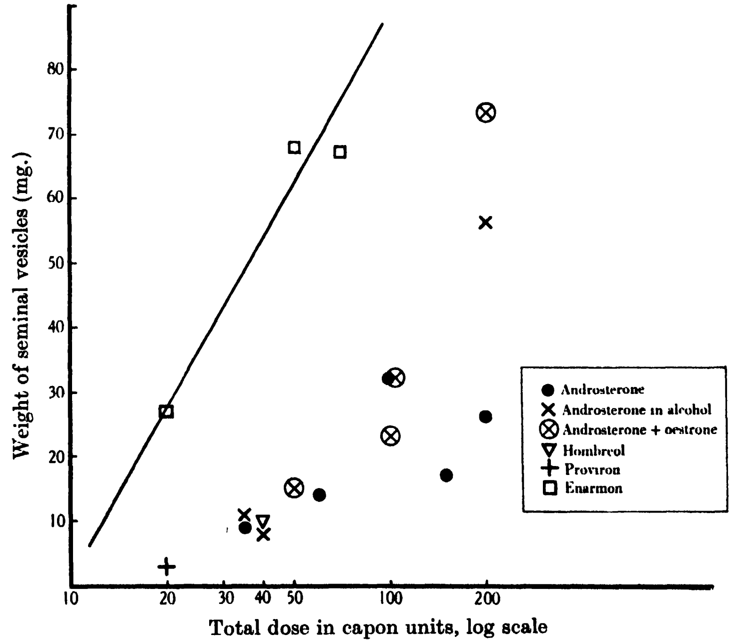

Fig. 9. Relation between growth of seminal vesicles and log dose.

of oestrone varying from 25γ (250 international units) to 1 mg. were given over 10 days; the amount of androsterone varied from 5 mg. to 20 mg. From the results in Table V it will be seen that in 3 of the 4 experiments no increase as compared with the androsterone series in Table III was evident in either seminal vesicles or prostate. In Exp. 41 the maximum dose of androsterone, *plus* 100γ oestrone, produced a prostate almost identical in size with that produced by the same dose of androsterone alone (Table III). The combined dose produced seminal vesicles slightly larger than the same dose of androsterone alone, but even so, 200 capon units of androsterone *plus* oestrone produced seminal vesicles hardly larger than those resulting from 50 capon units of "Enarmon". These results show that, under the conditions of the experiments, there is no synergistic action between androsterone and oestrone. At most there is a summation of the two different responses, the size increase of the seminal vesicles with oestrone being more marked than that of the prostate. These experiments lend no support to the idea that the extraordinary efficiency of "Enarmon" per capon unit can be due to its slight oestrin content. In Figs. 8 and 9 the responses of the prostate and seminal vesicles, respectively, have been plotted against the logarithm of the dose in terms of capon units, on the supposition that the logarithmic relation might be followed. It is actually found that in the case of the prostate (Fig. 8) the points fall roughly on two lines. There is no clear distinction between the points corresponding to androsterone, whether in oil or alcohol, androsterone *plus* oestrone, "Hombreol" or "Proviron". The results with "Enarmon" however fall quite outside the range of the others on a separate line corresponding to an activity per capon unit about three times that of the other substances. In the case of the seminal vesicles (Fig. 9) the inherent variability of the test object causes difficulty, but it is possible to suggest a line passing through the "Enarmon" points corresponding to about four times the activity per capon unit of the other materials.

(*g*) *Administration of* iso*androsterone*. Five immature castrated rats each received a total dose of 24·5 mg. of *iso*androsterone given in 0·2 ml. arachis oil daily for 10 days. This was equivalent in capon units to 4·0 mg. of androsterone, and although the reaction to the *iso*-hormone was slightly less than to 3·5 mg. of androsterone in oil (prostates 37 mg., seminal vesicles 6 mg.), it is doubtful if it was significantly different, especially in view of the larger volume of oil used for the *iso*-hormone. It is hoped to make further experiments on this substance.

VII. EXPERIMENTS ON MICE.

(*a*) *Stimulation of growth in rudimentary or vestigial seminal vesicles*. Attempts have been made to grow the rudimentary (2 mg.) seminal vesicles in mice, some time after prepubertal castration. Crude testis and urine extracts, administered in various forms, have been employed, the mice being usually injected for 10 days before killing. Many of the extracts either were not absorbed or had a deleterious effect on the animals, and insufficient material has been available up to date in a suitable form for the preparation of a dose-response curve on mice. Although it is easy to produce cytological changes in mouse seminal vesicles, such as have been described by Voss and Loewe [1931], the organs have in most experiments shown very small weight increases (up to 8–10 mg.) after 10 days' injection. Such a period is long enough under optimum conditions of dosage to produce seminal vesicles up to 140 mg. Ten days' stimulation of the testes of 10 normal immature 10–15 g. mice by prolan produced seminal vesicles having an average weight of 101 mg. The largest seminal vesicles so far developed in an immature castrated mouse weighed 46 mg.; this animal had received about 100 capon units of a urine concentrate in 10 days. A crude testicular extract produced growth of seminal vesicles to a weight of 35 mg. in another mouse, which was given 6 injections on alternate days and then killed 10 days after the last injection. A group of five immature castrated mice each received a total of 3·5 mg. androsterone in dilute alcohol during 10 days; the seminal vesicles were very small, averaging just over 5 mg., but the epithelium was glandular in comparison with that of a castrated control.

Experiments with crude extracts were also carried out on mice castrated postpubertally at various body weights; in these the seminal vesicles had atrophied completely and weighed 5–20 mg. Such seminal vesicles naturally reached a larger size than those of the immature castrates, but the extent of their reaction was more difficult to gauge owing to the greater variation of the vestigial gland. In these tests seminal vesicles of 30–40 mg. were not uncommonly produced, but the largest ones obtained were only 58 mg. after 10 days' injection with testis extract, and 50 mg. after a total of 16 capon units of "Enarmon", compared with 20 mg. controls. On the whole the larger initial size of the atrophied adult, as against the rudimentary, seminal vesicles, probably does not counterbalance the disadvantage of their greater variability, although the weighing of the seminal vesicles after small doses of male hormone can be more readily carried out.

(*b*) *Maintenance of seminal vesicles in adults.* Several attempts were made to maintain the size of the seminal vesicles for 10 or 14 days in castrated adult mice by means of injections of male hormone and of oestrin begun on the day of castration..

It was assumed from earlier work [Deanesly and Parkes, 1933] that there would be less variation in initial seminal vesicle weight if large mice with a body weight of 24–30 g. were selected for these experiments; they therefore differ from the maintenance experiments on rats (Section V), since they are concerned not with the period of rapid growth, but with the later phase of seminal vesicle enlargement in which the rate of increase is slackening. Unfortunately it is found that in such mice, 10 days after castration, the range of variation in seminal vesicle weight is so great that even in groups of 20, one or two animals in which the seminal vesicles have remained large will materially affect the group average, and in groups of 10 or less only a large difference in seminal vesicle weights from the controls can be considered significant. The results of these experiments, which can only be regarded as preliminary, are set out in Table VI; the controls include those mentioned in an earlier paper

Table VI. *Maintenance of mouse seminal vesicles after postpubertal castration.*

Average normal seminal vesicle weight 246 mg. at an average body weight of 27 g.

No. of exp.	Average body weight at castration g.	Days after castration	No. of mice	Daily injection	Average seminal vesicle weight mg.
Controls	27·5	10	39	None	100

[Deanesly and Parkes, 1933] with some additional mice. In all the experimental groups, except the 3 mice in Exp. 58, the average seminal vesicle weight is nearer to that of the corresponding castrated controls than to that of normal mice of the same body weight. Exp. 20, in which the seminal vesicle weights are below those of the controls, should probably be regarded as negative, since it is unlikely, though not impossible, that injections of oestriol would accelerate the shrinkage of the glands which at this stage is brought about mainly by the loss of secretion [*cf.* Moore and Price, 1932]. Exps. 12–14, 50 and 58, though far from conclusive, seem to show partial maintenance of the glands, and this is corroborated for the last two experiments by the histological appearance of the cranial (anterior) prostate attached to the seminal vesicles. It should certainly be possible to maintain the size of the mouse seminal vesicles after castration by injections of male hormone; the relatively large dose which seems to be needed is probably due to the conditions of absorption from oily solutions which are more unfavourable in the mouse than in the rat.

VIII. EXPERIMENTS ON GUINEA-PIGS.

Two groups of prepubertally castrated guinea-pigs were injected with androsterone alone and in conjunction with oestrone and were killed 24 hours after the last injection; the results are summarised in Table VII. The accessory glands of guinea-pigs, in our experience, are slower to shrink in weight after castration than those of the rat or mouse. After prepubertal castration there seems to be little or no shrinkage of the comparatively undeveloped glands. The high average weight for the prostate in the control castrated animals in Table VII is due to one animal in which it was exceptionally large. On such small numbers the figures for the average weights can only be regarded as approximate, but the results are very consistent. In the two experimental groups the average weights of prostate and seminal vesicles were almost exactly the same; the addition of oestrone had not reinforced the androsterone, and the experiment confirmed the conclusion reached as the result of experiments with rats (Section VI *f*). A total dose of 15 mg. androsterone caused an increase in the seminal vesicles from 40–50 mg. to 120 mg., which suggests that they are more responsive to this substance than are the rat seminal vesicles: the effect however may be due less to greater sensitivity than to the larger size of the rudiment. The prostate had also tripled in size in the experimental guinea-pigs; its average weight, 183 mg., may be compared with the average weight of the prostate, 129 mg., in rats receiving

Table VII. *Average weights of prostate and seminal vesicles in control and injected guinea-pigs.*

No. of animals	Body weight at castration g.	Body weight at death g.	Condition at autopsy	Average prostate weight mg.	Average seminal vesicles weight mg.
4	—	200	Normal immature	57	42
3	200	250–450	21–89 days after castration, not injected	76	53
3	193	473	88 days after castration: had 15 daily injections of 1 mg. androsterone in arachis oil	186	121
3	197	442	88–89 days after castration: had 15 daily injections of 1 mg. androsterone + 10γ oestrone in arachis oil	180	120

the same doses of androsterone over a slightly shorter period (Tables III and V). Allowing for the difference in size of the rudiment, the actual gain in weight in the two species is very similar.

IX. HISTOLOGICAL OBSERVATIONS.

(*a*) *Rats and mice.* The prostate and seminal vesicles of one or more animals from most of the experimental groups were examined microscopically, all material having been fixed in Bouin's fluid as a routine. Sections were cut at 7μ and 10μ and stained in haematoxylin and eosin. Since the histological changes in the rudimentary accessory glands of rats and mice giving a positive response to male hormone have been described in detail in a number of papers by earlier workers already cited, no account of these will be given here. The present observations were intended to be mainly quantitative and histological examination was used as a means of distinguishing any abnormal growth stage that might be produced experimentally, *e.g.* by oestrin injections [David *et al.*, 1934]. The glands from injected rats were therefore compared with normal seminal vesicles and prostates of similar weight, as well as with those of the appropriate castrate controls. Owing to the variations both in the normal growth rate of the accessory organs and in the structure of different parts of the glands, a histological basis for standardising extracts seems undesirable if not impossible. Hansen [1933] has drawn attention to some of the difficulties involved.

Since the rat prostate lobes differ histologically [Walker, 1910], complete serial sections were cut through the glands of a young animal (one in five being mounted). These showed that, at the early spermatogenetic stage examined, three types of glandular tissue could be distinguished in the cranial, dorso-lateral and ventral lobes respectively. Moore, Price and Gallagher [1930] describe the last two as histologically similar but actually, though both are prostatic in type, they can be readily distinguished in section, since there is less fibrous tissue in the ventral lobes and the alveoli are much larger. For routine examination transverse sections were cut through a ventral prostate lobe, the cranial lobe being similarly examined in some rats and in the adult experimental mice.

The general conclusions drawn from the histological observations may be summarised as follows:

(1) In the rat maintenance experiments (Section V) all prostate sections examined appeared to be histologically normal; they showed none of the castration changes described by Moore, Price and Gallagher [1930]. No attempt was made to section the seminal vesicles in these experiments, since the weights seemed to be an adequate guide to their condition.

(2) The developing prostates of the prepubertally castrated rats injected with androsterone were not obviously different in any way from normal glands of the same size. In other words, androsterone, *iso*androsterone and the urine concentrates tested will all cause normal development to a greater or lesser extent in a gland ordinarily controlled by the secretion of the gonad. When oestrin is injected in conjunction with the male hormone, the greater activity of the latter on the prostate tends to mask any oestrin effect. Further, if oestrin is injected alone for 10 days the reaction of the rat prostate is very slight [David *et al.*, 1934] and not easily distinguishable in section.

The largest seminal vesicles grown with androsterone in prepubertally castrated rats weighed only 82 mg.; they appeared to be histologically normal for their size and contained secretion. The largest glands produced by the same dose of androsterone (20 mg.) *plus* 100γ of oestrone weighed 94 mg. and were slightly better developed, but similarly normal. The only essential effect of the oestrone seems to be the acceleration of the earliest stages of seminal vesicle growth by the development of fibrous tissue [David *et al.*, 1934; Korenchevsky *et al.*, 1934, 1, 2]. This is well shown in the rats receiving oestrone alone, where the seminal vesicle epithelium has not reacted. No fresh observations worth recording were made on the seminal vesicles of immature castrated mice receiving male hormone injections. The cranial (anterior), prostate lobes of the mice injected with 1 or 2 mg. of androsterone daily in the maintenance experiments show some alveolar shrinkage as compared with the prostates of normal mice, but the epithelium is comparatively normal and is still secreting.

The adrenals were examined from 7 injected mice and 5 controls from these experiments (Nos. 50 and 58, Table VI) in order to see whether male hormone had inhibited the changes towards a female type of cortex normally following castration [Howard-Miller 1927; Deanesly, 1928]. The zona reticularis, which tends to atrophy in the 21-day male mouse and can hardly be distinguished in the adrenal of the adult, reappears after castration and forms a dark-staining band round the medulla, consisting of small cells free from fatty inclusions. No distinction could be made however between the experimental and control groups. It is probable that the adrenal is not affected directly by the testicular hormone, but only indirectly through the pituitary, and the present injections of androsterone were inadequate to influence the latter gland.

(*b*) *Guinea-pigs.* The seminal vesicles and prostate were examined histologically in one animal from each of the groups listed in Table VII. In the immature 200 g. guinea-pig the seminal vesicles and prostate, though small, are already actively secreting. In the corresponding castrated animal, which has the largest accessory glands in the group, the glandular epithelium appears definitely inert, but its regression is much less conspicuous 89 days after castration than in a similar mouse or rat. The prostatic alveoli are as large as in the corresponding normal animal, but the epithelium is disorganised. In guinea-pigs from both experimental groups, the seminal vesicles and prostate, including the coagulating glands, showed well-marked growth and secretion, and there were no obvious differences between the two. The histological changes were of the usual type, including distention of the prostatic alveoli and of the seminal vesicles, and need not be described in detail.

X. Discussion.

The most striking observation in the course of this work is that, although maintenance of the accessory glands of postpubertally castrated rats was achieved, the highest doses of androsterone administered for 10 days failed to produce much growth of the accessory organs of prepubertally castrated rats. In particular, androsterone seems least effective on the seminal vesicles. Although the growth of these glands normally starts later than that of the prostate, yet in the experimental animals receiving androsterone, the seminal vesicles tended to remain disproportionately small. Moreover, when, as in the 28-day experiment, there was considerable growth of the prostate, that of the seminal vesicles lagged far behind. Even when allowance is made for inefficiency in the form of administration and unsatisfactory absorption, there would be some difficulty in assuming that sufficient androsterone is normally secreted by the testis to account for its male endocrine activity.

A clue to the existence of other active substances is provided by comparison of a concentrate from natural sources with androsterone on the basis of two different responses, namely, growth of the comb in the capon and of accessory organs in the rat. It is then found that one concentrate from urine, "Enarmon", when administered to rats in the same dosage as androsterone, on the basis of capon units, is several times as active as the latter, the contrast being particularly marked in the effects on the seminal vesicles (Figs. 8 and 9). The discrepancy is analogous, in fact, to that which has been observed in the last four years in the comparison of male hormone concentrates from testis and from urine. In 1931, Laqueur, de Fremery *et al.* discussed fluctuations in the ratio rat unit/bird unit in preparations from testis, and, in a later paper Laqueur, Dingemanse *et al.* [1931] speak of a "seminal vesicle hormone". They followed this work by putting forward the view that testicular extracts were superior to urine extracts on mammals [Freud and Laqueur, 1934; Freud, 1934; Dingemanse *et al.*, 1935][1]. The assumption that testicular extracts contain an active substance chemically different from that in urine extracts is confirmed by the work of Gallagher and Koch [1934, 1, 2; *cf.* also Matsuzaki, 1933, 1934; Ogata and Hirano, 1933].

There is some evidence however that crude urine concentrates may also contain a substance active on accessory glands which is lost on further purification. Our own results have shown a significant difference between "Enarmon" on the one hand and "Proviron" and "Hombreol" on the other. Korenchevsky also seems to have detected significant differences between urine concentrates of the same capon titre [Korenchevsky *et al.*, 1933, 1, 2; 1934, 2], though he emphasises rather the superiority of his own method of assay as a measure of male hormone activity than the implication that the materials differ in any essential way. Freud [1933] refers to "the loss of potency with respect to seminal vesicles without corresponding loss of potency in capons" when male hormone extracts are purified. This observation actually led the Amsterdam school to the abandonment, for a time, of the "seminal vesicle hormone" hypothesis, and to its replacement by the hypothesis that synergism of oestrin and male hormone stimulated complete seminal vesicle growth.

Undoubtedly, not only is oestrogenic material produced by the male organism, but oestrin itself has a definite stimulating effect on the fibromuscular tissue of the seminal vesicles [Freud, 1933]. The experiments recorded here however convince us that administration of a mixture of androsterone and oestrone does not reproduce the results of administration of a crude urine concentrate of slight oestrogenic potency. This point may be made clear by reference to Figs. 8 and 9, from which it is seen that with one exception the combination of oestrone with androsterone has little or no extra effect on the accessory organs as compared with androsterone alone. The exceptional case is that of the highest dose of androsterone *plus* oestrone, which caused slightly greater growth of the seminal vesicles (Tables III and V), but this is little more than that provoked by one-fourth the number of capon units administered in the form of "Enarmon". The reaction of the prostate to androsterone over 10 days was not increased by oestrone, and the greater activity of "Enarmon" was still obvious.

One is left therefore with the conclusion that crude urine extracts, and presumably testicular extracts also, contain some other androkinetic substance, either (*a*) supplementary to, or synergistic with, androsterone or (*b*) acting independently of androsterone, possessing a greater ratio of accessory organ activity to comb growth activity than androsterone and being the chief or only male hormone produced by the testis. The comparative success of the maintenance experiments and the nature of the histological findings suggest strongly that androsterone is quantitatively rather than qualitatively deficient and dispose of the necessity for a supplementary or synergistic substance. The existence in the body of a more active form of male hormone present to some extent in urine, and *a fortiori* in testis, is much more likely.

---

[1] *Note added to proof.* In a further short note, seen after completion of this paper, David and Freud (*Acta Brev. Neerl.* 1935, 5, 31) compare the activities of androsterone, "Hombreol" and testis extract on the growth of the accessory glands of immature castrated rats. Administered in equal capon unit dosage, the first two are of equal potency whereas testis extract is much more active, particularly on the seminal vesicles.

An analogy may be drawn between the male and female hormones in this connection. In each case the characteristic hormonal activity can be exercised by more than one compound. Oestrone and oestriol, both capable of producing the same effects, have a different ratio of activity on different test-objects, *e.g.* cornification of the vagina of the immature rat and of the ovariectomised adult. Oestradiol (so-called "dihydro-oestrin") appears to be the most active oestrogenic compound, and it is likely that it is the primary form of the oestrogenic hormone in the body, since it can be extracted from ovaries [Doisy *et al.*, 1935]. The artificially prepared dihydroxy-derivative of androsterone possesses a similarly enhanced activity in capons [Ruzicka *et al.*, 1935] but there is as yet no evidence of its natural occurrence or of its relative activities in mammals and birds. The analogies between the two hormones suggest strongly the possibility that there remains to be isolated from natural sources some derivative of androsterone which possesses not only a higher degree of activity but also a different ratio of activity on accessory organs in the mammal and on the comb of birds.

SUMMARY.

1. Androsterone, *iso*androsterone, and various urine concentrates have been tested on the accessory reproductive glands of castrated rats, mice and guinea-pigs.

2. Androsterone was injected into groups of adult rats for 14 days, beginning on the day of castration; 1 mg. daily was enough to maintain growth and normal structure in the prostate of 140–160 g. rats but more than 2 mg. daily were required for maintenance of the seminal vesicles. Larger rats, castrated and injected daily with 3 mg. androsterone, had prostates above the normal size and normal seminal vesicles.

In similar experiments with mice 1 and 2 mg. daily of androsterone failed to maintain completely the seminal vesicles or the cranial lobes of the prostate.

3. Androsterone, in both oily and alcoholic solution, was injected into groups of immature castrated rats for 10-day periods in an attempt to grow the rudimentary accessory glands; on a total dose of 20 mg. of androsterone the largest prostate produced in these experiments was 212 mg. or about a quarter of the full size, and the largest seminal vesicles were 82 mg., about one-tenth of the full size. In most of the androsterone experiments however, particularly with oily solutions, the seminal vesicles of the rats gave a very poor reaction as compared with the prostate. This was particularly obvious in a 28-day experiment; on 1 mg. daily the prostate reached a maximum of 433 mg. whilst the largest seminal vesicles were only 63 mg.

4. A comparison of different urine concentrates on the basis of the number of capon units contained in each showed that, whereas in two of them the effect per capon unit on the accessory glands of rats was much the same as that produced per capon unit (100γ) of crystalline androsterone, in the third urine preparation the activity on rats was more than three to four times as great.

5. It was shown that the activity of the most effective urine concentrate could not be reproduced by combined administration of oestrone and androsterone, which gave results little, if any, better than androsterone alone.

6. Experiments were also carried out with castrated mice and guinea-pigs.

7. It is concluded that certain urine concentrates may contain a male hormone other than androsterone, with a much greater activity per capon unit on the accessory glands of mammals.

We wish to thank Prof. L. Ruzicka for facilitating this work, Dr A. W. Greenwood for the capons used in the comb test, Prof. E. C. Dodds for a testis extract, and Mr T. F. M. Smart of Ciba Ltd. for his cooperation.

We are indebted to Dr A. S. Parkes for many useful suggestions and criticisms.

CLXXV. DIFFUSION EQUILIBRIA FOR THE ISOLATED FROG'S KIDNEY.

II. UREA.

By EDWARD JOSEPH CONWAY AND FRANK KANE.

From the Department of Physiology and Biochemistry, University College, Dublin.

(*Received April 9th, 1935.*)

In a previous communication [Conway and Kane, 1934] it was shown that urea existed in the normal frog's kidney considerably in excess of that in the blood or of the sartorius muscle. This latter was found to have a urea concentration which might be expected to arise from a passive equilibration with the blood, the urea diffusing into all the water of the tissue.

It was also shown that the urea in the normal frog's kidney diffused outwards at the same rate as it diffuses into or out of muscle or into the inactive kidney. The diffusion coefficient of urea was found to be the same for the kidney as for muscle within the error limits of such determinations, its value being $1 \cdot 1 \times 10^{-5}$ (cm.^{2}/min.).

In the present investigation the point of chief interest was to discover the urea diffusion equilibria for active and inactive kidneys immersed in urea solutions. It will be shown that urea passes from urea-Locke solutions into active kidneys having a lower urea concentration until the total concentration of the tissue far exceeds that of the external fluid. When the tissue is rendered inactive by cyanide the urea enters only to the extent that may be expected for a passive equilibration with the tissue water.

In this process a freely soluble substance is being concentrated by the active kidney and the form in which it is concentrated appears to leave it in free solution and in such a condition that it can diffuse outwards at the same rate as urea from the inactive kidney or from muscle.

The facts of this urea diffusion are of such importance for renal theory that the method used for the analyses should be very carefully certified to give accurate data for the true urea content. There is all the more reason for this as the urease ferment extracts as ordinarily prepared may react to produce ammonia with the frog's kidney in addition to the urea ammonia and the free ammonia which is formed in all such surviving tissues.

It will be shown that bringing the kidney suspension to the boiling point in a small tube, and then immersing this in boiling water for five minutes completely eliminates the production of "extra" ammonia (*i.e.* other than urea ammonia) by the urease ferment. The procedure also stops any further production of free ammonia in the tissue suspension itself.

The results so obtained with the urease method used on boiled tissue suspension have been compared with xanthydrol determinations in a sufficient number of analyses to show that both methods give identical results.

The nature of the "extra" ammonia formed by urease ferment extracts on fresh unboiled renal suspension is in itself of much interest, and though not concerning us particularly in this communication, some of the main conditions of its formation will be necessarily demonstrated in a critical analysis of the urease method.

As a result of this investigation of method it might be inferred that the results given in the previous communication were a little too high. The error would not exceed 7 mg. per 100 mg. kidney, and this amount does not invalidate any of the conclusions there drawn. It necessitated a further investigation of the diffusion coefficient. We expected to find this somewhat higher than in the last determination—namely about $1{\cdot}2\times10^{-5}$, instead of $1{\cdot}1\times10^{-5}$. However, the repeated determinations in November and December gave again the same figure (in fact very slightly less). We may explain this by supposing that the "extra" ammonia in the earlier experiments was, as previously considered, entirely negligible.

METHODS.

(a) *Urease method.*

The method used has been described in detail in previous communications [Conway, 1933; Conway and Kane, 1934]. In the present determinations a weighed amount of tissue was ground with a measured volume of water and a little pure quartz sand (Merck) in an agate mortar. The quantities used were such that 0·5 ml. of the centrifuged ground mixture contained as a rule about 5–20 mg. tissue. The fluid was decanted after centrifuging to another rather narrow tube, and after the level had been marked was brought momentarily to the boiling point. The tube was then immersed in a beaker of boiling water for five minutes, being covered with a watch glass. Any fluid loss was made up after cooling—the loss being generally negligible.

0·5 ml., as an aliquot part of the fluid, was transferred to the outer chamber of an absorbing "unit", the inner chamber containing 1 ml. 0·001 *N* sulphuric acid (made up with 20 % alcohol and containing methylene blue and methyl red [Conway and Byrne, 1933]. The remaining procedure has been already described in detail. The titrations at the end were carried out with 0·005 *N* carbon dioxide-free alkali from the horizontal micro-burette previously described [Conway, 1934].

The accuracy of the method. It has been already shown [Conway, 1933] that the degree of hydrolysis of the urea by the urease ferment, and the absorption of the formed ammonia proceed to 99 % at least of the theoretical. The relative absorption rate for ammonia quantities of say 10 γ ammonia-nitrogen is the same as for 10,000γ. The variable error of ammonia determinations down to quantities of 10γ ammonia-nitrogen was approximately 0·5 % expressed as a coefficient of variation. The determination of urea quantities of the order of 40γ urea-nitrogen had a coefficient of variation of 1·2 %. The slight difference may be attributed in part to the use of 1 ml. of fluid in one procedure and only 0·2 ml. in the latter. No very appreciable variable error is therefore introduced by the hydrolysis of the urea itself.

In the present investigation we are concerned with the analyses of urea or ammonia quantities of the order of 3γ of nitrogen or less. From an examination of the analyses of the ammonia content of the stock urease extract an excellent opportunity presents itself of examining the variable error in the routine determination of urea- or ammonia-nitrogen of about 1γ. In four experiments following on one another 20 such determinations were carried out. The average nitrogen analysed was 0·65γ. Eighteen of the results did not deviate from this figure by more than 0·1γ, the standard deviation of the series being 0·06γ. It is possible to reduce the error further by slower titrations and stricter attention to the practically complete absence of carbon dioxide from the titrating alkali. Without this refinement however the accuracy attained is quite sufficient for the present investigation and represents no more than 3–5 % error in the analysis of 3 γ of ammonia- or urea-nitrogen.

We doubt if any other method could compare with this for combined accuracy, simplicity and ease of working with such minute quantities of ammonia. The present and the previous communication are based on over 1000 such analyses.

The question of the "extra" ammonia produced by the urease extract. The various ammonia fractions (other than the reagent ammonia) that arise in a urease analysis of fresh kidney suspension may be listed as follows:

(1) Ammonia from the urea in the frog's kidney.

(2) Ammonia from such precursors as adenylic acid and formed in all such surviving tissues, the amount increasing with the time after removal.

(3) Ammonia formed from an interaction between some substance in jack bean extract interacting with some substance other than urea in the kidney.

To investigate the amounts and changes of these quantities during the course of extended incubation the following experiments were carried out, the volume and reaction of the analysed mixture being in each case the same. Groups of units were set up for the addition of 1 ml. of saturated potassium carbonate after various incubation times (conducted at 37°). These units contained the following mixtures in the outer chamber:

I. 0·5 ml. neutral phosphate (0·05 *M*).
0·5 ml. of centrifuged kidney suspension (containing about 5–20 mg. per ml.).
0·5 ml. glycerol (diluted 1 in 20).
0·5 ml. water.

I *a*. Same as I except that the centrifuged suspension was boiled in the manner already described.

II. 0·5 ml. of glycerol-urease extract (diluted 1 in 20).
0·5 ml. centrifuged kidney suspension.
0·5 ml. neutral phosphate (0·05 *M*).
0·5 ml. water.

II *a*. Same as II except that boiled centrifuged kidney suspension was used.

Similar units were set up containing the phosphate, glycerol and urease in the same volume of fluid, and also containing merely the phosphate and glycerol in order to ascertain the reagent ammonia.

Subtracting the reagent ammonia in each case, the ammonia from I and I *a* gives the free ammonia in the unboiled kidney suspension and the boiled respectively. Subtracting these values as well as the reagent ammonia from II and II *a* respectively one obtains the ammonia produced by the interaction of the urease ferment extract with the unboiled and boiled kidney suspensions.

Fig. 1 shows the mean results obtained in five experimental series, in each of which the incubation periods (before the addition of saturated carbonate) were maintained from 15 minutes to 3 hours.

A number of conclusions may be drawn from these results.

(1) After 15 minutes' incubation with urease all further ammonia formation stops in the boiled kidney suspension. The ammonia so formed (the original free ammonia being allowed for in Fig. 1) represents beyond any doubt the true urea content of the tissue and is identical with that found in xanthydrol determinations.

(2) The ammonia formed by the action of the urease extract on the fresh kidney suspension shows a linear increase up to 90 minutes' incubation and then remains steady up to 180 minutes. Extrapolation to zero time meets the line for the boiled suspension.

(3) The free ammonia of the boiled suspension also does not alter with incubation.

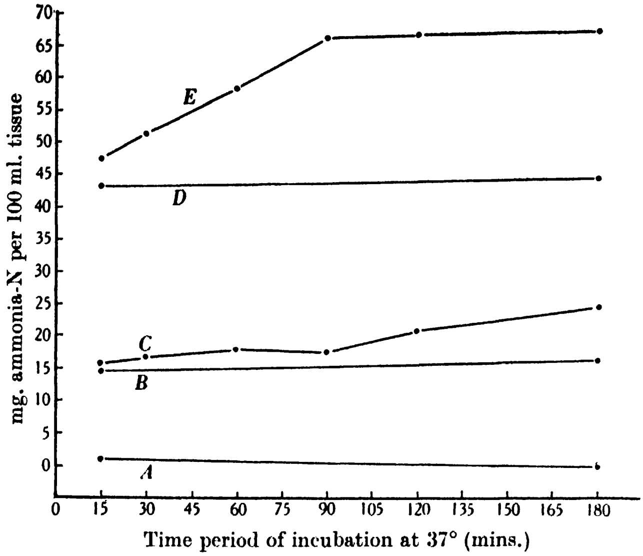

Fig. 1. The experiments from which the above figure is drawn are described in the text. The points are the means obtained in five experimental sets. *A*, Ammonia-N formed by interaction of boiled urease and kidney suspension; *B*, free ammonia-N in boiled suspension; *C*, free ammonia-N in unboiled suspension; *D*, ammonia-N formed by interaction of urease and boiled kidney suspension; *E*, ammonia-N formed by interaction of urease and unboiled kidney suspension.

(4) The free ammonia of the unboiled suspension rises slightly as the incubation time increases to 90 minutes and then begins to rise steeply. Clearly some marked change occurs around this period, with unboiled suspension under the above conditions. (The further precise elucidation of the "extra" ammonia formation by the interaction of the fresh kidney suspension and the urease extract does not concern us here. As a working hypothesis we may suppose however that a ferment such as arginase or a deaminase exists also in the urease extract and acts on arginine or a similar substance produced by proteolysis in the incubated tissue. Some further facts may be mentioned in support of this hypothesis. Doubling the concentration of the urease doubles the rate of formation of this "extra" ammonia. Doubling the concentration of the renal suspension causes the same result. Boiling the urease extract eliminates any ammonia formation due to the interaction of the extract and the suspension.)

(*b*) *Xanthydrol method.*

The xanthydrol method was also used in a certain number of analyses of kidney suspensions, diffusates and blood from the same frogs, to confirm further the findings of the urease method. In using this method 4 ml. of the renal suspension or diffusate containing approximately 1 mg. urea per 100 ml. were measured into a 15 ml. centrifuge-tube, and 1 ml. of the Tanret-Polonowski reagent was added (tungstic acid precipitation was used for the first experiment). The tube was centrifuged for 15 minutes, 4 ml. of the clear fluid being taken in another 15 ml. centrifuge-tube and 4 ml. of a xanthydrol mixture (freshly formed by the addition of 5 parts of 5 % xanthydrol in methyl alcohol to 3 parts of glacial acetic acid) added, the fluids being mixed with a thin glass rod. The mixture was allowed to stand overnight. It was then centrifuged for 15 minutes. The fluid was very carefully decanted and the tube allowed to drain upright for a few minutes on absorbing filter-paper. 2 ml. methyl alcohol saturated with dixanthydryl urea were then added to the tube and the solid residue was stirred up. The tube was again centrifuged and the procedure repeated. After the final centrifuging the draining was allowed to continue for 5 minutes and then the end of the tube wiped with filter-paper. Up to this point the method used was largely similar to that used by Rehberg *et al.* [1932]. The further procedure consisted in adding 2–5 ml. of 50 % sulphuric acid and stirring with a glass rod. This is an adaptation of the method used by Beattie [1928].

After some time the yellow colour produced was examined in a micro-colorimeter, using a standard formed by dealing in an exactly similar manner with 4 ml. of a 1 mg. per 100 ml. urea solution instead of the kidney suspension. Suitable blanks were also carried out. Duplicate analyses were made in each case and colorimeter readings taken by independent observers.

The normal relation between the urea concentrations in the blood and kidney of the frog (Rana temporaria).

The relation found in the spring frogs has a mean value of 45 mg. per 100 ml. blood to 85 mg. per 100 ml. in the kidney. A new series of 14 analyses, with the revised technique, on boiled kidney suspensions gave an average of 82 mg. per 100 ml. The corresponding blood values (for 10 experiments) were higher for these months (November to February) than in summer, giving an average value of 56 mg. urea per 100 ml. The individual results are given in Table I. For the blood analyses 0·1 ml. was taken from each frog and mixed, the analysis being subsequently carried out on the mixed blood.

In a series of seven experiments not only was the urea in the boiled kidney suspensions and corresponding blood samples determined, but also the amount that diffused freely outwards in two hours from the companion control kidneys. These were immersed in about 50 times their volume of Locke solution and stirred by a stream of oxygen. The average value for urea in the kidneys of this series was found to be 85 mg. per 100 ml. The analyses of the diffusate showed that on the average 75 mg. urea per 100 ml. kidney diffused out in two hours into the Locke solution. One set (No. 5 in Table I) shows an aberrant figure for the renal urea in relation to the diffused quantities. Omitting this as probably erroneous the average values are 83 mg. urea per 100 ml. for the kidney and 76 mg. urea diffused per 100 ml. The average blood value in these six sets was 55 mg. per 100 ml. An excess of 40 % over the blood urea value has therefore diffused freely from the kidneys in two hours.

An average value of 1·3 mg. urea per 100 ml. was present in the Locke solution at the end of the diffusion period and this we may presume to be in equilibrium with about 2 mg. per 100 ml. of kidney tissue. The total diffusing concentration was therefore 81 mg. urea per 100 ml., so that 94 % of the total possible has diffused in two hours (practically the same figure is maintained if we include two extra sets for which the blood analyses are not available, the average percentage diffused is then in fact 95.

Table I.

13	2	65	93	—	—	—	—	—	—
14	2	71	79	—	—	—	—	—	—

The amount of tissue analysed ranged from 7 to 13 mg. in 0·5 ml. of suspension. Where diffusions (2 hours' duration in Locke, stirred with oxygen) were carried out, one kidney from each frog was taken and the group transferred to Locke, the companion tissues being ground to a suspension in the usual way and analysed. For further details see text.

The average weight of the kidneys examined was 40 mg. and the theoretical amount that would diffuse in two hours—the diffusion coefficient being $1{\cdot}1 \times 10^{-5}$ is 98 %. The difference between the actual and the theoretical is therefore insignificant, and, as shown in section III, after three hours' diffusion 97 % is recoverable from the Locke fluid.

Table II.

No. of frogs	Av. wt. of single kidney mg.	Urea conc. of kidney mg. per 100 ml.		Urea diffused in 2 hrs. mg. per 100 ml. of kidney		Urea conc. of blood mg. per 100 ml.	
		Urease	Xanthydrol	Urease	Xanthydrol	Urease	Xanthydrol
6	51	—	104	—	101	—	72
5	40	70	69	61	59	36	36
4	41	65	66	64	61	48	49

One kidney from each frog was grouped and a suspension made in 12 ml. water; 4 ml. quantities were taken for the xanthydrol analyses, 0·5 ml. quantities were taken for the urease analyses. For the analysis of the diffused quantities the companion tissues were immersed in 12 ml. of Locke and stirred with a stream of oxygen for 2 hours, the Locke fluid being subsequently analysed. 0·1 ml. blood was taken from each frog and the mixed blood analysed.

The first experiment with the kidneys from 6 frogs was carried out in December, the remaining experiments in February from fresh consignments.

The ratio between the blood urea and the renal urea in the summer frogs was found to be 1 : 1·89, the ratio for the winter frogs 1 : 1·49, and as we have seen, nearly the entire amount of the renal urea freely diffuses outwards. Three sets of experiments in which the xanthydrol method was used with duplicate analyses, gave a ratio of blood to kidney urea of 1: 1·43 for winter frogs. The average urea content of the kidney was 80 mg. per 100 ml. and the average diffused quantity into a large volume of Locke 74 mg. urea per 100 ml. tissue. Using the same considerations as above this means that 95 % of the total possible has diffused, the theoretical quantity being again 98 %. Table II contains the details of these experiments and shows that in two sets where series of corresponding analyses were made with the urease method, practically identical results were obtained.

The xanthydrol results are therefore in complete agreement with the urease figures.

Diffusion relations of urea for the isolated frog's kidney.

(*a*) *The diffusion coefficient.* It was considered advisable to make a repeated determination of this coefficient with the revised technique. In the method adopted 12 kidneys were immersed in 20 ml. cyanide-Locke (cyanide concentration—0·02 % KCN) and kept stirred with a stream of oxygen saturated with water vapour.

0·5 ml. was removed at varying intervals ranging from 5 to 180 minutes. Over this period about three additional quantities of 0·5 ml. were removed to determine the free ammonia content. The whole course of the diffusion could be examined from the one group of kidneys without the need of comparing with the companion tissues for each determination after a given time period. The results are given in Table III. The mean value of the diffusion coefficient up to a period when 70 % was diffused was found to be $1{\cdot}09 \times 10^{-5}$, showing therefore no change from the previous determination and indicating that the analyses summarised in the previous paper, from which the diffusion coefficient was determined, were inappreciably different from the true figure. Table III shows also that the whole course of the diffusion is very close to the theoretical curve based on a coefficient of $1{\cdot}095 \times 10^{-5}$ and that after three hours' diffusion 97 % of the theoretical is recoverable.

Table III.

Diffusion period mins.	Amount diffused per 100 ml. kidney mg.	Amount diffused calculated from diff. coeff. of $1{\cdot}095 \times 10^{-5}$ mg. per 100 ml. kidney	Diffusion coeff. calculated from the diffused quantities (cm.^{2}/mins.)
5	25·2	23·6	$1{\cdot}26 \times 10^{-5}$
10	32·9	33·7	$1{\cdot}03 \times 10^{-5}$
20	45·3	48·0	$0{\cdot}99 \times 10^{-5}$
30	57·8	57·1	$1{\cdot}10 \times 10^{-5}$
60	71·0	73·3	—
180	78·0	81·3	—

Temperature, 17°.

In the above experiment 12 kidneys from six frogs of one consignment and weighing 533 mg. were introduced into 20 ml. Locke's fluid and stirred with oxygen. 0·5 ml. quantities were removed at definite times for the urea analysis, three extra quantities of 0·5 ml. being taken over the three hours' period of the immersion for determination of the ammonia content. The kidneys at the end were also analysed, being ground up in 3 ml. of water.

The urea content of the kidneys at the beginning of the immersion was calculated from the analyses as 84·3 mg. per 100 ml. At the end the Locke fluid had a concentration of 2·25 mg. urea per 100 ml., the diffusing concentration therefore being approximately 82 mg.

The slight difference at the end of the experiment between the actual and theoretical quantities diffused may be attributed to the swelling of the kidneys.

(*b*) *Urea diffusion equilibria for the isolated kidney.* Before immersing the isolated kidneys in urea-Locke solutions they were previously washed in ordinary Locke for 20–30 minutes. In this way the concentration of urea was reduced from approximately 80 mg. to about 30 mg. per 100 ml. One of each pair of kidneys were then grouped together and analysed, the companion tissues being immersed and stirred with oxygen in urea-Locke and urea-cyanide-Locke solution respectively. In this re-immersion—if we consider the diffusion coefficient of $1{\cdot}1 \times 10^{-5}$—it would take over two hours before a practically complete equilibrium would occur; after this time there appeared some danger of the activity of the kidney being much reduced. For this reason the time of re-immersion in the urea-Locke was confined to 30–45 minutes, the movement of the urea being studied over this period. The results of this study are sufficient and conclusive in establishing the main point of interest—namely, the concentration of urea by the active kidney from an external fluid. That the time was insufficient for establishing full equilibrium only lends emphasis to the results. At the same time it may be pointed out that about 70–80 % of the total movement of the urea towards equilibrium will have occurred and that from a consideration of the diffusion coefficient the equilibrium figure may be calculated.

A large number of experiments of this type were collected before the revised technique was set going. The individual results were obtained from the one pair of kidneys, one kidney being analysed after the 30-minute washing period and the other immersed for a further 30 minutes in urea-Locke (or urea-cyanide-Locke), the kidneys being stirred in all cases with a stream of oxygen. The concentration of the urea in the external Locke was either 20, 40 or 80 mg. per 100 ml. The results are summarised in Table IV.

Table IV.

		Inactive kidneys (cyanide)			Active kidneys			
Conc. of urea in the urea-Locke mg per 100 ml.	Av. wt of single kidney mg.	No. of exps.	Mean conc. before immersion in urea-Locke mg. urea per 100 ml.	Mean conc. after immersion in urea-Locke mg urea per 100 ml.	No of exps.	Mean conc before immersion in urea-Locke mg. urea per 100 ml	Mean conc. after immersion in urea-Locke mg. urea per 100 ml.	Increase in mean conc of active over inactive kidneys mg urea per 100 ml
20	40	4	27	24 (21–26)	6	31	41 (27–71)	+17
40	33	6	31	37 (30–48)	14	33	50 (31–103)	+13
80	45	5	29	56 (51–60)	17	26	72 (42–104)	+16

In each experiment one kidney from one frog was analysed after the washing period of 30 minutes in Locke, and the companion kidney after the immersion period in urea-Locke.

The mean value of the urea content of the kidneys after the 30-minute washing is in all the groups within the range 30 ± 4 mg. per 100 ml. After re-immersion for 30 minutes in Locke containing 20, 40 or 80 mg. urea per 100 ml. the mean values for the inactive (cyanide) kidneys were 24, 37 and 56 mg. urea per 100 ml. respectively. The mean values for the active kidneys re-immersed in Locke containing the same urea concentration, but without cyanide, were 46, 50 and 72 mg. per 100 ml. In each group, therefore, a large excess of urea has diffused into the active kidney in comparison with the inactive kidney. It will be seen from the table that after re-immersion in urea-cyanide-Locke containing 20 mg. per 100 ml. urea the value falls over the period from a mean value of 27 mg. urea per 100 ml. to a mean value of 24 mg., whereas the urea content for the active kidneys rises from 31 to 46 mg. urea per 100 ml.

After immersion in the 80 mg. per 100 ml. urea solution, the content of the active kidney increases on the average from 26 to 72 mg. per 100 ml. There is here insufficient time for the value of the kidney to exceed that of the external fluid, but it exceeds the corresponding value for the inactive kidney by 16 mg. urea per 100 ml.

The question arises—does the movement of urea in the inactive kidneys indicate a passage towards a mere passive equilibrium? Considering the average weights of the kidneys examined in the three groups of cyanide-urea immersions, namely, 40, 33 and 45 mg., it may be calculated from the diffusion coefficient ($1{\cdot}1 \times 10^{-5}$) that in 30 minutes 72, 76 and 70 % of the equilibrium amount will have diffused. From these figures and those in Table IV the equilibrium values for the three groups of cyanide immersions will be 23, 39 and 68 mg. per 100 ml. (the values after 30 minutes being 24, 37 and 56). From a mere passive equilibrium we should expect 17, 34 and 67 mg. urea per 100 ml. The experimental values exceed the theoretical therefore by +6, +5 and +1 mg. urea per 100 ml. or an average of +4 mg. per 100 ml.

Apart from the fact that this quantity is in itself small, it is probably due to an analytical error arising from the "extra" ammonia formed after 15 minutes' action of the urease extract on the kidney suspensions.

Applying the same calculations to the three groups of active kidneys, the equilibrium values are 51, 55 and 95 (the 30-minute values being 46, 50 and 72). These values exceed those for a passive equilibrium (17, 34 and 67) by +34, +21 and +28 mg. urea per 100 ml. They are of about the same order as the difference in urea concentration between the normal frog's kidney and that of the blood, namely 40 mg. per 100 ml. found for the summer frogs and 27 per 100 ml. for the winter frogs.

In the above analyses we were concerned with individual tissues the average values of which are summarised. The individual results, particularly of the active kidneys, gave, as may be expected, rather wide variations. A further group of five experiments was carried out with the revised technique, groups of three kidneys being used for each analysis. The conditions in these experiments were made as uniform as possible in comparing the active with the inactive kidneys. In each experiment of this group 6 pairs of kidneys were taken from six frogs of the same consignment and selected for their similarity in size. The 6 pairs were washed in Locke, being stirred with oxygen for 20 minutes. Three of the pairs were divided (all the pairs were held together by a small amount of uncut tissue) and three of the kidneys taken for analyses, the remaining three being immersed in Locke containing 40 mg. urea per 100 ml. The three remaining pairs were treated similarly, the companion tissues being immersed in cyanide-Locke containing also 40 mg. urea per 100 ml. The kidneys were immersed in the respective urea solution for 45 minutes, being subsequently analysed.

Table V.

			Inactive kidneys (cyanide)		Active kidneys		
No. of exp.	Av. wt of single kidney mg.	Temp.	Conc. of urea in 3 kidneys before immersion in urea-Locke mg per 100 ml.	Conc. of urea in companion tissues after immersion in urea-Locke mg. per 100 ml.	Conc. of urea in 3 kidneys before immersion in urea-Locke mg. per 100 ml.	Conc. of urea in companion tissues after immersion in urea-Locke mg. per 100 ml.	Increase in mean conc. of active over inactive kidneys mg. urea per 100 ml.
1	31	12	32	33	32	42	+ 9
2	31	17	27	42	30	51	+ 9
3	44	18	32	35	30	47	+12
4	39	19	37	34	39	57	+23
5	35	19	33	34	40	59	+25

The experiments are described in the text. In the table the results are arranged in order of the room temperatures at which the experiments were conducted.

Each analysis in the above table has been determined from a group of three kidneys.

The results are shown in Table V and completely confirm the previous results. After the 20 minutes' washing the average value of the companion tissues to those immersed subsequently in the cyanide-urea-Locke is 32·2 mg. urea per 100 ml. After immersion the average is 35·6. The average weight of the kidneys is 36 mg. After 45 minutes with a diffusion coefficient of $1{\cdot}1 \times 10^{-5}$, 86 % will have diffused, so that the final equilibrium value should be 36·2—very slightly above the 45-minute figure. The amount for a purely passive equilibrium is

34 mg. urea per 100 ml. This is in fact the figure reached in four out of five of the experiments, the remaining figure of 42 mg. per 100 ml. being somewhat aberrant.

Reviewing now the active kidneys of this series, in each experimental group the value is much higher than for the inactive kidneys, the difference ranging from 9 to 25 mg. urea per 100 ml. with a mean value of 16 mg. It may be noted that the lower figures of the group are associated with low external temperatures.

Prior to immersion in urea-Locke the average value for the companion (control) tissues of the active kidneys is 34 mg. urea per 100 ml., the average after immersion being 51 mg. urea per 100 ml.

Applying the same calculation as above, with the cyanide kidneys the equilibrium value appears as 54 mg. urea per 100 ml. or 18 mg. in excess of the 36 mg. found with the cyanide kidneys.

Discussion.

Here we may emphasise the fact that the concentration of urea by the active isolated frog's kidney from an external fluid has been definitely proved, the formation of a glomerular fluid by filtration during this process of concentration being an impossibility.

The proof depends on a large number of experiments, and selecting one group of these for illustration, it is briefly as follows. The kidneys of a number of frogs were removed and washed in Locke's fluid for 20 minutes, being stirred—as in all the immersions described here—by a stream of oxygen. Their concentration was thereby reduced to 34 mg. urea per 100 ml. Some were now immersed in Locke containing 40 mg. per 100 ml. of urea, and others in a similar urea-Locke containing cyanide, the immersion being continued for 45 minutes. The resulting concentration of the inactive (cyanide) kidneys was 35·6 mg. urea per 100 ml., that of the active kidneys being 51 mg. urea per 100 ml. Urea has, therefore, been concentrated from an external fluid by the active kidneys, but not by the inactive.

To reconcile these facts with the theory of urea concentration by water reabsorption, we believe that only one explanation is possible, and we shall show that this explanation must in turn be definitely abandoned.

It may be held that after the 20-minute washing period in Locke when the concentration of the kidneys is 34 mg. urea per 100 ml. about 16 mg. of this urea are present in the urine contained within the uriniferous tubules, and that during the remaining 45 minutes' immersion in the urea-Locke this is held there, whereas with the immersion in urea-cyanide-Locke it is practically all released, the external urea reaching then a mere passive equilibrium with the urea of the renal cells. This it might be alleged would account for the difference, so that the excess urea in the active kidneys was not concentrated from an external fluid, but was held there from the beginning of the experiment, in the urine of the tubules. This explanation involves, as a necessary consequence, that if, for the 45-minute period of re-immersion, the Locke and cyanide-Locke fluids contained no urea, then the same difference as before must be manifested at the end between the active and inactive tissues, about 16 mg. per 100 ml. should be retained by the active tissue in excess of the inactive tissue. We have, therefore, conducted a series of experiments to decide this point (which might likewise have been refuted from other available facts—but not perhaps so directly or simply).

Table VI.

Period of re-immersion in Locke after preliminary washing mins.	Active kidneys		Inactive kidneys (cyanide)		Increase in mean conc. of active over inactive kidneys mg. urea per 100 ml.
	Av. wt. of single kidney mg.	mg. urea per 100 ml. after re-immersion	Av. wt. of single kidney mg.	mg. urea per 100 ml. after re-immersion	
20	26	21	27	18	+3
20	22	19	23	18	+1
20	30	12	33	13	-1
45	25	9	30	8	+1
45	19	13	20	10	+3
45	20	13	23	12	+2

In the above experiments six pairs of kidneys were taken and washed in Locke for 20 minutes, six kidneys, one from each pair, being then removed to cyanide-Locke. These and the remaining six in ordinary Locke were washed for a further period of 20 or 45 minutes. The fluid was renewed a few times in this latter washing.

The mean difference at the end between the active and inactive kidneys is 1 mg. urea per 100 ml.

Six pairs of kidneys were selected for each experimental set and washed for 20 minutes in Locke, then three re-immersed in Locke and the companion tissues in cyanide-Locke for another 45 minutes, the conditions being therefore as before, except that the Locke for re-immersion contained no urea, and during the second period of 45 minutes was changed twice to reduce the external urea concentration to an insignificant figure. The results of these experiments are contained in Table VI. The average concentration of the active kidneys at the end of the period is 11·7 mg. per 100 ml. and that of the inactive is 10·0 mg. per 100ml. The average difference is therefore only 1·7 mg. urea per 100 ml., whereas 16 mg. would have to be accounted for. Table II also shows the results of a similar set of experiments with a 20-minute period of re-immersion instead of 45 minutes. The mean urea value for the active kidneys was 17 and for the inactive 16 mg. per 100 ml. Over the whole period of 45 minutes' re-immersion, therefore, there is—for the purpose of the present discussion—no significant difference between active and inactive kidneys.

It is certain, therefore, that the large difference between the active and inactive tissues after re-immersion in urea-Locke is not due to the mere liberation of urea held up in the tubule lumen by the action of cyanide.

A point that may be mentioned in connection with the immersions of the kidneys in Locke and cyanide-Locke is that the weights of the kidneys alter. We have already studied this in some detail, and with results of much interest to be described in a subsequent communication. Here it may be said that if the original washing in Locke has been for 30 minutes with a subsequent 30 minutes' immersion in Locke or cyanide-Locke (cyanide concentration—0·02 % KCN) the difference between the final weights of the kidneys active and inactive, is less than 5 %. (This applies to the experiments of Table IV.) When the original washing in Locke was only for 20 minutes, with subsequent 45-minute immersions in Locke or cyanide-Locke, as in the experiments of Table V, the mean difference between the active and inactive kidneys was found to be about 7 %. The active kidneys summarised in Table V lost 10 % of their weight during the 45-minute re-immersion and the inactive lost 3 %. These changes in volume however will not influence the nature of the results obtained, since it is concentration equilibria we are dealing with and these are nearly reached at 45 minutes. If however the volume changes are reckoned as exercising the maximum conceivable effect, in a manner of argument opposing the above, then if we calculate the final concentrations of the kidneys in terms of the weights before instead of after immersion in the urea-Locke or urea-cyanide-Locke, the average concentration for the active kidneys of Table V becomes 46 mg. per 100 ml. and for the inactive 35 mg. (the external fluid having a urea concentration of 40 mg. per 100 ml.).

This, therefore, could not affect the argument, the inactive kidney having still only 76 % of the urea content of the active, the latter being 15 % more concentrated in urea than the external fluid—and this after attaining to less than 80 % of the final equilibrium value.

Concerning the technical side of the analyses the opinion may be entertained that since differences between urease and xanthydrol determinations on kidney suspensions have been recorded in the literature, urea analyses of the frog's kidney are uncertain. The reason for such differences has been demonstrated above in the section on methods. The following facts may also be noted.

(1) From the Locke fluid in which fresh kidneys are immersed 95 % of the total urea originally present—as determined from companion tissues—can be recovered after 3 hours, and this amount corresponds to 97 % of the theoretically diffusing quantity. The remaining 3 % may even be accounted for by the swelling of the tissues after this period.

(2) The differences in urea concentration of the active and inactive kidneys, on which the proof turns, can be shown either from unboiled suspensions, boiled suspensions, or by xanthydrol analyses. There is no difference in the figures obtained by us using the xanthydrol method with unboiled suspension, or the urease method with boiled suspension. A slight difference existed between the absolute urea concentration as determined from boiled and unboiled suspensions with our method of analysis by urease. This difference was due to the inclusion of some "extra" ammonia formed by the urease extract on the unboiled suspension, already considered in detail in the first section.

The amount of this "extra" ammonia could be considerably increased by prolonging the time of incubation of the suspension with the urease extract and also by increasing the concentration of the extract itself.

From the existence of this "extra" ammonia Rehberg has even invented the conception that one moiety of urea in the frog's kidney exists in a freely diffusible form—such as was given by the xanthydrol measurements—and another as "bound" urea which could be slowly acted upon by the ferment urease and in quantity corresponding to this "extra" ammonia.

The freely diffusible form of urea was present—according to Rehberg—in quantities little if at all greater than that of the fluid with which he perfused the kidney. The truth is however that the urea in the blood of the normal frog is only 60–70 % of the true and freely diffusible urea of the kidney, and this is so whether we analyse the urea by the xanthydrol method or by the urease method—employing the latter correctly—or whether in fact we determine the urea which has freely diffused into an external Locke solution.

Not only does this relationship of blood urea to renal urea normally exist, but if we isolate the kidney and wash it so that its concentration is well below the normal blood level and then re-immerse it in Locke solution containing urea of similar or lower concentration to that of the blood, the concentration relationships of blood and renal tissue are re-established, the urea-Locke solution in this case replacing the plasma.

The concentration of urea from an external urea-Locke being demonstrated, the question arises, where is the urea stored? Does a gradient exist across the tubule cells reaching the maximum concentration in the urine or does all the stored urea pass into the urine, the concentration of the cells being that of a passive equilibrium with the external fluid? The average urea figures found for the winter frogs was 55 mg. per 100 ml. blood and 82 mg. per 100 ml. kidney. If we assume that the urea in excess of the blood is all present in the urine, and that the urine occupies—as a maximum value—5 % of the whole tissue, then the urea in the urine must be 11 times more concentrated than the blood, which is a not improbable figure for the urine concentration when this is slowly excreted. It is possible, therefore, that all the urea concentrated from the external fluid exists in the urine. This is in fact a point of view we had previously taken in relation to substances actively secreted, and that there was no evident reason for the supposition that such substances must be concentrated within the cells, though this possibility must be allowed pending further proof.

In conclusion it may be noted that whereas in the present communication we have shown that for a secreted substance the active isolated frog's kidney comes into equilibrium with a much higher concentration than the inactive (and higher than the external fluid), the reverse effect was demonstrated for an absorbed substance. The absorbed substance in question is sodium sulphate, which in about nine cases out of ten appears in the urine of the frog (*Rana temporaria*) with only one-third or less the plasma concentration.

SUMMARY.

1. The concentration of urea from an external urea-Locke solution by the active isolated kidney of the frog has been definitely proved.

2. The proof consists in washing pairs of fresh kidneys in Locke for 20 minutes, retaining one member of each pair for a grouped analysis, the companion tissues being immersed for 45 minutes in urea-Locke, containing 40 mg. urea per 100 ml., and subsequently analysed. After the initial washing the mean urea concentration was 34 mg. per 100 ml. and after re-immersion in urea-Locke it rose to 51 mg. urea per 100 ml. When the re-immersion was made in urea-cyanide-Locke—containing also 40 mg. urea per 100 ml.—the concentration found was 35·6 mg. urea per 100 ml.

A large number of similar experiments were also carried out in which the external concentrations *etc.* were varied. The results in all cases supported the above findings.

3. When the re-immersions after the initial washing were made for 45 minutes in Locke or cyanide-Locke containing no urea, the mean difference of urea content between the active and inactive tissues did not exceed 2 mg. urea per 100 ml.

4. Changes in the volume of active and inactive (cyanide) kidneys under the conditions examined have no appreciable effect on a consideration of the results.

5. Xanthydrol determinations of the urea in the frog's kidney gave identical results with the urease method used. This latter was subjected to a detailed examination in so far as it could have any bearing on the results obtained.

CLXXVI. STUDIES ON THE ANAEROBIC DECOMPOSITION OF PLANT MATERIALS.

IV. THE DECOMPOSITION OF PLANT SUBSTANCES OF VARYING COMPOSITION.

By CADAMBI NARASIMHA ACHARYA.

From The Fermentation Department, Rothamsted Experimental Station, Harpenden, Herts.

(*Received May 1st, 1935.*)

The course of anaerobic decomposition of rice straw in relation to losses of straw constituents, products formed and nitrogen transformations, has been examined in some detail in earlier communications [Acharya, 1935, 1, 2, 3]. The present paper reports the results of the anaerobic digestion of oat, wheat and barley straws, bracken leaves, young grass (lawn mowings) and rape seed cake in comparison with the decomposition of rice straw.

In one set of experiments 20 g. portions of the materials were digested without the addition of nitrogen, but with 3 g. $KHCO_3$ added to neutralise the acids formed. Wherever this amount of bicarbonate was not enough to keep the reaction alkaline, and as a result stoppage of gas evolution occurred, additions of NaOH were made from time to time. In a parallel set of experiments, ammonium carbonate equivalent to 1 % N on the material taken was added. The other experimental details and analytical methods adopted were the same as those previously described [1935, 1].

Besides the above, a few digestions were also made of the cellulose, hemicellulose and lignin fractions isolated from oat straw.

The results of anaerobic decomposition, as shown by losses of plant constituents, were also compared with the losses brought about by 3 different types of acid treatment: (1) aqueous acid, 5 % H_2SO_4; (2) alcoholic acid, a solution of

5 % HCl in 95 % alcohol; and (3) an oxidising acid agent, 2 % and 5 % HNO_3. The aim of the comparison was to examine whether any of the treatments could be used as a rapid method for forecasting the degree of anaerobic digestion and the probable amount of acid or gas obtainable as a result of such digestion; ordinarily several months elapse before gas evolution stops.

Data for the composition of the seven materials under examination, given in Tables I and II, show that whilst rice, oat, wheat and barley straws resemble one another in general composition, bracken leaves, grass and rape cake differ from these and among themselves. Bracken leaves are poor in hemicelluloses (as measured by furfuraldehyde yield) and cellulose, but rich in lignin and fairly rich in protein. Grass contains a good proportion of protein and cellulose, while rape seed cake is poor in hemicelluloses but rich in proteins.

The losses of constituents as a result of anaerobic digestion are given in Table II and the products formed in Table III.

1. *Losses of constituents.*

It is noteworthy that a considerable proportion of the total decomposition can be brought about without the addition of nitrogen if the p_H and other factors influencing anaerobic digestion [Acharya, 1935, 2] are maintained at the optimum. Still, the addition of nitrogen in the form of ammonium carbonate

stimulates the decomposition, as measured by losses of plant constituents and by-products formed, in the case of materials like straws poor in nitrogen. The effect of addition of nitrogen, however, is much less than that noted for aerobic decomposition [Hutchinson and Richards, 1921].

The degree of decomposition is approximately the same in the case of the 4 straws, about 45–50 % of cellulose, 55–60 % of hemicellulose and 25–30 % of lignin, calculated on the amounts originally present, being destroyed. With bracken, only 22 % of cellulose and 41 % of hemicellulose are decomposed and the destruction of protein is also low. This partial digestion is associated with the high lignin content of the material which, it is suggested, prejudicially affects the decomposition of the other constituents. Levine *et al.* [1935] recently found that additions of lignin to actively fermenting corn stalk flour or packing house (anaerobic) sludge inhibited gas formation, attributing this to chemical combination of lignin with the material under decomposition and formation of complexes resistant to microbial decomposition. In grass and rape seed cake cellulose and hemicelluloses suffer considerable loss; the decomposition of the proteins is also high. This rapid destruction is associated with the comparatively low content of lignin in the two materials.

2. *Products formed.*

The general nature of the by-products is the same in the seven cases, CO_2, CH_4, acetic and butyric acids being the chief substances formed. The relative amounts of acids and gases present at the end of 6 months vary, however, with the different materials, probably owing to the differing relative rates of the two stages of anaerobic decomposition, *viz.* acid formation and gas production [Acharya, 1935, 1, 2]. The gas yield is very low with rape seed cake, on account of the rapid accumulation of acids and the lack of enough $KHCO_3$ to maintain the p_H in the range favourable for gas formation.

Table III. *Products formed by anaerobic fermentation for 6 months*

Per 100 g. of material	Volume of CO_2 (corrected for carbonates) ml.	Volume of CH_4 evolved ml.	Wt. of CO_2 g.	Wt. of CH_4 g.	Acetic acid present g.	Butyric acid present g.	Total products g.
1. Rice straw, without N addition	8010	8660	15·84	6·21	2·46	0·82	25·33
Rice straw, with N addition	10870	10570	21·49	7·58	1·03	0·27	30·37
2. Oat straw, without N addition	7040	7720	13·92	5·54	7·57	1·52	28·55
Oat straw with N addition	6050	6960	11·96	4·99	11·43	4·13	32·51
3. Wheat straw, without N addition	4010	4960	7·93	3·56	10·14	3·52	25·15
Wheat straw, with N addition	9420	10150	18·62	7·27	4·29	1·63	31·81
4. Barley straw, without N addition	5240	6120	10·36	4·39	7·36	3·08	25·19
Barley straw, with N addition	7110	7980	14·06	5·72	7·22	2·52	29·52
5. Bracken leaves, without N addition	4850	6240	9·59	4·47	4·28	4·24	22·58
Bracken leaves, with N addition	5120	5910	10·13	4·23	6·23	2·83	23·42
6. Grass (lawn mowings), without N addition	9220	13240	18·23	9·49	2·52	4·26	34·50
Grass (lawn mowings), with N addition	9670	13720	19·12	9·83	1·32	4·86	35·13
7. Rape seed cake, without N addition	1920	3075	3·80	2·20	16·85	18·05	40·90
Rape seed cake, with N addition	1630	2880	3·22	2·07	17·57	18·55	41·41

The largest amount of products per 100 g. of material is obtained from rape seed cake (41 g.) followed by grass (35 g.), oat straw (33 g.), wheat straw (32 g.), rice straw (30 g.), barley straw (29 g.) and bracken (23 g.).

Whereas with straws the relative proportions of CO_2 and CH_4 evolved (after correcting CO_2 for the fraction evolved from carbonates) are of the same order, in the case of grass and rape cake the amount of CH_4 formed is much higher than that of CO_2. This difference is associated with a relatively low amount of butyric acid present in the former group and higher amounts in the latter. The bulk of the butyric acid seems to originate from the protein fraction in the case of rape seed cake, for the amount present cannot be accounted for by the losses of other constituents. It has already been noted [1935, 2] that when proteins, such as caseinogen, blood albumin and egg albumin, were added to decomposing rice straw, the proportion of butyric acid formed showed a rapid rise.

The increase in the amount of CH_4 formed and its relationship to the CO_2 produced and the butyric acid present lend support to the view advanced by Symons and Buswell [1933] that anaerobic digestion consists of a series of oxidation-reduction reactions in which water plays an important part.

3. *Nitrogen transformations.*

The nitrogen transformations during anaerobic digestion of the different materials are shown in Table IV. Positive values for nitrogen factor and nitrogen equivalent carry meanings assigned to them by Rege [1927] and Richards and Norman [1931], while negative values represent the net amount of nitrogen mineralised or the proportion of original protein reduced to ammonia at the end of the decomposition.

Table IV. *Nitrogen transformations in anaerobic decomposition.*

		After fermentation for 6 months				
Plant material	N in 100 g. of original material g.	Protein-N in residue g.	Protein-N in aqueous extract g.	Total protein-N g.	N immobilised or N factor g.	Nitrogen equivalent g.
1. Rice straw, without N addition	0·461	0·297	0·129	0·426	−0·035	−0·112
Rice straw, with N addition	0·461	0·323	0·207	0·530	+0·069	+0·196
2. Oat straw, without N addition	0·401	0·205	0·163	0·368	−0·033	−0·088
Oat straw, with N addition	0·401	0·237	0·305	0·542	+0·141	+0·343
3. Wheat straw, without N addition	0·369	0·225	0·095	0·320	−0·049	−0·168
Wheat straw, with N addition	0·369	0·305	0·230	0·535	+0·166	+0·451
4. Barley straw, without N addition	0·570	0·265	0·225	0·490	−0·080	−0·228
Barley straw, with N addition	0·570	0·344	0·420	0·764	+0·194	+0·485
5. Bracken leaves, without N addition	1·867	1·665	0·125	1·790	−0·077	−0·265
Bracken leaves, with N addition	1·867	1·727	0·155	1·882	+0·015	+0·050
6. Grass, without N addition	3·664	1·011	0·425	1·436	−2·228	−4·895
Grass, with N addition	3·664	1·197	0·505	1·702	−1·962	−4·247
7. Rape seed cake, without N addition	5·646	0·712	0·675	1·387	−4·259	−7·739
Rape seed cake, with N addition	5·646	0·888	0·510	1·398	−4·248	−7·668

The data show that when no additional nitrogen is added, about 10 % of the original protein is converted into ammonia with the straws, while the proportion is much higher with grass (60·8 %) and rape seed cake (75·4 %). Though bracken contains a comparatively high percentage of nitrogen (1·867 %) only 4·1 % of it is converted into ammonia. This may be due either to the difference in the nature of the proteins present or to the protective action exercised by the high lignin content in the bracken.

The distinct, though slight, stimulating action exercised by addition of available nitrogen on the degree of decomposition and the amount of decomposition products, has been referred to above. Nitrogen supply appears also to modify the course of nitrogen transformations in the anaerobic system, as shown by the values for nitrogen factor and equivalent. With materials poor in nitrogen, *e.g.* straws, these values are negative in the absence of added nitrogen and positive in its presence. The positive values represent a net gain of synthesised protein during the period of digestion. They are, however, much lower than the figures given for aerobic decomposition [Richards and Norman, 1931]. With materials rich in anaerobically available nitrogen, *e.g.* rape seed cake or grass, the nitrogen factor and equivalent give high negative values, both in presence and absence of added nitrogen, showing that the net result in either case at the end of the digestion is the reduction of a considerable portion of the original protein to ammonia. Bracken, however, differs in showing a low negative value in the absence of nitrogen addition and a small positive value in its presence, thus resembling the straws poor in nitrogen. This behaviour of bracken could be explained if it be assumed that for purposes of anaerobic digestion the protein is not available.

4. *Comparison of the losses during anaerobic digestion with those during acid hydrolysis.*

10 g. portions of the materials were boiled for one hour with 200 ml. of (1) aqueous 5 % H_2SO_4; (2) a solution of 5 % HCl in 95 % alcohol; (3) aqueous 2 % HNO_3; (4) aqueous 5 % HNO_3. The residues were weighed and analysed for cellulose, furfuraldehyde yield, lignin and protein. The losses of constituents by the different treatments, calculated on 100 g. of original material, are presented in Table II.

It will be noted that none of the acid treatments gives the same results as those obtained by anaerobic digestion, the difference being most marked in the case of cellulose. A considerable proportion of cellulose, varying from 40–60 % of the amount originally present, is lost by anaerobic digestion, whilst the losses by acid treatment amount to 25–30 % only. The higher concentration of nitric acid (5 %) was used to oxidise the cellulose, if possible, and so secure a greater loss; but the attempt was unsuccessful.

A second difference between the two kinds of decomposition lies in the relative proportions of cellulose to xylan, associated with cellulose, left after decomposition. In anaerobic fermentation the amount of cellulose which disappears is roughly proportional to the loss of xylan associated with it. But acid treatments disturb this ratio by removing a much higher proportion of the associated xylan than of cellulose.

The differential removal of the straw constituents by the four acid treatments is worth noting. While 5 % H_2SO_4, 2 % HNO_3 and 5 % HNO_3 remove most of the xylan not associated with cellulose and also a large portion of the xylan so associated, 5 % alcoholic HCl acts mostly on the xylan fraction associated with cellulose and much less on the fraction not so associated.

Nitric acid at 2 % as well as 5 % concentration oxidises and dissolves large proportions of the lignin originally present, ranging from 60 to 80 %, and would therefore be unsuitable for purposes of comparison with anaerobic treatment, where the losses average about 25–30 % only. With bracken leaves the loss of lignin is low with 2 % HNO_3; this is associated with a smaller loss of protein as compared with the other acid treatments. It is probable that a portion of the protein might have been oxidised by the nitric acid with the formation of "apparent" lignin [Norman and Jenkins, 1934] which may mask the loss of lignin originally present.

With straws the losses in protein are higher during acid treatment than during anaerobic digestion, but there is good agreement in the case of materials richer in nitrogen, *e.g.* grass and rape seed cake. Bracken, however, is an exception since its protein is less soluble under anaerobic conditions than with acid treatment. This low solubility under biological action may be due, as already observed, to the protective action of lignin. The nitrogen losses on treatment with nitric acid are irregular, owing possibly to the nitrating action of the acid on the constituents.

Of the four acid treatments tried, that with 5 % H_2SO_4 seems to come closer to the results of anaerobic digestion than the others. The attack on cellulose is no doubt distinctly lower than occurs in the biological action, but this is to a certain extent made up by the greater attack on the xylans. Considering the widely varying composition of the straws on the one hand and of bracken, grass and rape cake on the other, the agreement may be considered satisfactory. Bearing in mind the remarks made above in regard to the attack on cellulose and xylans, the method can be put forward as one which could rapidly give some idea of the anaerobic decomposability of a plant material and the approximate amount of products, either acid or gas, which could be obtained from it. More work with a larger variety of substances is necessary before any definite recommendations in the matter can be made.

5. *Decomposition of constituents isolated from oat straw.*

A comparative study of the anaerobic decomposition of the different constituents of oat straw was made using preparations of lignin, hemicellulose and cellulose isolated from it. The sample of lignin was obtained by treatment with 72 % H_2SO_4, of hemicellulose by boiling with 4 % NaOH and subsequent precipitation with acetic acid and alcohol, and of straw cellulose by the method of Norman and Jenkins [1933]. A portion of the cellulose was treated with boiling 5 % H_2SO_4 for one hour to remove a part of the xylan contained and was also fermented for purposes of comparison. The sample of crude hemicellulose gave a furfuraldehyde yield equivalent to 76·8 % xylan. The sample of oat cellulose and that treated with acid contained 30·81 and 19·64 % respectively of xylan.

To 5 g. portions of the substances 2 g. $KHCO_3$, 2 g. NH_4HCO_3, 0·2 g. K_2HPO_4, 0·05 g. $MgSO_4,7H_2O$, 10 ml. of an extract from a rice soil, 10 g. of asbestos to allow for the surface development of a bacterial film and 100 ml. of water were added, the other experimental details being as usual. Gas evolution began earliest with the hemicellulose preparation, but in all cases there was a rapid accumulation of acids with consequent lowering of p_H and fall in gas yield.

The data given in Table V show that "acid" lignin does not undergo any appreciable decomposition and yields no gases or acids. Hemicellulose is more rapidly decomposed than cellulose as shown by the larger yield of gases and smaller accumulation of acids at the end of 6 months. There is no appreciable difference between the rates of fermentation of oat cellulose and that treated with 5 % H_2SO_4 for one hour.

Table V. *Decomposition of constituents isolated from oat straw.*

g. per 100 g. after 6 months' fermentation.

	Acid lignin	Crude hemi-cellulose	Oat cellulose	Purified oat cellulose
Unfermented insoluble residue	97·2	8·2	17·2	18·1
Volume of CO_2 (corrected) for carbonates (ml.)	Nil	11,120	3,820	3,340
Volume of CH_4 evolved (ml.)	,,	12,830	4,410	3,860
Weight of CO_2	,,	21·99	7·55	6·60
Weight of CH_4	,,	9·20	3·16	2·77
Acetic acid present	,,	31·32	50·56	53·58
Butyric acid present	,,	8·27	13·34	14·70
Total products	,,	70·78	74·61	77·65
Nitrogen immobilised or nitrogen factor	,,	0·280	0·320	0·340
Nitrogen equivalent	,,	0·305	0·387	0·415

It is interesting to note that though the amounts of gases and acids formed vary considerably between the hemicellulose and cellulose preparations used in the present experiment, the proportions of acetic to butyric acids and of CO_2 to CH_4 in the two cases appear to be similar. Thus with both the ratio of acetic to butyric is roughly 4 : 1 and that of CO_2 to CH_4 by volume, roughly 7 : 8. The bearing of this relationship on the decomposition of straws, where cellulose and hemicellulose are the chief constituents decomposed, will be discussed later.

The hemicellulose and cellulose preparations also show similar values for nitrogen factor and nitrogen equivalent. The values for nitrogen factor are higher than with straws, probably owing to more complete utilisation of the extracted constituents than of the plant material as a whole. The nitrogen equivalent values, representing the nitrogen immobilised per 100 g. of material actually decomposed, are of the same order for straw and for its isolated constituents.

DISCUSSION.

In the aerobic decomposition of plant materials it has been observed that lignin inhibits the decomposition of pentosans and cellulose; Rege [1927] proposed a pentosan/lignin factor as a means of predicting decomposability of substances [*cf.* Norman, 1929]. The present experiments indicate that lignin may act as a still more powerful inhibitor in anaerobic decomposition, not only of hemicelluloses and cellulose but also of proteins as well.

In all the plant residues examined there are appreciable fractions of cellulose, hemicelluloses and proteins which are left undecomposed. This may be due either to the inhibitory action of lignin or to the above fractions being encrusted on the cell wall so as not to be easily accessible for microbial attack. It should be noted that a large proportion of the cellulose and appreciable proportions of hemicelluloses and proteins remain also unattacked by weak acids.

The experiments on the nitrogen relationships confirm what has already been described for rice straw regarding the low nitrogen requirements of anaerobic digestion and the absence of any considerable synthesis of proteins from ammonia.

The products obtained by anaerobic decomposition of the cellulose and hemicellulose fractions isolated from oat straw show an interesting similarity both as to the qualitative and quantitative nature of the components. Thus the proportion of acetic to butyric acids is roughly 4 : 1. The approximate constancy of this proportion leads us to expect a similar ratio with straws, where loss of cellulose and hemicellulose accounts for the greater part of the organic matter which disappears. It is proposed to extend this work to an examination of the products obtained by anaerobic digestion, under conditions favouring acid and gas production respectively, of a large variety of cellulose, hemicellulose, protein and other fractions isolated from different plant materials and to compare the data obtained with those for plant materials pretreated so as to remove most of certain constituents.

The absence of gas or acid production from "acid" lignin confirms the work of others [Levine *et al.*, 1935], but it must be noted that the susceptibility of lignin in the natural state to anaerobic attack may be different from that of the fraction isolated by acid or alkali treatment. Recently Levine *et al.* [1935] have suggested that much of the loss of lignin hitherto reported in anaerobic digestion [*cf.* Boruff and Buswell, 1930] may be due to the mechanical solution of lignin rather than to its chemical decomposition. But in the experiment on "acid" lignin there was an almost complete recovery of added lignin, indicating that at the p_H maintained the solution of "acid" lignin was not appreciable. However, further work is necessary before this point can be satisfactorily settled.

The results of acid treatment show marked differences from those obtained by anaerobic digestion. During the course of decomposition by micro-organisms, cellulose is destroyed more rapidly than with mineral acids and the losses in cellulose keep pace with those in the xylan fraction associated with it. The preferential extraction by alcoholic acid of the xylan fraction associated with cellulose is also noteworthy. The use of an alcoholic solution of sulphuric acid and a correction factor applied for the cellulose actually decomposed, might perhaps give results which approximate to the losses found under anaerobic conditions.

SUMMARY.

1. The anaerobic decomposition of oat, wheat, rice and barley straws, bracken leaves, young grass (lawn mowings) and rape seed cake has been studied with reference to losses of constituents, products formed and nitrogen transformations.

2. A good proportion of the total decomposition could be brought about by digesting the materials without the addition of nitrogen, under conditions of optimum temperature and reaction. With materials poor in available nitrogen, however, *e.g.* straws, the addition of nitrogen exerts a distinct, though slight, stimulating effect.

3. The chief products obtained are the same in all the cases: *viz.* acetic and butyric acids, CO_2 and CH_4.

4. Whilst the straws yield a large amount of acetic and small amounts of butyric acid, the reverse is the case with materials rich in available protein, *e.g.* grass and cake. The $CO_2 : CH_4$ ratio is roughly unity in the former case, while in the latter the proportion of CH_4 is much higher.

5. The losses of plant constituents by anaerobic fermentation have been compared with those brought about by boiling for one hour with (1) aqueous 5 % H_2SO_4; (2) alcoholic 5 % HCl; (3) aqueous 2 % and 5 % HNO_3. The cellulose fraction destroyed by acid treatment was smaller and the hemicelluloses decomposed greater than by biological agency. It is suggested that the losses on treatment with 5 % H_2SO_4 for one hour, with a correction for the cellulose decomposed, might be used to forecast the anaerobic decomposability of a plant material and the probable yield of acid and gaseous products.

6. The decomposition of lignin, hemicellulose and cellulose fractions isolated from oat straw has been studied. Lignin is not fermented. Hemicellulose and cellulose fractions are fermented, the former more readily than the latter, yielding acetic and butyric acids in the proportion of 4 : 1 (approx.) and CO_2 and CH_4 in the ratio of 7 : 8 (approx.).

7. The presence of a high lignin content markedly inhibits the anaerobic decomposition of protein and other constituents.

The author's thanks are due to Sir E. J. Russell for placing the facilities of the Rothamsted Experimental Station at his disposal, to Mr E. H. Richards for guidance, to Dr S. H. Jenkins for helpful suggestions and to Dr A. G. Norman for preparations of oat cellulose and hemicellulose.

CLXXVII. THE METABOLISM OF NORMAL AND TUMOUR TISSUE.

XIII. NEUTRAL SALT EFFECTS.

BY FRANK DICKENS AND GUY DRUMMOND GREVILLE[1].

From the Cancer Research Laboratory, North of England Council of the British Empire Cancer Campaign, Royal Victoria Infirmary, Newcastle-upon-Tyne, and the Courtauld Institute of Biochemistry, Middlesex Hospital, London.

(*Received May 1st, 1935.*)

THE study of the metabolism of surviving tissue in the form of slices, that is, in the form in which least damage has occurred, is being pursued by many workers as a method of elucidating the metabolism of the living body cells. This method, whilst having the great advantage of using intact cells, is limited in comparison with the analytical method in which tissue enzymes, carriers *etc.* are extracted and studied; nevertheless, much has been, and is being, learnt by making changes in the medium in which the slices are suspended, particularly by the addition of substances foreign to the body. A better understanding of the nature of the effects produced, and a correlation of the action of different substances, is however needed before theories of cell metabolism, based on these actions, can usefully be evolved.

It has recently been found that when 0·1M KCl is added to the Ringer solution in which slices of rabbit brain cortex are respiring, both the respiration and aerobic glucolysis assume values much larger than the values in pure Ringer solution [Ashford and Dixon, 1935]. This profound alteration of the metabolism is of great interest to the writers, since they have observed similar actions on various kinds of tissue by certain organic coloured substances in very low concentrations. Thus, thionine increases the respiration of tumours without changing the aerobic glucolysis [Dickens, 1934], whilst phenosafranine increases the aerobic glucolysis of brain and tumours without affecting the respiration [Dickens, 1935]. Further, dinitro-*o*-cresol simultaneously increases the respiration and aerobic glucolysis, not only in tumours [Dodds and Greville, 1934], but also in brain tissue [Greville, unpublished observations], thus producing in the latter exactly the same effect as potassium chloride. We were led, therefore, to study the potassium effect more closely in order to seek its cause; to observe the result of other alterations of the cations in the medium; and to enquire whether the potassium effect, like the action of the coloured substances, occurs with tissues other than the brain cortex.

EXPERIMENTAL METHODS AND RESULTS.

The measurements of respiration in phosphate medium and of anaerobic glucolysis in bicarbonate medium were made in the usual way [Warburg, 1926]. Simultaneous measurements of respiration and aerobic glucolysis were made sometimes by the two-vessel method [Warburg, 1924] and sometimes by the method of Dickens and Šimer [1930, 1] for the determination of R.Q. The latter, as ordinarily used, gives low values for the aerobic glucolysis when this is high compared with the respiration. If however the amount of tissue and the duration of the experiment be reduced so that the change in bound CO_2 does not exceed say 250 μl., then, although the R.Q. cannot be measured accurately, good values are obtained for the respiration and aerobic glucolysis, and the advantage of the method is retained, the actual measurement being made on one tissue slice.

---

[1] Halley-Stewart Research Fellow.

Media.

Unless otherwise stated, the suspension media were the following:

	Bicarbonate medium		Phosphate medium	
	%	M	%	M
NaCl	0·70	0·120	As in bicarbonate medium	
KCl	0·018	0·0024		
$CaCl_2$	0·019	0·0017		
$MgCl_2$	0·0076	0·0008		
Glucose	0·20	0·011		
$NaHCO_3$	0·21	0·025	—	—
NaH_2PO_4	—	—	0·040	0·0033
Na_2HPO_4	—	—	0·21	0·015

The salt concentrations are those used by Warburg [1923], except that a small quantity of $MgCl_2$ is introduced (*cf.* Tyrode's solution).

Effect of high concentrations of neutral salts on the metabolism of brain tissue.

1. *Rat brain.* Ashford and Dixon used rabbit brain. We have found that addition of 0·1 M KCl increases the respiration and aerobic glucolysis in rat brain also; and rat tissues only have been used by us.

In the experiments in phosphate medium, solid KCl was weighed into the side-bulb of the manometric vessels, and after a period of 30–40 mins., during which the oxygen uptake was noted, the KCl was washed into the medium by tipping backwards and forwards. The readings for the next 10 mins. were neglected, owing to a pressure increase on addition of the solid to the solution; thereafter a greatly increased respiration was observed. This was not however steadily maintained; often it fell off severely with time, so that 90 mins. after the addition the respiration might be little higher than that in the control where no KCl was added. For this reason most of the experiments were of short duration.

In the experiments in bicarbonate medium the solid KCl was dissolved in the medium before it was measured into the vessels. The large increase in respiration (Q_{O_2}) and aerobic glucolysis ($Q_G^{O_2}$) which occurs under these conditions is seen in Exp. 4 of Table I.

2. *Effect of substrate.* 0·1 M KCl still produces a large increase in respiration when the glucose in the medium is replaced by an equal concentration of lactate, pyruvate or fructose (Exps. 1, 2, 3, Table I). It follows that the increased respiration in glucose is not a result of increased lactic acid production.

There is no increase in the absence of added substrate (Exp. 5); and when the tissue is removed from a glucose-containing solution in which an increased metabolism has been produced by 0·1 M KCl, the solution itself has a negligible oxygen uptake. Hence 0·1 M KCl produces a general stimulation of carbo hydrate respiration, and the increased oxygen uptake is apparently not due to oxidation of cell material, either inside or outside the tissue. R.Q. measurements in phosphate medium by the method of Dickens and Šimer [1930, 1] showed that the increased oxidation occurring in presence of excess KCl proceeds, like the normal glucose oxidation of brain tissue, at R.Q. unity:

3. *Effect of other cations.* Rubidium and caesium chlorides in $0{\cdot}1M$ concentration produce increases in respiration of the same order as KCl; $0{\cdot}1M$ NaCl and $0{\cdot}1M$ LiCl have small effects; $0{\cdot}1M$ $MgCl_2$ has none (Table II). Hence for the effect produced by the alkali cations, Li, Na $<$ K, Rb, Cs. It follows that the "potassium effect" is not an effect specific to the potassium ion, but rather that the increase of respiration in brain may be produced by the metals at a particular end of the lyotropic series of the cations.

Ashford and Dixon [1935] observed that $0{\cdot}1M$ KCl decreased the anaerobic glucolysis of rabbit brain: this was confirmed for rat brain; and it was found that the same concentration of NaCl had little effect:

Exp. 9. Anaerobic glucolysis.

Influence of the constituents of the medium on the metabolism of brain.

The effects described above, increases of respiration and aerobic glucolysis, are produced by raising the proportion of one constituent of the suspension medium. Now this medium is a "balanced" salt solution, the cations being in proportions which have been found most suitable for the maintenance of physiological function. Decreasing the concentration of the other constituents might well have a similar effect to increasing the concentration of K. It has indeed been found that Ca, K and Mg, in the concentrations in which they are usually present in the suspension medium, have a profound effect on the respiration of brain.

Effect on respiration. A number of experiments in which Ca, K and Mg were left out in turn are summarised in Table III. The concentration of Na was kept constant; the table shows the effect of adding the chlorides of calcium, potassium and magnesium singly, in pairs, or altogether, in the concentrations in which they are normally present in the suspension medium (*i.e.* $0{\cdot}0024M$ K, $0{\cdot}0017M$ Ca and $0{\cdot}0008M$ Mg), to the sodium chloride-sodium phosphate mixture. Glucose was present in $0{\cdot}2\ \%$ concentration, and the Q_{O_2} values, most of which represent the mean values of several simultaneous measurements, refer to the first 30 or 40 mins. of the experiment.

Some typical experiments are reported in Table IV and from these and Figs. 1 and 2 it will be seen that the respiration falls off rapidly in the absence of Ca, K and Mg. Addition of K makes the respiration steadier, but the respiration is most nearly constant when Ca, K and Mg are all present. In every experiment the respiration in the first half hour is highest when the cations present are Na and K. Addition of Ca to this mixture always lowers the respiration, and the addition of Mg to the mixture of Na, K and Ca lowers the respiration still further. This is seen best from the mean values given below.

(Experiment repeated with similar result.)

* Mg present as 0·0008 *M* $MgSO_4$.

Simultaneous measurements in all the media to be compared were not made in all the experiments of Table III. It is therefore necessary to take the media in pairs, and in reckoning the mean values for each pair, only to consider those experiments in which measurements were made simultaneously in both media. We then obtain the following mean values of Q_{O_2}:

Na+K	-18·0	Na+K	-18·0
Na+Ca+K	-15·4	Na+Ca+K+Mg	-11·5
(10 experiments)		(8 experiments)	
Na+Ca+K	-15·8	Na+K	-17·3
Na+Ca+K+Mg	-11·8	Na+Ca	-13·6
(6 experiments)		(6 experiments)	

Not much attention should be paid to the respiration figures in the medium containing Na as the only cation, owing to the rapid fall of Q_{O_2} with time (Fig. 1), but it is probable that the initial rate is very high.

The effect of Mg in lowering the respiration not only in the Na+K medium (Exp. 11), but also in the medium containing Na, K and Ca, is very striking, the concentration of Mg achieving this effect being only $8 \times 10^{-4} M$. As certain balanced solutions contain magnesium sulphate (*e.g.* artificial sea-water and the suspension medium used by Krebs and Henseleit [1932]), the effect of this salt was tried (Exp. 11). It lowers the respiration, and apparently slightly more so than an equivalent concentration of magnesium chloride.

After the completion of this work, it was reported by Chang *et al.* [1935] that the equivalence of Mg and Ca in lowering the respiration of nerve "does not extend to the grey matter of the brain, magnesium ion appearing indifferent to the respiration of this tissue despite its well-known 'anaesthetic' action". Our own experiments are so clear-cut that we can only ascribe these contradictory findings to the very different experimental conditions employed.

Effect on aerobic glucolysis. It will be remembered that 0·1 *M* KCl increases not only the respiration but also the aerobic glucolysis of brain. It might therefore be that removal of Ca from the suspension medium would also lead to an increased aerobic glucolysis, as well as an increased respiration. This is indeed so (Table V). In a solution containing Na as the only cation, the aerobic glucolysis is very high. This high acid production does not result from damage to the respiration without accompanying damage to the glucolysis (as with cyanide addition or as a result of physical damage to the tissue [Warburg, 1929]), since it appears while the respiration is higher than in the medium containing bivalent cations. Its appearance has been confirmed by the method of Dickens and Šimer (Exp. 13). Lactic acid determinations by the method of Friedemann and Graeser [1933] have shown that the acid produced is in the highest probability lactic acid.

Whilst, as we have seen, the respiration is highest in the absence of bivalent cations and the presence of K, this is not true of the aerobic glucolysis. The presence of either K or Ca in the NaCl medium lowers the aerobic glucolysis, though perhaps not so efficiently as the presence of these two ions together:

Reversal of the NaCl effect. To test whether the NaCl action could be reversed by the addition of Ca and K ions, the brain slices were suspended in NaCl-NaHCO$_3$-glucose solution in Warburg box-shaped vessels (two-vessel method) with side-bulbs. The latter contained amounts of isotonic solutions of KCl and CaCl$_2$ which on addition to the medium would give the usual concentrations of those salts. It was first found that the separate addition of either CaCl$_2$ or KCl to the NaCl medium caused the aerobic glucolysis immediately to fall from its high level. At the same time, however, the respiration decreased rapidly. On addition of Ca and K together the glucolysis fell to a still lower value, but the respiration was now maintained at a level only slightly below that of the control in which all three cations had been present throughout (Table VI). Hence the action of Na ion on brain is reversed by addition of the other cations of Ringer solution. The exposure of the tissue to NaCl before the addition should not exceed about 40 mins.

Effect on anaerobic glucolysis. We have seen that removing all the cations except Na from the suspension medium has the same effect on the aerobic glucolysis as adding 0·1 *M* KCl to the medium. Is the effect on the anaerobic glucolysis the same? Addition of 0·1 *M* KCl to the suspension medium decreases the anaerobic glucolysis of brain [Ashford and Dixon, 1935]: we find that removal of all the cations except Na lowers the anaerobic acid production in just the same way (Table VII).

Influence of the constituents of the medium on the effect of high concentrations of potassium chloride.

In all experiments so far described in which an increase of brain metabolism is evoked by the addition of 0·1 *M* KCl to the medium, the tissue has been under conditions of considerable hypertonicity. We have also studied the effect of 0·1 *M* KCl in an isotonic medium, by replacing part of the NaCl with isotonic KCl to give a final K concentration of *M*/10 (Table VIII). The respiration was actually decreased in three experiments out of four, but there was a slight increase in the aerobic glucolysis (Table VIII). These results, which are in striking contrast to the effects in hypertonic solution, we ascribe to the lowering of the Na ion concentration. This view has received a certain amount of confirmation. In Exp. 24 the NaCl in the medium (which contained the usual concentrations of $CaCl_2$ and KCl but no $MgCl_2$) was replaced by glucose to give a final glucose concentration of 4·5 %. It was considered from the experiments of Loeb [1913] on the change in weight of muscle in glucose solutions that this solution should be roughly "isotonic". The addition of 0·1 *M* KCl (as solid) to this medium caused no marked increase in respiration.

Table VIII.

It thus seems to be necessary to have a fairly high concentration of Na ions present before the addition of 0·1 *M* KCl can increase the respiration. In the experiments of Table IX we added 0·1 *M* KCl to brain tissue respiring in media from which the other cations were omitted in turn. From these experiments we draw the following conclusions:

(1) In the absence of all cations but Na, addition of 0·1 *M* KCl provokes no increase in the respiration.

(2) When in addition to Na the usual concentrations of K, or K + Ca or K + Ca + Mg are present, addition of 0·1 *M* KCl increases the respiration. In all three media the respiration is raised to about the same level, but the relative increase is least in Na + K, since the initial respiration in this medium is highest.

(3) When Ca alone is present in addition to the Na, addition of 0·1 *M* KCl causes no increase in the respiration.

(4) It thus seems that the tissue undergoes some change in a medium free from K, as a result of which the respiration can no longer be increased by the addition of 0·1 *M* KCl; and that low concentrations of K, but not of Ca, can prevent this change.

* This experiment was carried out by the original Warburg [1923] technique (low bicarbonate concentration: CO_2 absorption by potash).

Effect of neutral salts on the metabolism of tissues other than brain cortex.

It is important to discover whether the neutral salt effects, which have been observed with brain, can be shown in other surviving tissues; especially since the coloured substances, which produce changes in brain metabolism similar to those produced by neutral salts, also cause these effects in kidney, tumour and other surviving tissues.

In the experiments of Table X, KCl, in 0·1 *M* and lower concentrations, was added to the usual medium, in which slices of various kinds of rat tissue were respiring. The substrate, unless otherwise stated, was glucose. Not once did the addition of KCl provoke an increase of respiration: usually there was a

slight fall, the more marked the higher the KCl concentration. We would lay stress on the following:

(1) Testis resembles brain cortex in having a slight aerobic glucolysis.

(2) Rat yolk-sac resembles brain cortex in having a high anaerobic glucolysis and a R.Q. of unity [Dickens and Šimer, 1930, 2].

(3) Retina resembles brain cortex in having a high anaerobic glucolysis and a R.Q. of unity [Dickens and Šimer, 1930, 2], a respiration dependent on the presence of carbohydrate, and a capability of oxidising fructose directly [Dickens and Greville, 1933].

But as none of these tissues suffers an increase of respiration on the addition of 0·1*M* KCl we may conclude that the effect on brain is not associated with any particular metabolic characteristic of that tissue.

(4) Tumour tissues show a marked decrease in aerobic glucolysis, both when 0·1*M* KCl is added to the usual medium and also when part of the NaCl of the medium is replaced by isotonic KCl to give an isotonic medium containing 0·1*M* KCl (Exps. 34–38 inclusive). This effect is in marked contrast to the effect of KCl on brain and to the effect of dinitro-*o*-cresol on both brain and tumour tissue.

The anaerobic glucolysis of tumours is also decreased by the addition of 0·1*M* KCl to the usual bicarbonate medium (Exp. 39).

We have seen that the respiration of brain is very considerably raised when the calcium and magnesium are left out of the usual medium. With the other tissues tested (kidney, testis, tumour) the respiration is unaffected, or insignificantly compared with that of brain, under these conditions (Table XI).

We have seen that the aerobic glucolysis of brain is enormously increased when the K, Ca and Mg are left out of the usual medium. The aerobic glucolysis of testis and yolk-sac is unaffected, and that of tumours is slightly decreased, under these conditions (Table XII).

We may therefore say that there is no evidence that any of the effects of neutral salts on the aerobic metabolism of brain tissue, which are described in this paper and that of Ashford and Dixon, are to be observed with slices of any surviving tissue other than brain.

Discussion.

From our results we draw these conclusions. When brain grey matter is respiring in a salt solution, the respiration is steadiest when, in addition to Na, K and Ca are present. K tends to increase the respiration, the bivalent cations Ca and Mg to lower it. Thus, if we leave the Ca out of the Ringer solution, the respiration is higher in the solution containing Na and K only than in the full Ringer solution. The action of the Ca in keeping the respiration small is not overcome by the low concentration of K in the Ringer solution, but it can be overcome by higher concentrations, so that the respiration reaches high values when KCl is added in concentrations of the order of $0 \cdot 1 M$ to the full Ringer solution. When bivalent ions are absent from the medium, the respiration is not a maximum with K present in the concentration in which it is put in Ringer solution; the respiration can be raised further by the addition of $0 \cdot 1 M$ KCl. It may be that the effect of residual bivalent ions in the tissue has to be overcome.

The effect of neutral salts on aerobic glucolysis cannot be easily formulated. Aerobic glucolysis is high when all cations are absent except Na, or when excess K is added to a medium containing Na and Ca. Here the effect of the excess K cannot be regarded as overcoming that of the low concentration of Ca, since the aerobic glucolysis is not high when a low concentration of K is added to the calcium-free medium. The aerobic glucolysis, however, depends on several factors, including, possibly, the respiration. The nature of the Pasteur reaction in muscle, the tissue most studied, is a controversial matter. New ideas on its mechanism in brain have just appeared [Geiger, 1935; see also Dixon, 1935]. It would therefore be unwise to attempt to explain the effect of neutral salts on the aerobic glucolysis at the present time.

Lyotropic effects. We have seen that the acceleration of brain respiration by a high concentration of KCl is associated with no particular substrate and no particular metabolic characteristic of the tissue. We may consider that it is the result of some physical change in the tissue. This is left beyond doubt by our observation that an increase is produced by other cations, the order of activity being:

$$\text{Mg} < \text{Li, Na} < \text{K, Rb, Cs.}$$

This is clearly a lyotropic series. A vast amount of work on many different types of living cell [*v.* Höber, 1926; Gellhorn, 1929] has shown that K has a much greater effect than Li and Na in promoting the swelling of tissues, in increasing the permeability of cell membranes to salts and to cell constituents, in breaking down the normal impermeability of membranes or even in visibly damaging them [*e.g.* Spek, 1921]. Of particular interest is the following. Haldi *et al.* [1927] found that solutions of the alkali chlorides permitted water imbibition by the cerebral hemispheres of the rabbit brain in the order Li, Na < K, Rb, Cs. Thus the swelling of brain tissue and its respiration are increased by alkali cations in the same order. There can be no doubt that the action of these cations on brain respiration results from an alteration by them of the colloidal state of the tissue protoplasm.

Ion antagonism. It is well known that a large number of organisms of most varied type cannot survive in pure solutions of alkali metal salts, but that the addition of a small quantity of the salt of a bivalent metal such as calcium "detoxicates" the solution and permits survival and even growth [for literature *v.* Beutner, 1933; Höber, 1926; Lillie, 1932; Stephenson, 1930]. The apparent "antagonism" of sodium and calcium may be regarded as an expression of their distance apart in the lyotropic series. Roughly we may write:

$$\overset{\xrightarrow{\text{Permeability}}}{\underset{\xrightarrow[\text{Swelling}]{}}{\mathrm{Ca}<\mathrm{Ba}<\mathrm{Mg}<\mathrm{Li}<\mathrm{Na}<\mathrm{Cs}<\mathrm{Rb}<\mathrm{K}}}$$

and say that Ca diffuses slowly, lowers permeability and favours contraction, whilst K diffuses rapidly, increases permeability and favours imbibition. If we start with the tissue in the condition corresponding to one cation, then addition of a cation to the right of the first in the series will cause a swelling and increased permeability, a cation to the left, a contraction and decreased permeability. Thus it is that an "antagonism", somewhat similar to that found between Na and Ca, is shown by Na and K, as in the growth of wheat roots [Osterhout, 1908], hypotonic haemolysis of red cells [Neuschloss, 1920] and the motility of spermatozoa [Gellhorn, 1922].

Neutral salt effects on brain respiration fall in well with these ideas. Ca lowers the respiration, K raises it. In the presence of Na alone, the respiration falls rapidly: the fall is considerably checked by the addition of small quantities of K. As a further expression of the disturbed condition when Na is the only cation, a large aerobic glucolysis appears which is to a great extent removed if K be present. The tissue is in its least deranged state when K and Ca are both present. This state is characterised by a low, steady respiration. Alteration of the colloidal state by removal of Ca or by addition of excess K results in a raised, rather unsteady, respiration, to be regarded as accompanying a deranged condition of the cell.

Na and Ca form a less satisfactory medium than Na and K, since on addition of $0{\cdot}1M$ KCl to the former medium the respiration is not increased. This we cannot explain: the reverse might be expected here, if the controlling factor were simply the salt balance in the solution.

Nature of neutral salt effects. Whilst we have no doubt that the effects of Ca and K on brain respiration are connected with a change in the colloidal state of the protoplasm, the nature of this change remains undecided. It may be a change in the cell membrane, so that the permeability towards reactants or resultants in the respiratory reactions is altered (see for example Warburg's interpretation of his finding that the poisonous action of pure NaCl solution on the ova of *Strongylocentrotus lividus* is exerted through a great increase of the respiration of the eggs [Warburg, 1910]); or it may be a change in the protoplasm affecting the activity of the enzymes, possibly by altering the extent of their active surfaces. As examples of the latter, we may cite the demonstration of ion antagonisms in the effect of neutral salts on the activity of impure invertase solutions [Neuschloss, 1920], and the demonstration by Raab [1927] of a lyotropic series in the inhibitory effect of cations on the oxygen uptake of lysed avian erythrocytes [*cf.* Warburg, 1911].

Anaerobic glucolysis. We have seen that the addition of $0{\cdot}1\,M$ KCl to the usual medium, or the removal of all the cations but Na, leads to a fall in the anaerobic glucolysis, the opposite of the effect on the aerobic glucolysis. This may be explained by an increased permeability in anaerobiosis; it has been shown that anaerobiosis renders muscle membranes more permeable to chloride [Winterstein and Hirschberg, 1927; see also Gerard, 1932, for nerve]. Then $0{\cdot}1\,M$ KCl, which in aerobiosis is favourable to metabolism, becomes on account of increased diffusibility toxic in anaerobiosis. Again, when the K and Ca are left out of the Ringer solution, the increased permeability which results is favourable to aerobic metabolism, but, since the permeability is already raised by anaerobiosis, unfavourable to anaerobic metabolism. Anaerobic glucolysis by tumour as well as brain decreases when Ca and K are removed from the medium [Lasnitzki, 1933; Lasnitzki and Rosenthal, 1933; see also Exp. 44].

Anions. In most neutral salt actions, the action of the cations is much modified by the nature of the anions [*e.g.* Pauli, 1903; Mathews, 1904; Overton, 1904; Kahho, 1921]. Thiocyanate and iodide are in general similar in their effects to K and promote its action. We have however found that $0{\cdot}05$–$0{\cdot}1\,M$ KI and KCNS in their effect on brain respiration differ little from KCl of the same concentration, and that NaCNS has no greater action than NaCl. In this indifference to anions, brain resembles nerve but is in contrast to intact muscle [Chang *et al.*, 1935].

Other tissues. We have seen that the effect of addition of excess KCl on the respiration of brain is in great contrast to the effect on the respiration of all the other surviving tissues tested. The same is true of the effect of Ca removal on the respiration, and of Ca and K removal on the aerobic glucolysis. Our observations on kidney agree with those of Siebeck [1912], who found that the respiration of whole frog kidneys *in vitro* is slightly decreased by the addition of KCl.

Of all the tissues, intact muscle seems to be the only one which resembles brain in the way in which the respiration is affected by KCl. Claude Bernard observed that muscles become non-excitable in KCl. Frog muscle can become non-excitable when immersed in Ringer solution containing only three times the normal amount of K: lowering the Ca has the same effect [Sereni, 1925]. K also produces a contracture [Ringer, 1886]. The contracture and loss of irritability are accompanied by increased oxygen uptake, whilst with the higher concentrations of K glycolysis appears [Fenn, 1931; Hegnauer *et al.*, 1934]. It seems, however, that K effects on intact muscle are hardly to be compared with those on brain slices. According to Fenn [1931], there is "strong evidence in favour of the view that chemical stimuli act through the normal contractile mechanism"; and Chang *et al.* [1935] go so far as to say that the increase of muscle respiration caused by KCl "is most probably due to the contracture induced by this salt, and the fundamental effect may be a depression. This is at least the case for heart muscle, the respiration (and tone) of which is decreased by excess potassium, as in nerve".

One is tempted to suggest that the peculiar behaviour of brain tissue is at any rate in part due to its lipin nature: this is its chief difference from retina, for example. Höber [1926] suggested that a state of dispersion between lyophile and lyophobe is the most favourable for ion antagonisms; whilst Schürmeyer [1925] found that the activity of purified invertase was not ordinarily subject to salt effects, but became so when lecithin, but not gelatin or albumin, was added.

Whether this hypothesis be acceptable or no, we cannot escape the conclusion that the metabolism of brain tissue is subject to control by alterations in the medium in a way that is not open to most other surviving tissues, and that this control bears a remarkable resemblance to the control of muscle contraction.

SUMMARY.

1. Following the observation of Ashford and Dixon that the respiration and aerobic glucolysis of rabbit brain slices are increased by the addition of $0{\cdot}1\,M$ KCl to the medium, a study has been made of the effect of neutral salts on the metabolism in salt solutions of brain and other surviving tissues.

2. The results of Ashford and Dixon have been confirmed with rat brain, and rat tissues have been used throughout.

3. $0{\cdot}1\,M$ KCl added to the medium increases the respiration of brain tissue whether glucose, lactate, pyruvate or fructose is the substrate. The increased glucose oxidation is complete.

4. All the alkali metal chlorides increase the respiration of brain tissue when added in $0{\cdot}1\,M$ concentration to the medium. The order of activity is

$$\text{Li, Na} < \text{Rb, Cs, K.}$$

5. The effect on brain metabolism of leaving the various cations in turn out of the medium has been tested:

(*a*) Ca and Mg lower the respiration, K raises it.

(*b*) In the presence of Ca, K and Na the respiration is low and steady.

(*c*) In the presence of K and Na the respiration is high and not very steady.

(*d*) When Na is the only cation the respiration is initially high but falls rapidly.

(*e*) When Na is the only cation there is a high aerobic glucolysis, which does not appear when Ca and K are added.

6. In agreement with Ashford and Dixon, it is found that $0{\cdot}1\,M$ KCl added to the medium decreases the anaerobic glucolysis. When Na is the only cation, increased aerobic glucolysis is again accompanied by decreased anaerobic glucolysis. It is suggested that these effects are due to increased cell permeability in anaerobiosis.

7. The conditions in the media which produce large changes in brain metabolism do not produce such effects on any other surviving normal or tumour tissue tested. In these:

(*a*) $0{\cdot}1\,M$ KCl added to the medium never causes a rise of respiration or aerobic glucolysis. Usually a fall is observed.

(*b*) The respiration is no higher in presence of K and Na than in presence of Na, Ca and K.

(*c*) When Na is the only cation there is no increased aerobic glucolysis.

8. The effects of neutral salts on brain metabolism are ascribed to changes in the colloidal state of the protoplasm. The similarity between the control of brain metabolism by changes in the medium and the control of muscle contraction is pointed out.

It is a pleasure to acknowledge the interest taken by Prof. E. C. Dodds in these experiments. One of us (G. D. G.) makes acknowledgment to the International Cancer Research Foundation for the provision of assistance.

CLXXVIII. THE OPTICAL PROPERTIES OF SOME BILE ACIDS.

BY BERTIL JOSEPHSON.

From the Chemical Department of the Caroline Institute, Stockholm.

(*Received April 15th, 1935.*)

THE rotatory power of the bile acids has acquired a new practical interest in connection with the method of Jenke [1928] for their determination in bile. For most of these acids and their sodium salts the optical rotations have been determined by several investigators, but except for one [Hoppe-Seyler, 1863] all have used only sodium light. In many cases the figures given in the different publications also show quite large differences.

The principle of Jenke's method is, (1) hydrolysis of the conjugated bile acids with strong alkalis, (2) extraction with ether-light petroleum of the free acids precipitated by acidification, and (3) polarimetric determination of the extracted unconjugated acids in alcoholic solution. This alcoholic solution however usually contains a considerable amount of bile pigments, which are optically inactive but make polarimetric reading in sodium light difficult or impossible. As will be shown in a later publication it is even possible in many cases by selection of light of suitable wave length to make the polarimetric determination of the bile acids as salts in the alkaline hydrolysis solution without the time-consuming acid extraction.

The determination of the rotatory dispersion of the common bile acids is also of interest as an addition to other well-known and characteristic physical data for these substances; in particular it seemed desirable to compare the specific rotations and rotatory dispersions of the bile acids and their salts in different solvents.

An investigation of the rotatory dispersions of glycocholic, taurocholic and cholic acids and their salts was made by Hoppe-Seyler [1863]: his substances however were probably impure, as will be seen from the description of their preparation, and his polarimetric apparatus was rather primitive. His values were thus very irregular and do not agree well with those found by later investigators including myself.

My determinations were made in a Schmidt and Haentsch Lippich-polarimeter readable to 0·01° and with a Hoffmann monochromator. Half-shadow angle 5°. The instrument was tested at the various wave lengths with a controlled quartz prism. The temperature was 20 ± 1°. All observations were made in 4 dm. tubes.

The following wave lengths were used: 6863 (B), 6563 (C), 5893 (D), 5463 (Hg), 4861 (F) and 4388 (Hg) Å.

The substances examined were the same as in earlier work, where description of the preparations and analyses can be found [Josephson, 1933]. Cholic, deoxycholic, glycocholic and taurocholic acids and their sodium and potassium salts were investigated.

The salts were examined in aqueous solution of 0·5, 1, 2·5, 5 (and 15) % concentration calculated on the bile acids. The cholates and deoxycholates were also tested in KCl solutions and in excess of sodium and potassium hydroxides of various concentrations. The free acids were examined in alcoholic solutions of various concentrations, depending on their solubilities. Cholic and deoxycholic acids were also examined in solution in acetic acid, acetone, chloroform, benzene and ether. The solubilities in benzene and ether are however so low that no satisfactory values could be obtained, and these observations are therefore not recorded.

The specific rotations and dispersion coefficients found, $\frac{[\alpha]_\lambda}{[\alpha]_{6867}}$, are shown in the tables.

For *cholic acid* in alcoholic solution Hoppe-Seyler found $[\alpha]_D$ 33·9°, Pregl [1910] 35·1° and Vahlen [1895] 37·0° independent of the concentration. Pregl's value agrees very well with mine ($[\alpha]_D$ 35·07°, Table I). In acetic acid and acetone the rotation and dispersion were very similar to those in alcohol, but in chloroform the rotation was much less, and the dispersion larger.

Table I.

Cholic acid.

Solvent ...	Alcohol		Acetic acid		Acetone		Chloroform	
c	0·432–1·440		0·5–5·0		0·277–1·107		0·197 %	
	$[\alpha]$	d	$[\alpha]$	d	$[\alpha]$	d	$[\alpha]$	d
6867 λ	25·4	—	26·70	—	28·13	—	15·77	—
6563	27·78	1·09	29·21	1·09	30·71	1·09	17·77	1·13
5893	35·07	1·38	37·52	1·40	37·94	1·35	24·11	1·53
5463	41·67	1·64	45·60	1·69	45·88	1·63	30·46	1·93
4861	55·03	2·17	59·19	2·22	60·52	2·15	45·69	2·90
4388	73·44	2·89	77·51	2·89	79·04	2·81	71·07	4·51

In this and following tables c = g./100 ml. solution and $d = \frac{[\alpha]_\lambda}{[\alpha]_{6867}}$.

For Na cholate in water from 30 to 9 % concentration Hoppe-Seyler found $[\alpha]_D$ 26·0–28·5° and for K cholate $[\alpha]_D$ 27·2–31·8°. Vahlen found the rotation of a 4 % solution of the Na salt to be $[\alpha]_D$ 27·6° and of a 3 % solution of K salt $[\alpha]_D$ 27·0–27·6°. My values (Table II) coincide fairly well with those of Vahlen but not with those of Hoppe-Seyler. I found the optical activity of the Na and K salts dissolved in water to be very similar, the latter being about 1–2 % lower than the former. For want of space the K values therefore are not recorded. Between 15 and 5 % the activity of the salts seemed to be independent of the concentration, but below 5 % the activity increased with decreasing concentration, and below about 1·5 % this increase became rather large. It therefore seems as if there were some alteration in the molecular state at this concentration limit. The rotatory dispersion of the salts was independent of the concentration and very similar to that of the free acid. As shown in Table III the activity was only very slightly changed by the presence of other electrolytes (KOH, KCl, NaOH).

For *deoxycholic acid* (Table IV) the following figures for $[\alpha]_D$ have been recorded: Langheld [1908] 53·28°; Vahlen [1895] 49·86°; Pregl [1910] 51·86°; Fischer [1911] 55·20°; Wieland and Sorge [1916] 57·02°. No examination of its rotatory dispersion seems to have been published. I found the specific rotation as well as the rotatory dispersion to be almost identical in alcoholic, acetic acid and acetone solutions. As for cholic acid the specific rotation was less and the dispersion higher in chloroform than in alcoholic solution. For this acid also the rotation and the dispersion were rather similar to those of the Na (Table V) and the K (Table VI) salts in water, the K salt being about 2–4 % more active than the Na salt. As for the cholates the specific rotation increased with decreasing

concentration, and this increase was much more rapid below a concentration of about 2 %, indicating some change in the molecule. The dispersions were very similar for the free acid and the alkali salts, and somewhat less than that of cholic acid. The deoxycholates are much more sensitive to other electrolytes in the solution than the cholates; it seems however as if the decrease in optical activity caused by electrolytes depends more on their concentration than on their chemical nature (Table VI), as it is approximately proportional to the molecular concentration of the added electrolyte.

Glycocholic acid and its sodium salt have been investigated by Hoppe-Seyler and by Letsche [1909]. The former found $[\alpha]_D$ for the free acid in alcoholic solution to be 29·0° and for the Na salt in water 21·8°, both independent of the concentration. Letsche found for the free acid $[\alpha]_D$ 32·3° and for the salt in 8·5 % aqueous solution 24·5°. The figures of Letsche agree well with mine. I did not, as for cholic and deoxycholic acids, find the rotation of the free acid in alcohol to be independent of the concentration; there was a slight increase in activity with decreasing concentration. Even the rotatory dispersion increased slightly with decreasing concentration (Table VII). The Na and K salts in water also showed an increase at decreasing concentration, which was obviously larger below about 1·75 %. The activities of the Na and K salts were almost identical, and the dispersions seemed to be nearly independent of the concentration (Table VIII). The dispersion was also somewhat larger for the free acid than for the salts.

Taurocholic acid has been examined by Kazumo and Yamazaki [1934], who found $[\alpha]_D$ 38·8° in diluted alcohol, but this value was calculated from one reading ($\alpha = +0{\cdot}2°$), and they do not mention the concentration of the alcohol. The specific rotation of the Na salt was measured by Hoppe-Seyler, who found $[\alpha]_D$ in water 22·4° independent of the concentration, and by Hammarsten [1909], who found $[\alpha]_D$ 23·27–24·14° between 2·32 and 5·42 %. Tanaka [1933] found $[\alpha]_D$ 23·87° ($c = 1{\cdot}28$), Makimo [1934] 24·44° ($c = 0{\cdot}9$) and Kazumo and Yamazaki 23·9° in diluted alcohol (from one value $\alpha = 0{\cdot}1°$). For the free acid, dissolved in alcohol, I found, as for glycocholic acid, slightly increasing specific rotation and rotatory dispersion with decreasing concentration (Table IX). The Na salt in

water also showed increasing activity with decreasing concentration, and this increase was larger below about 0·75 % (Table X). The rotatory dispersion of the sodium salt seemed to be independent of the concentration; it was much larger than that of the free acid.

None of the substances examined satisfied the Lommel or the Drude formula, so their rotatory dispersions may be characterised as complex. As the deviation in most cases was rather large, the calculated values are not given.

Summary.

The specific rotation and rotatory dispersion were determined for the following bile acids and their alkali salts: cholic, deoxycholic, glycocholic and taurocholic acids.

For cholic and deoxycholic acids the specific rotations were very similar in alcohol, acetone and acetic acid, and the rotatory dispersions were nearly identical in all these solvents and for the alkali salts in water. In chloroform the rotation was lower and the dispersion higher. The rotatory dispersions of these two acids were very similar.

The specific rotations of the sodium and potassium salts showed only minimum differences. The optical activity of the salts of cholic acid was scarcely influenced by other electrolytes in the solution, but that of the deoxycholic salts was obviously decreased.

In alcoholic solution glycocholic and taurocholic acids have higher specific rotations at low concentrations than at higher. Their dispersions were somewhat similar to those of the unconjugated acids.

It was found that in aqueous solution the alkali salts of all the acids examined showed increasing optical activity at decreasing concentration. This increase was much larger below a certain critical concentration, which was different for the different acids; for taurocholic acid it was about 0·75 % and for the others between 1·5 and 2·0 %. This change in the rate of increase may possibly be due to some alteration in the state of the bile acid ion.
